

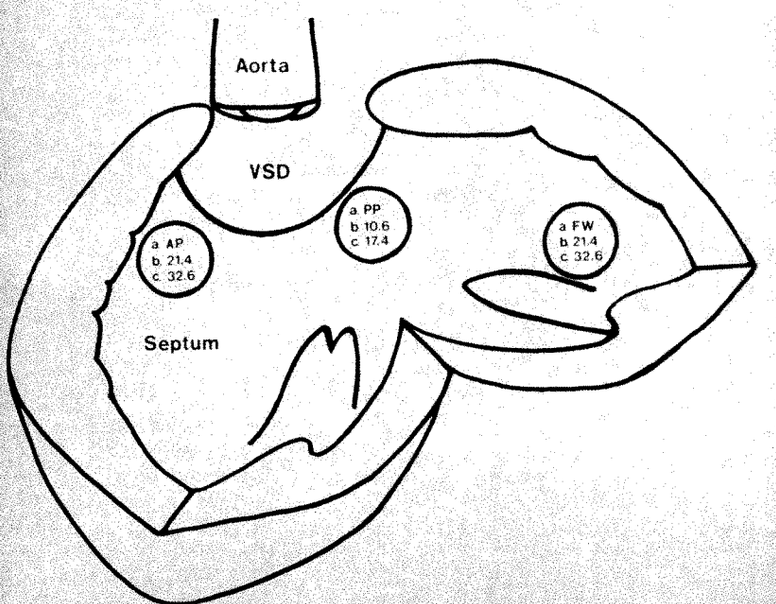

**FIGURE 1.** Composite map of left ventricular endocardial activation, with the left ventricle opened as a book. Mapping sites (a) are shown at PP (posterior paraseptal), AP (anterior paraseptal), and FW (free wall). Arrival of local activation at each site is recorded as mean milliseconds after QRS onset (b) and mean percent latest epicardial activation (c). Earliest left ventricular activation occurs posteriorly, with subsequent activation anteriorly and laterally. VSD = ventricular septal defect.

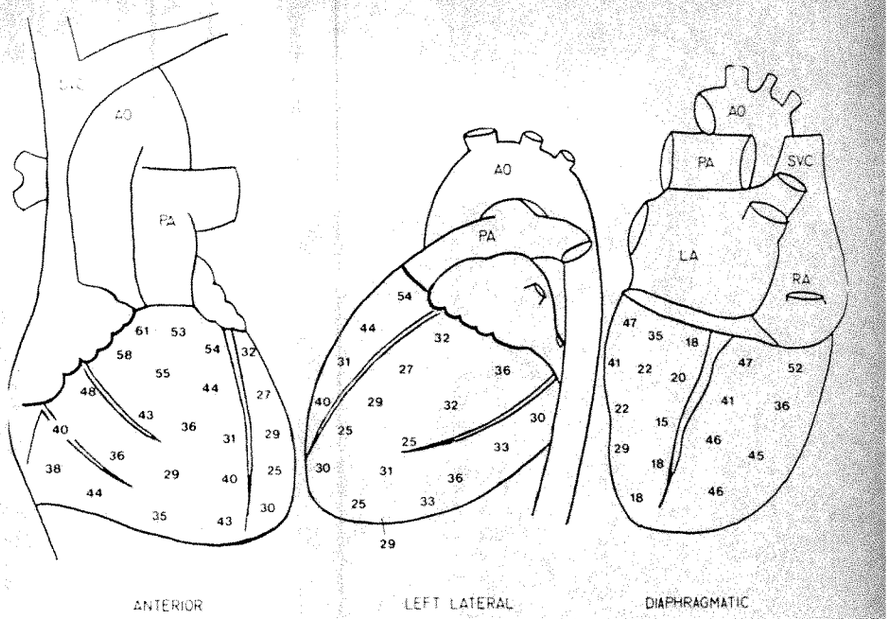

**FIGURE 2.** Epicardial maps from Patient 3. In this and Figure 3, the anterior, left lateral, and diaphragmatic views are shown. Each data point reflects arrival (in milliseconds) of local activation. Earliest epicardial activation occurs over the diaphragmatic left ventricle 15 ms after QRS onset. Activation then sweeps anteriorly and laterally to merge with an anterior right ventricular wavefront. Terminal left ventricular activation occurs over the anterobasal area. Terminal epicardial activation is recorded over the right ventricular inflow area. AO = aorta; LA = left atrium; PA = pulmonary artery; RA = right atrium; SVC = superior vena cava.

**Epicardial breakthrough:** EBT sites for both the left ventricle and the right ventricle are summarized in Table II. The distribution of left ventricular EBT sites was similar in all 5 patients. In each patient earliest left ventricular EBT (as well as earliest overall epicardial activation) was demonstrated over the diaphragmatic left ventricular surface, occurring 4 to 15 ms (mean 11.2) after the QRS onset. A subsequent left ventricular EBT site was observed along the anterolateral left ventricle in each patient (located toward the apical anterolateral left ventricle in Patients 3 and 4). The mean activation time at this left ventricular EBT site was 18.0 ms (range 14 to 15). The earliest right ventricular EBT site varied among the 5 patients; in Patients 1 and 3, the anterior paraseptal right ventricle was activated 22 and 29 ms, respectively, after QRS onset. The posterior right ventricle was activated in advance of the anterior paraseptal right ventricle in patients 2 and 5 (23 and 20 ms, respectively). The anterior paraseptal right ventricular and posterior right ventricular activations were virtually simultaneous (23 and 24 ms) in the remaining patient (Patient 4).

**Latest epicardial activation:** The site and timing of LEA are summarized in Table II. The latest left ventricular activation site was abnormally located in each of the 5 patients. In 4, the basal areas of the anterolateral left ventricle were activated last (34 to 50 ms after QRS onset, mean 45); in Patient 4, the anterior left ventricle and the basal segment of the anterolateral left ventricle were simultaneously activated (34 ms), forming the site of latest left ventricular activation. The diaphragmatic left ventricle was never the site of latest left ventricular activation. The site of latest right ventricular activation was in each patient the latest activated site on the ventricular epicardium, occurring 52 to 92 ms after onset of the QRS. In Patients 1 and 5, the inferior lateral inflow area of the right ventricle was the latest right ventricular site activated (63 and 52 ms,

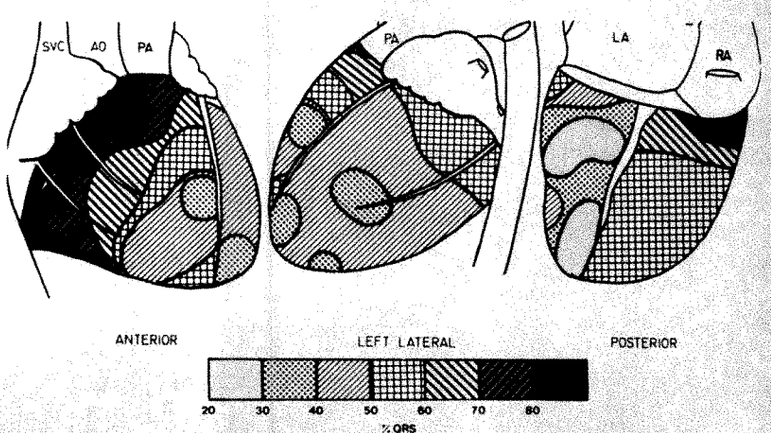

**FIGURE 3.** Composite epicardial map. Each point reflects mean percent latest epicardial activation at that point. Isochronic lines are drawn at 10 ms intervals. The pattern of epicardial activation corresponds to that described in Figure 2, and is discussed in the text. AO = aorta; LA = left atrium; PA = pulmonary artery; RA = right atrium; SVC = superior vena cava.

**TABLE II Epicardial and Endocardial Activation Data**

| Patient | EBT Site, Timing (ms) | | | | LEA Site, Timing (ms) | | Endocardial Activation Site Timing (ms) | | |
|---|---|---|---|---|---|---|---|---|---|
| | LV | | RV | | | | Posterior Paraseptal | Free Wall | Anterior Paraseptal |
| | EBT1 | EBT2 | EBT1 | EBT2 | LV | RV | | | |
| 1 | DLV, 4 | ALLV, 20 | ARV, 22 | PRV, 30 | BALV, 50 | RVI, 63 | 11 | 20 | 12 |
| 2 | DLV, 9 | ALLV, 14 | PRV, 23 | ARV, 36 | BALV, 47 | RVI, 92 | 0 | 11 | 19 |
| 3 | DLV, 15 | AALV, 25 | ARV, 29 | PRV, 36 | BALV, 47 | RVI, 61 | 8 | 35 | 39 |
| 4 | DLV, 14 | AALV, 16 | PRV, 23 | ARV, 24 | ALV, 34 BALV | RVI, 71 | 18 | 25 | 24 |
| 5 | DLV, 14 | ALLV, 15 | PRV, 20 | ARV, 26 | BALV, 37 | RVI, 52 | 16 | 17 | 13 |
| Mean (ms) | 11.2 | 18.0 | 23.4 | 30.4 | 43.0 | 69.6 | 10.6 | 21.6 | 21.4 |
| % LEA | 25 | 34 | 36 | ... | ... | ... | 17.4 | 33.8 | 32.6 |

AALV = apical anterolateral left ventricle; ALV = anterior left ventricle; ALLV = anterolateral left ventricle; ARV = anterior right ventricle; BALV = basal anterolateral left ventricle; DLV = diaphragmatic left ventricle; LV = left ventricle; PRV = posterior right ventricle; RV = right ventricle; RVI = right ventricular inflow area.

respectively); in the remaining 3 patients, activation terminated over the high anterior right ventricular inflow area near the proximal right coronary artery (61 to 92 ms, mean 75).

**Pattern of epicardial activation:** The pattern of epicardial activation—earliest to latest—was examined. Because the pattern of activation was similar in direction among the 5 patients, mean percent of LEA for each site among the patients was computed. A composite isochronic map for epicardial activation was constructed using these mean values (Fig. 3). Earliest EBT occurred at the diaphragmatic left ventricular surface at 25% LEA (mean 11.2 ms after QRS onset). A second left ventricular EBT site occurred at the left ventricular apical anterolateral surface at 34% LEA (mean 18 ms after QRS onset). Epicardial activation began over the diaphragmatic left ventricle and then fused with activation from the second left ventricular EBT site. Left ventricular activation advanced anterolaterally to the basal area of the anterolateral left ventricle. At 36% LEA (mean 23.4 ms) an anterior paraseptal right ventricular breakthrough site was observed. Activation from this epicardial site spread in a regular tangential manner over the anterior right ventricle to the atrioventricular groove and merged posteriorly with the advancing left ventricular wavefront. Latest right ventricular activation (and overall epicardial activation) was recorded over the anterior basal right ventricle.

**Endocardial activation:** Directed by the anatomic landmarks of the mitral valve commissures, we measured local excitation times at 3 widely separated left ventricular endocardial sites. The sequence of endocardial activation recorded from our patients with ECD is markedly different compared with that recorded from isolated adult human hearts by Durrer et al.[7] In 4 of our 5 patients, earliest left ventricular endocardial excitation was recorded from the posterior paraseptal segment (mean 9.3 ms after QRS onset, 14% LEA). In Patient 5 left ventricular endocardial activation at each of the 3 sites occurred within a 4 ms span (13 to 17 ms after QRS onset), virtually simultaneous with earliest recorded epicardial activity. In Patient 2, earliest left ventricular endocardial activity occurred simultaneously with the onset of the electrocardiographic QRS complex. Subsequent endocardial excitation, on the average, occurred at the left ventricular anterior paraseptal and anterolateral free wall at 33% and 34% LEA, respectively (Fig. 1). Thus, in 4 of our 5 patients, left ventricular activation sequence proceeded from the posterior segment anteriorly and laterally within the ventricle, an abnormal sequence.

## Discussion

In 1958, Lev[1] demonstrated anatomic posterior displacement of the left bundle by anatomic dissection of the conduction system in 4 hearts with ECD. Subsequent anatomic studies[2] confirmed posterior displacement of the atrioventricular node, common bundle, and short posteriorly directed left bundle fibers. In addition, anteriorly directed left bundle fascicles were decreased in number and increased in length; the right bundle branch fibers were also longer than normal. Durrer et al[3] demonstrated with epicardial mapping abnormally early activation of the posterior basal left ventricle, and Spach et al,[4] using isopotential body surface mapping, recorded an abnormal pattern of ventricular activation in ECD, best explained by earliest left ventricular diaphragmatic excitation with subsequent spread of the activation superiorly. The electrophysiologic study of Boineau et al[5] in 4 patients with ECD revealed earliest diaphragmatic left ventricular wall and later anterior left ventricular wall activation, with latest activation in the anterior right ventricular epicardium. In the same report, the sequence of endocardial Purkinje activation (recorded from a dog with congenital atrial septal defect, primum, by means of plunge electrodes) corresponds to the aforementioned anatomic developmental asymmetry of the ventricular conduction system. Our data confirm these studies and correlate for the first time in human subjects recordings from both the epicardial and left ventricular endocardial surfaces of the heart.

No published data of ventricular activation in human hearts from children of this age exist. Therefore, our data were compared to activation sequences obtained from studies in adults with normal QRS morphology and axis.[6,7] In our study, earliest epicardial activation of either ventricle occurred on the diaphragmatic sur-

face of the left ventricle between 4 and 15 ms (mean 11.2). Likewise, latest left ventricular epicardial activation was abnormal; in patients with a normal QRS, latest left ventricular epicardial activation occurred inferiorly 60 to 86 ms (mean 70) after QRS onset. In our patients, latest left ventricular activation never occurred inferiorly, but at the basal region of the anterolateral left ventricle between 34 and 50 ms (mean 43) after QRS onset.

The pattern of epicardial activation in our patients was likewise abnormal. In patients with a normal QRS morphology and axis, anterior right ventricular epicardial activation occurred before left ventricular epicardial activation.[6] In general, depolarization of the right ventricular outflow tract actually preceded posterobasal left ventricular activation. In contrast, the sequence of ventricular epicardial activation was altered in our patients with ECD; after early diaphragmatic left ventricular activation, the wavefront spread laterally and superiorly to the anterior left ventricle, with terminal anterior right ventricular activation. This abnormal early diaphragmatic left ventricular activation corresponds to the documented posterior displacement of the His bundle and shortened left bundle fascicles directed toward the posterior wall,[2] as well as a decreased number, increased length, or both, of anteriorly directed left bundle fascicles and right bundle branch fibers which has been observed in patients with ECD.

Our left ventricular endocardial data corresponded to the observed epicardial activation sequence; earliest left ventricular endocardial activation was recorded at the posterior segment with subsequent endocardial depolarization occurring along the anterolateral free wall and anterior paraseptal left ventricle. This endocardial activation sequence differs from previously described activation in isolated normal human hearts.[7] Four of our 5 patients with ECD revealed earliest posterior left ventricular endocardial activation, followed by free wall and anterior paraseptal areas. Patient 5 showed virtually simultaneous anterior, posterior, and free wall endocardial depolarization. The discrepancy in this patient may be explained by a lack of exact correspondence between the recorded and the actual sites of early left ventricular endocardial activation.

The clinical significance of this study is evident. Preliminary reports have suggested that both abnormal hemodynamic function and an imbalance between right and left ventricular mass may contribute to the superior meanrontal plane QRS axis in patients with ECD[8] and tricuspid atresia.[9] In view of the observation that the earliest points of endocardial and epicardial ventricular activation in our patients were displaced from the anterior left ventricle to the diaphragmatic left ventricle, our data reinforce the interpretation of others who have suggested that the major determinant of the superior mean frontal plane QRS axis in patients with ECD is due to the posterior and inferior displacement of the specialized atrioventricular conduction tissue,[1–5] rather than to either congenitally or hemodynamically induced ventricular hypertrophy. Ventricular epicardial and endocardial mapping would further clarify these and other variables (differential [right versus left] ventricular volume or pressure load), contributing to the superior QRS axis in patients with tricuspid atresia and other congenital cardiac defects (such as tetralogy of Fallot, double-outlet right ventricle, pulmonary stenosis, and ventricular septal defect) which can be associated with a superior mean frontal plane QRS axis.

# Atypical Fallot's Tetralogy With Doubly Committed Subarterial Ventricular Septal Defect

## Diagnostic Value of 2-Dimensional Echocardiography

HORACIO CAPELLI, MD and JANE SOMERVILLE, MD, FRCP

**Five patients with clinical features of tetralogy of Fallot had subarterial doubly committed ventricular septal defect (VSD) with absence or deficiency of the infundibular septum. Two-dimensional (2-D) echocardiography differentiated this special group from those with the usual Fallot's anatomy. In addition to the long-axis view of the left ventricle which showed the subaortic VSD and the aortic and mitral fibrous continuity, the short-axis view at the cardiac base clearly demonstrated the subpulmonary extension of the VSD in the atypical group. Two-dimensional echocardiography was found superior to biplane angiography, which in 3 patients suggested the erroneous diagnosis of double-outlet right ventricle with pulmonic valve stenosis. This variant form of Fallot's tetralogy poses special surgical problems.**

The usual type of VSD found in patients with Fallot's tetralogy is large and subaortic: that is, it lies immediately beneath the aortic cusps which form the superior border.[1] The defect extends posteriorly to the tricuspid anulus. Thus, the posterosuperior border of the VSD is formed by the fibrous continuity between the aortic and tricuspid valves, and aortic and mitral continuity is also present.[2] A variant form has been recognized in patients with the clinical features of tetralogy of Fallot in which the VSD is below the aortic valve and extends up into the right ventricular outflow tract beneath the pulmonic valve because part or all of the infundibular septum is absent or deficient.[3,4] The posterosuperior border of this VSD is separated from the tricuspid anulus by muscle and the superior border is formed by the aortic valve and also part or all of the pulmonic valve. It is rightly described as subarterial[5] but it is also doubly committed to both aortic and pulmonic valves. In these patients the right ventricular obstruction is mainly due to pulmonic valve stenosis.[3,4] Although this variant form may appear as a case of mild Fallot's tetralogy, it requires an outflow patch enlargement across the pulmonic ring.[3]

Before operation, an erroneous diagnosis of double-outlet right ventricle is frequently made from angiographic appearances. The reliability of 2-D echocardiography in the recognition of Fallot's tetralogy with doubly committed subarterial VSD in 5 patients is reported herein.

### Methods

Five consecutive patients aged 4 months to 28 years with Fallot's tetralogy and doubly committed subarterial VSD were investigated between March 1981 and November 1981. They had full preoperative evaluation with 2-D echocardiography and biplane angiography using conventional anteroposterior and lateral views. Additional angiography using the elongated right anterior oblique projection with 30° craniocaudal tilt was used in 2. The anatomy of the VSD and the right ventricular outflow tract was demonstrated at open heart surgery in 4 and at necropsy in 1 patient who died from cerebral damage which occurred before an emergency Blalock shunt.

The 2-D echocardiograms were performed with an advanced laboratory mechanical sector scanner at 3.0 MHz (ATL-Mark 300). Patients were studied in the supine or left lateral 30° decubitus position. The transducer was placed to obtain the long- and short-axis views from the parasternal position, apical 4-chamber view, and the short-axis and 4-chamber views at the level of the great vessels from the subcostal position.[6] During the same period, 20 patients aged 6 months to 15 years with the classic form of Fallot's tetralogy and subsequent radical correction were studied; the 2-D echocardiographic findings were used for comparison.

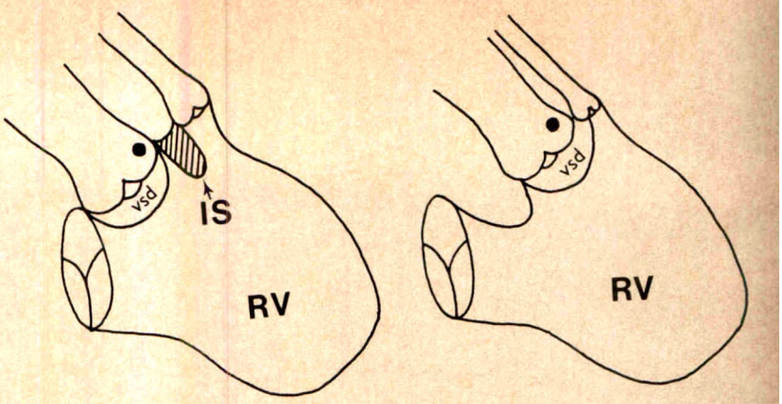

**FIGURE 1.** Anatomy of the ventricular septal defect (VSD) in patients with Fallot's tetralogy as viewed from the right ventricle (RV). **Left,** classic Fallot. Here, the ventricular septal defect lies beneath the aortic valve cusps (subaortic) and extends to the tricuspid anulus. It is separated from the pulmonic anulus by hypertrophied and displaced infundibular septum (IS). **Right,** Fallot tetralogy with doubly committed subarterial ventricular septal defect. The defect is still beneath the aortic cusps and does not extend posteriorly to the tricuspid anulus. It extends into the right ventricular outflow beneath the pulmonic anulus; the infundibular septum is absent.

## Results

**Pathologic anatomy:** The anatomy of the VSD in the 5 patients with the variant form was, at operation in 4 patients and at necropsy in 1, as described in Figure 1. In all instances the pulmonic valve was stenotic, bicuspid, and associated with a small ring. The right ventricular outflow tract appeared narrowed despite absence (4 patients) or hypoplasia (1 patient) of infundibular septum; no infundibular ostium was present. There was fibrous continuity between the anterior mitral valve and the aortic wall seen through the defect.

Two patients, aged 13 and 28 years, had associated aortic regurgitation due to prolapsing right coronary cusp, the aortic ring being completely calcified in the older patient.

**Two-dimensional echocardiographic findings:** *Classic Fallot's tetralogy:* The parasternal long-axis view of the left ventricle allowed clear visualization of the subaortic VSD, the malalignment of the ventricular septum, and the aortic-mitral fibrous continuity (Fig. 2). The relation of the VSD to the aortic valve cusps and to the infundibular septum and pulmonic valve was best seen in the short-axis view of the great vessels from the parasternal and subcostal positions. In these views, it was obvious that the large VSD was beneath the right coronary cusp and part of the noncoronary cusp extending to the tricuspid valve (Fig. 3). In both short-axis views the right ventricular outflow tract was obviously narrowed, and a conspicuous mass of tissue—hypertrophied infundibular septum—was identified between the aortic and pulmonic anuli. The pulmonic valve was in the usual position, that is, anterior to the right of the aortic valve in the echocardiographic image.

**Fallot's tetralogy with doubly committed subarterial ventricular septal defect:** The echocardiographic findings in the long-axis parasternal view were the same as in classic Fallot's tetralogy, which were described and shown previously (Fig. 2).

The position and anatomy of the VSD was also delineated in the short-axis view of the great vessels from

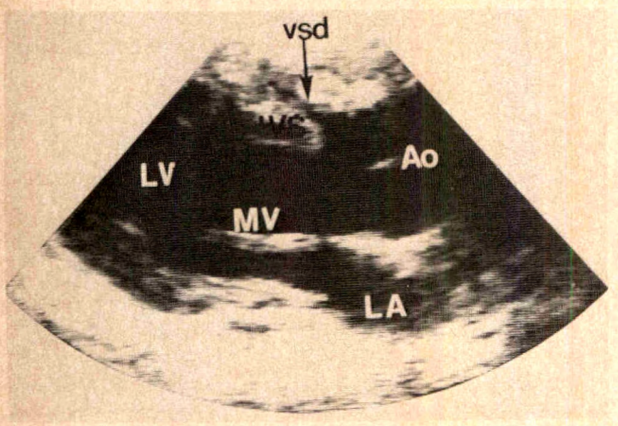

**FIGURE 2.** Two-dimensional echocardiographic long-axis view of the left ventricle (LV) in a patient aged 6 years with classic Fallot's tetralogy. It shows the large aorta overriding the subaortic ventricular septal defect (VSD) and the aortic-mitral fibrous continuity. Ao = aortic valve; IVS = intraventricular septum; LA = left atrium; MV = mitral valve.

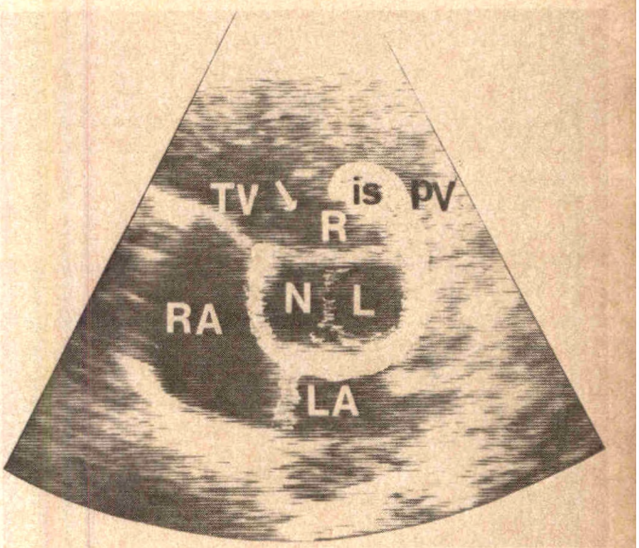

**FIGURE 3.** Two-dimensional echocardiographic parasternal short-axis view of the aorta from a patient aged 12 years with classic Fallot's tetralogy. It shows the ventricular septal defect lying beneath the right coronary cusp (R) extending to the noncoronary cusp (N). It reaches the tricuspid anulus by hypertrophied infundibular septum (IS). (This figure was retouched.) L = left coronary cusp; LA = left atrium; PV = pulmonic valve; RA = right atrium; TV = tricuspid valve.

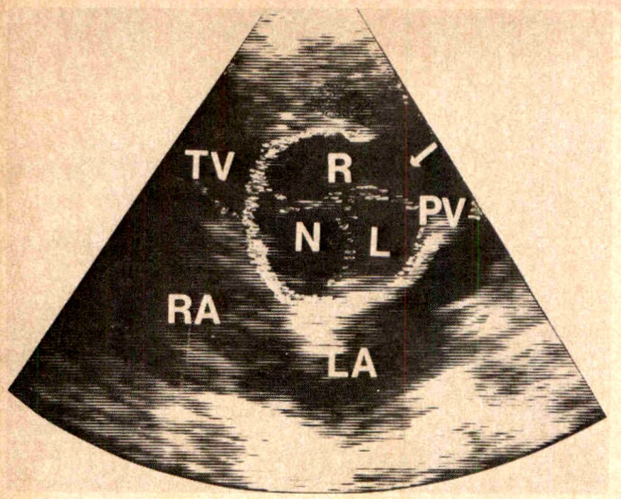

**FIGURE 4.** Two-dimensional echocardiographic parasternal short-axis view of the aorta in a patient aged 13 years with Fallot's tetralogy with doubly committed subarterial ventricular septal defect. Here, the ventricular septal defect lies beneath the right coronary cusp extending to the left coronary cusp. It is separated from the tricuspid anulus and extends into the outflow beneath the pulmonic valve. The infundibular septum is absent. (This figure was retouched.) Abbreviations as in Figure 3.

parasternal and subcostal positions. However, in this group the VSD was seen not only under the right coronary cusp, but also extended to the left commissure and below the pulmonic anulus, being clearly separated from the tricuspid valve (Fig. 4). The right ventricular outflow tract looked mildly narrowed, and there was no tissue separating the aortic and pulmonic valve rings. In these patients both arteries appeared adjacent to each other.

**Angiographic findings:** The right ventricular angiogram in the anteroposterior view showed the aortic and pulmonic rings side by side without the negative image of tissue separating the valves below (Fig. 5, top). In the lateral view the VSD looked classically subaortic and the aorta appeared much more anterior than in classic Fallot, suggesting that the aorta was coming directly off the right ventricle as in double-outlet right ventricle (Fig. 5, bottom), aortic-mitral continuity was difficult to identify. In 3, aged 4 months to 28 years, the appearances suggested discontinuity favoring the diagnosis of double-outlet right ventricle and pulmonic valve stenosis but 2-D echocardiography clearly demonstrated continuity.

## Discussion

Real-time 2-D echocardiography has been reported to be helpful in demonstrating the intracardiac anatomy in Fallot's tetralogy.[7–9] The standard parasternal long-axis view allows appreciation of the dilated aortic root overriding a large subaortic VSD and is reliable in demonstrating the aortic-mitral fibrous continuity. This was clearly seen in all of our patients irrespective of angiographic findings. However, in this view it was not possible to see the diagnostic subpulmonary extension of the VSD in the variant form with doubly committed subarterial VSD since it is observed from the left ventricle and thus appears to be only subaortic. The short-axis view at the cardiac base from parasternal position best demonstrated the position of the VSD in relation to the aortic, pulmonic, and tricuspid valves. The same view from subcostal position usually allows a better definition of certain anterior structures than can be obtained from the precordial position.[6] It was the best projection in assessing the morphology of the right ventricular outflow tract and specifically in detecting the absent infundibular septum in the 4-month-old patient. However, in the other 4 patients over age 12 years, it was not a good view because of the long distance between the subcostal area and the base of the heart which impaired definition.

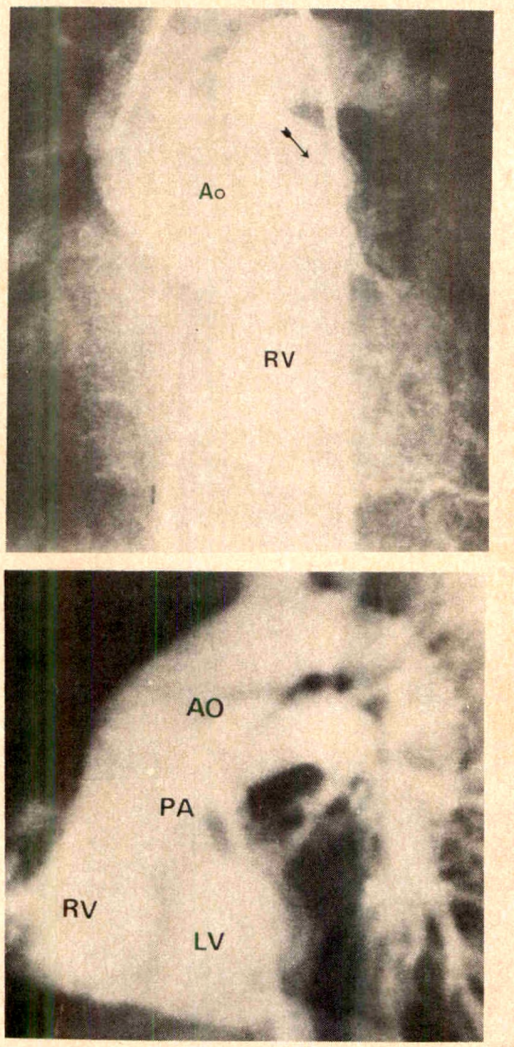

**FIGURE 5.** Right ventricular angiograms from patients with Fallot's tetralogy with doubly committed subarterial ventricular septal defect. Both have severe pulmonic valve stenosis. **Top,** anteroposterior view from a patient aged 16 years. It shows the aortic and pulmonic valves side by side without the negative image of tissue separating the valves below. **Arrow** indicates the pulmonic valve. **Bottom,** lateral view from a patient aged 4 months. The aorta (Ao) appears to be coming directly off the right ventricle as in double-outlet right ventricle. Aortic-mitral continuity is difficult to identify. LV = left ventricle; PA = pulmonary artery; RV = right ventricle.

Various descriptions have been used for this variant anatomic form of Fallot such as Fallot with subpulmonic,[3,4] subarterial,[5] or bulboventricular[10] VSD. We prefer simple descriptive terminology rather than nomenclature which involves imagination about cardiac embryology or development. Fallot's tetralogy with doubly committed subarterial VSD describes the defect simply. This entity is uncommon among series of Caucasian or European patients with tetralogy of Fallot. However, 4 of our 5 patients were Arabs from the Middle East. Our experience suggests that it occurs in at least 10% of patients with Fallot's tetralogy from the Arabian Gulf, an incidence similar to that in the Japanese.

A history of true cyanotic attacks was not present in any of our 5 patients. This is presumed to be related to the absence or deficiency of part of the anteriorly displaced infundibular septum which prevents development of a labile muscular and subsequently fixed obstruction in the right ventricular outflow tract. The severity of the right ventricular obstruction in these patients depends on the severity of the pulmonic valve stenosis and on the hypoplasia of the infundibulum or outflow tract of the right ventricle. After patching the VSD and opening the pulmonic valve once the ventriculotomy is closed, the surgeon may find important residual right outflow obstruction, irrespective of the resection of muscle. This results because the patch in the closed VSD extends up into the right ventricular outflow where previously a hole had been present, causing a narrowing beneath the pulmonic ring. Such cases require an outflow patch enlargement across the pulmonic ring, as did all 5 of our patients. Otherwise, right ventricular failure and unexpected death may complicate the postoperative course in what was thought to be a "good risk" patient.

Preoperative diagnosis may be difficult because in some patients the angiographic lateral view may suggest the diagnosis of double-outlet right ventricle with pulmonic valve stenosis. The absence of interposed muscle between aortic and pulmonic rings gives the erroneous impression of both vessels being committed to the right ventricle in a side-by-side position and appearing to be separated from the mitral valve. In the long-axis parasternal view of the left ventricle, 2-D echocardiography clearly delineates the aortic-mitral continuity and is therefore superior to angiography in ruling out double-outlet right ventricle.

Our patients were diagnosed as having Fallot's tetralogy with doubly committed subarterial VSD before surgery; however, angiography had been thought to show double-outlet right ventricle in 3. However, angiography was superior to echocardiography in assessing the size of the pulmonary arteries, particularly the left, which still remains as 1 of the unsolved challenges for echocardiography.

Two-dimensional echocardiography is a relevant noninvasive technique for diagnosing Fallot's tetralogy. However, it is important as part of a routine evaluation to delineate the VSD in both long- and short-axis parasternal views to see the boundaries of the defect in relation to the aortic cusps and pulmonic anulus. Without the short-axis parasternal view, the doubly committed subarterial VSD with absence or deficiency of the infundibular septum may be missed. The surgeon, particularly early in his experience, should be warned of the presence of this variant and the problems which may be encountered.

**Acknowledgment:** We thank Marc de Leval, MD, who operated on these patients and who carefully explained and described the intracardiac anatomy.

# Supraventricular Tachycardia in Infants: Use of the "Diving Reflex"

VELIO SPERANDEO, MD, DANIELE PIERI, MD, PASQUALE PALAZZOLO, MD, MARIO DONZELLI, MD, and GIUSEPPE SPATARO, MD

**The effectiveness of the "diving reflex" in treating paroxysmal supraventricular tachycardia (PSVT) in 10 infants aged under 6 months is demonstrated. No rhythm disturbances were encountered during the maneuver, even in patients receiving digitalis. The recommended water temperature is 5°C and the total time of facial immersion, between 6 and 7 seconds. The diving reflex might be considered the first therapeutic approach in infants under 6 months old with PSVT.**

PSVT is a commonly observed pediatric emergency[1] in infants, and rapid conversion to sinus mechanism is imperative. Many methods of treatment have been advocated, such as vagal maneuvers (stimulated by carotid sinus and unilateral eyeball pressure, induction of vomiting, breath-holding, or the Valsalva maneuver), which have rarely been successful in terminating tachycardia in infants. Other therapies such as intravenous digitalis, verapamil, and direct current countershock entail risks.

Immersion of the face in cold water, which stimulates the diving reflex, may stop attacks of PSVT in both adults and children,[2–4] but the procedure has not often been used in infants with PSVT.[5,6] We have used the diving reflex in the treatment of PSVT in 10 infants; our experience is reported herein.

## Methods

The patients ranged in age from 14 days to 5 months (average 55 days). Seven were boys and 3 were girls. Only 1 patient had associated congenital heart disease (moderate pulmonary valvular stenosis). Three patients were receiving digitalis therapy (15 μg/kg/day orally) when hospitalized but without beneficial effect.

All but 1 had features of congestive heart failure as judged by sweating, tachypnea, gallop rhythm, enlargement of liver, peripheral cyanosis, and restlessness. Five patients had type A and 1 had type B Wolff-Parkinson-White syndrome, 2 had normal electrocardiograms, and 1 had a short P-R interval with normal ventricular depolarization (Lown-Ganong-Levine pattern). The ventricular rate during PSVT varied from 270 to 320 beats/min (mean 295). The QRS configuration remained unchanged during the attacks in all patients. Carotid sinus massage, unilateral eyeball pressure, and induction of vomiting were unsuccessful in stopping the PSVT in all patients.

The diving maneuver was performed as follows: diving reflex was stimulated through immersion of the infant's face in a basin of ice water at 4 to 5°C for 6 to 7 seconds. Their nostrils were manually closed to prevent aspiration. A precordial lead (generally lead $V_1$) connected the patient to a continuous writing electrocardiograph before and during facial immersion. The sensitivity of the recorder was adjusted for optimal amplitude to keep note of a satisfactory P wave. A defibrillation machine was held in readiness throughout in case of serious ventricular tachyarrhythmias. A 24-hour Holter monitoring was performed on every patient the day after the conversion to sinus rhythm as a precaution and to confirm the results.

## Results

In all patients in whom the diving reflex maneuver was applied, sinus rhythm was restored immediately (Fig. 1). The diving reflex was used 13 times in the 10 patients because in 1 patient PSVT recurred once, and in another, twice. Ventricular arrhythmias did not occur during the maneuver or during Holter monitoring, even in the 3 patients receiving digitalis. After conversion to sinus rhythm, all patients were treated with digitalis (digoxin orally 10 to 15 μg/kg/day) which was continued for 1 year. Five patients were followed for 1 year, and none had any clinical recurrence of PSVT.

## Discussion

The diving reflex is an oxygen-conserving reflex consisting of striking bradycardia and peripheral vasoconstriction which results in increased blood flow to the brain and heart. This reflex was first observed in diving vertebrates such as seals and ducks.[7] In aquatic vertebrates, the diving reflex is strongly developed and occurs during both activity and rest.

This reflex is initiated partly through the stimulation of afferent nerve endings in the area of the mouth and nose by the cold water. The efferent limb of the reflex is mediated by increased sympathetic stimulation to peripheral vessels (except to the brain and heart) and, simultaneously, by intense vagal stimulation to the heart.[8,9] The increased vagal tone to the heart seems to produce the bradycardia connected with facial immersion. Apnea alone causes similar but much less extreme cardiovascular response.

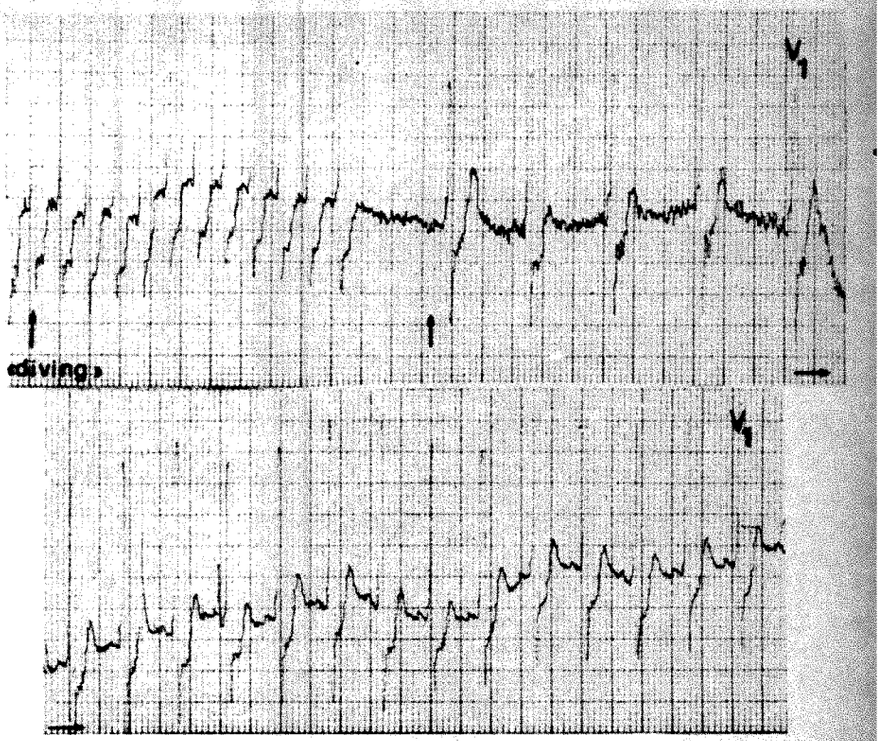

**FIGURE 1.** Continous tracing during immersion (**arrow**) that shows conversion of PSVT to normal sinus rhythm in approximately 3.5 seconds, by breaking the arrhythmias in the retrograde limb of the reentrant circuit through the atrioventricular node.

Investigations into the cardiovascular effects of facial immersion and into the factors affecting the diving reflex in man[10–16] have shown that the greatest decrease in the heart rate was during breath-holding in cold water immersion. Because the decrease in heart rate occurs rapidly and most prominently after facial immersion in cold water, diving bradycardia is believed to be a reflex mainly stimulated by facial immersion. Thus, asphyxia is not the main factor in evoking the diving reflex, but remains important in that it intensifies the bradycardia stimulated by facial immersion.

The first successful clinical applications of the diving reflex as a treatment for PSVT were recorded in adults.[2,3,17]

The temperature of the bath used for immersion has been noted to play an important role in decreasing the heart rate.

It was found that the vagal response becomes more intense when the temperature of the bath is <20°C, and it has been suggested that the diving bradycardia is most profound at about 18°C.[18,19]

Ventricular tachycardia has been observed in adults after facial immersion for 30 seconds in an ice-water bath at about 4°C.[20] Perhaps the severely cold temperature and the prolonged immersion resulted in a considerable catecholamine discharge which may have been responsible for ventricular dysrhythmias.

The diving reflex can be induced quite easily; it is a noninvasive, painless, and rapidly reversible procedure. This maneuver is also useful in patients who are receiving digitalis. This kind of treatment does not provide protection against future episodes of PSVT and, of course, it cannot replace conventional prophylactic therapy.

# Impact of 2-Dimensional Echocardiography on the Management of Distressed Newborns in Whom Cardiac Disease Is Suspected

MARY J. RICE, MD, JAMES B. SEWARD, MD, DONALD J. HAGLER, MD, DOUGLAS D. MAIR, MD, ROBERT H. FELDT, MD, FRANCISCO J. PUGA, MD, GORDON K. DANIELSON, MD, WILLIAM D. EDWARDS, MD, and ABDUL J. TAJIK, MD

**The course and management of 40 consecutive newborns (aged <2 weeks) who presented with signs and symptoms of congenital heart disease were reviewed to determine the impact of 2-dimensional (2-D) echocardiography on their subsequent management. Of the 40 patients with congenital heart disease, 60% did not undergo cardiac catheterization. Forty-two percent of the patients who were treated surgically went directly to operation without preoperative cardiac catheterization. Only 40% of the patients with congenital heart disease required cardiac catheterization in the newborn period, and 43% of these procedures were primarily therapeutic (that is, balloon atrial septostomy). In each patient 2-D echocardiography correctly identified the major cardiac malformation and there was good agreement with angiographic, surgical, and autopsy findings. The most commonly overlooked defect was a patent ductus arteriosus. Thus, 2-D echocardiography not only allows diagnosis of congenital heart disease in the newborn but can expedite clinical management. No longer is cardiac catheterization necessarily the primary means for an anatomic diagnosis of congenital cardiac malformations in the newborn.**

Most noncardiac causes of cyanosis can be excluded by clinical or laboratory findings.[1,2] In addition to the physical examination, laboratory results, chest x-ray study,[3] and electrocardiogram, cardiac catheterization has to date played a central role in the anatomic and hemodynamic assessment of the distressed newborn in whom a cardiac malformation is suspected. In the last few years, 2-D echocardiography has also become established as a tool for the diagnosis of congenital heart disease.[4–15] In addition, contrast[16,17] and Doppler[18–20] echocardiography have enhanced the echocardiographic examination, and high-frequency transducers have increased the feasibility of accurately examining the small neonatal heart.

Because the 2-D echocardiographic examination may allow a definitive anatomic diagnosis in cases of congenital heart disease, it therefore also has potential use in directing medical or surgical management and in changing the indications for cardiac catheterization. Although 2-D echocardiography is now an accepted part of the diagnostic evaluation, its impact on the subsequent management of the newborn has not previously been emphasized. Perhaps a complete 2-D echocardiographic examination may replace cardiac catheterization as the "examination of choice" in selected newborns with congenital heart disease.

This report reviews the course and management of 40 consecutive newborns aged <2 weeks who presented with clinical features suggesting congenital heart disease and emphasizes the increasing importance of high-resolution 2-D echocardiography in the evaluation and management of distressed newborns.

## Methods

Forty consecutive distressed newborns aged <2 weeks (mean 3.5 days) were suspected of having a significant cardiac problem. Usually clinical examination had taken place and the potential of a serious cardiac malformation had been recognized before the 2-D examination. Appropriate labora-

tory tests, chest x-ray examination, and electrocardiogram were not always available before the echocardiographic examination (12 of 40 patients, 30%) (Table I). In each case, the 2-D echocardiographic examination was performed early in the hospitalization before management decisions (medical treatment, cardiac catheterization, or surgery) were made (Table I).

To assess the role of echocardiography in the management of these newborns, we paid particular attention to our ability to establish complete and accurate anatomic diagnosis and determine appropriate further intervention on the basis of information obtained at echocardiography.

An Advanced Technology Laboratory (Mark V) 2-D mechanical sector scanner with a 5-MHz transducer and Doppler and M-mode capabilities was utilized. A detailed and complete 2-D echocardiographic examination of cardiac and extracardiac vascular structures was performed in each instance. The usual 2-D echocardiographic scanning techniques have been described,[13] including the use of contrast[16,17] and Doppler echocardiography.[18-20]

Echocardiographic findings were compared with angiographic and surgical findings when available (Table I). In patients who died and were autopsied, the pathologic anatomy of the cardiopulmonary specimen was studied in detail and

correlated with echocardiographic findings. The patients have been categorized according to whether they (1) had a noncardiac disorder (5 patients), (2) were managed without cardiac catheterization (21 patients), or (3) required either therapeutic or diagnostic cardiac catheterization (14 patients).

## Results

### Part I

**Noncardiac disorders (5 patients):** No structural cardiac abnormalities were found with 2-D echocardiography in 5 cyanotic patients. Three patients had persistent fetal cardiopulmonary circulation, 1 had transient tachypnea of the newborn, and 1 had transient cyanosis. All were managed medically without further diagnostic cardiac studies. One patient with persistent fetal circulation died from progressive hypoxia at age 3 days.

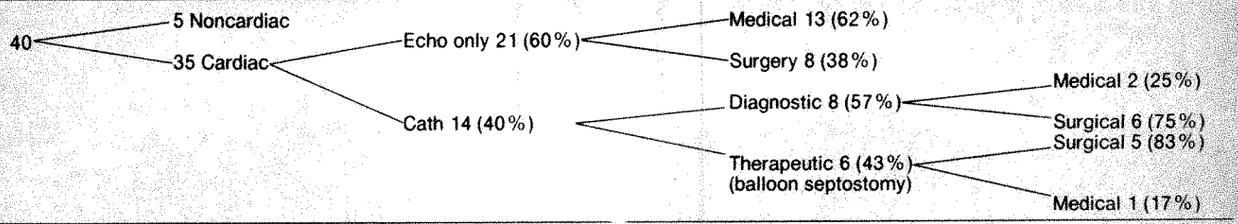
**Congenital heart disease (35 patients):** The 35 newborns with cardiac defects were reviewed in detail to assess the influence of 2-D echocardiography on their management. Three basic groups were analyzed: (1) no additional diagnostic studies needed (21 of 35, 60%); (2) diagnostic or therapeutic catheterization needed (14 of 35, 40%); and (3) operation needed (19 of 35, 54%; 8 of these 19 patients (42%) had no preoperative cardiac catheterization).

*1. No additional diagnostic studies needed:* Twenty-one patients (60%) underwent no further diagnostic cardiac studies in the neonatal period; 13 were managed medically and 8 went directly to operation after echocardiography. Two patients (Cases 17 and 18) had currently uncorrectable cardiac anatomy (hypoplastic left heart); 1 (Case 1) had trisomy 18 in addition to double-outlet right ventricle with pulmonary atresia. Of the remaining 10 medically treated patients, 3 had a patent ductus arteriosus. Five patients (Cases 6 and 14, tetralogy of Fallot; Case 16, complete atrioventricular canal; Case 20, supravalvular and valvular aortic stenosis; and Case 21, Shone's syndrome) are currently being treated medically. One patient (Case 13 Down's syndrome) underwent closure of a ventricular septal defect at age 8 months, without preoperative cardiac catheterization, and died postoperatively from respiratory insufficiency. One patient (Case 15) with complete atrioventricular canal died from severe congestive heart failure at age 1 day.

Eight additional patients had no further diagnostic studies but proceeded directly to operation (see later).

*2. Need for catheterization:* Fourteen newborns (40%) with cardiac anomalies detected with echocardiography had cardiac catheterization in the newborn period. Six patients (43%) underwent catheterization primarily for balloon atrial septostomy (therapeutic catheterization). After septostomy, angiography confirmed the echocardiographic diagnosis without demonstrating any other significant malformation. Four (Cases 24 to 27) had transposition of the great arteries, 1 (Case 23) had tricuspid atresia, and 1 (Case 22) had severe Ebstein's anomaly and associated pulmonary atresia. In these 6 patients, the balloon atrial septostomy was partly directed and its adequacy was confirmed by 2-D echocardiography. One patient has been managed medically and 5 subsequently required surgery, 3 of whom died.

Eight (57%) of the 14 patients required diagnostic cardiac catheterization in the first 2 weeks of life. These catheterizations were done (in addition to 2-D echocardiography) either to permit further delineation of extracardiac anatomy (Cases 28, 34, and 35) or to assess hemodynamic function (Cases 29 through 33). Interrupted aortic arch was suspected echocardiographically in 3 patients, and cardiac catheterization confirmed this diagnosis in 2 (Cases 34 and 35) but not in the third (Case 28). Five patients underwent cardiac catheterization for hemodynamic data—2 patients to assess right ventricular outflow gradient (Cases 29 and 30), 1 to evaluate tricuspid stenosis as a therapeutic baseline (Case 31), 1 to determine the degree of atrioventricular valve regurgitation in the presence of complete atrioventricular canal (Case 33), and 1 with a membranous ventricular septal defect to rule out associated muscular ventricular septal defects (Case 32). Two patients were subsequently managed medically and 6 were managed surgically. Three patients died, 2 treated surgically and 1 treated medically.



*3. Need for operation:* Nineteen newborns (54%) underwent surgery. Eight of the 19 surgical patients (42%) underwent an operation soon after 2-D echocardiographic evaluation without preoperative cardiac catheterization; 2 operations were for ligation of a patent ductus arteriosus. Most of the operations (5 patients) were emergency procedures and were confined to placement of a systemic-to-pulmonary artery shunt (Cases 2 to 5 and 7). One patient (Case 19) had an aortic valvotomy. In 5 of the remaining 11 patients who had preoperative cardiac catheterization, this examination was primarily therapeutic (balloon septostomy) and was not used as the primary diagnostic procedure.

For comparison with this recent experience, the preoperative management of 25 infants aged <2 weeks who underwent surgery from 1977 through 1980 was reviewed. Ten distressed newborns with an isolated patent ductus arteriosus went directly to surgery without cardiac catheterization. All of the remaining 15 patients had preoperative cardiac catheterization. In the present study, both patients with isolated patent ductus arteriosus went directly to surgery; however, 6 (35%) of the remaining 17 patients also went to surgery without catheterization. This later group consisted mainly of those who required an emergency shunt procedure and did not require further anatomic delineation other than that obtained with 2-D echocardiography (Table II).

### Part II

**Mortality:** Sixteen (46%) of the 35 newborns with a cardiac anomaly ultimately died. In addition, 1 patient with persistent fetal cardiopulmonary circulation died. Two patients (Cases 17 and 18) had a currently uncorrectable cardiac malformation and 1 (Case 1) had trisomy 18. All 3 died early in life. Seven patients (Cases

Cath = catheterization; echo = echocardiography.

2, 5, 7, 25, 26, 30, and 34) died in the immediate postoperative period. Two patients died from unrelated medical problems—myotonic dystrophy (Case 10) and after colostomy for imperforate anus (Case 33). Three patients died late after operation: 1 (Case 13, with Down's syndrome) from respiratory insufficiency, 1 (Case 12) from septic shock, and 1 (Case 22) from arrhythmias. One critically ill newborn (Case 15) with complete atrioventricular canal died from congestive heart failure in the first 24 hours of life.

### Part III

**Angiographic-surgical-autopsy correlation (Table I):** In 24 (69%) of 35 patients evaluation of the cardiac defect with angiography, during surgery, or at autopsy (or more than 1 of these methods) was possible: 14 with angiography, 13 during surgery, and 10 at autopsy. In all 24 patients, the major anatomic cardiac malformation was correctly diagnosed with 2-D echocardiography. The following lesions were missed or mistakenly interpreted by the echocardiographer:

*Patent ductus arteriosus:* Eight patients had an associated patent ductus arteriosus which was not visualized with 2-D echocardiography but was found during catheterization (4 patients), surgery (6 patients), or autopsy (1 patient). Thus, in 8 (47%) of 17 patients with patent ductus arteriosus, the echocardiographer failed to recognize the lesion; however, in all 5 patients with an isolated patent ductus arteriosus, the echocardiographer did recognize the lesion. Patent ductus arteriosus was commonly missed when associated with other, more significant cardiac defects.

*Extracardiac anatomy:* In 2 patients, 2-D echocardiographic assessment of extracardiac anatomy was incomplete. In 1 (Case 34) with a correct diagnosis by 2-D echocardiography of interrupted aortic arch, an additional distal coarctation was not recognized but was found on angiography. In the other patient (Case 28), severe valvular pulmonary stenosis was correctly diagnosed; however, the echocardiographic examination also suggested interruption of the aortic arch, which was not found at catheterization.

*Intracardiac anatomy:* In 2 patients, 2-D echocardiographic assessment of intracardiac anatomy was incomplete. In Patient 13, in whom a correct diagnosis of a large paramembranous ventricular septal defect was made by 2-D echocardiography, 3 additional clinically insignificant (<1 mm) muscular ventricular septal defects were found at autopsy. The sizes of these ventricular septal defects were considered beyond the resolution of available echocardiographic instrumentation and of no hemodynamic significance. In this same patient a small secundum atrial septal defect was also found at surgery. In Patient 22, with a correct 2-D echocardiographic diagnosis of severe Ebstein's anomaly, right ventricular outflow obstruction was suggested by the large amount of tricuspid valve tissue in the outflow tract. A right ventricular angiogram also showed no blood exiting the right ventricle through the right ventricular outflow tract, and a diagnosis of pulmonary valve atresia was "confirmed." However, at autopsy the right ventricular outflow tract was patent, and the echocardiographic and angiographic findings were attributed to redundant tricuspid valve tissue in the right ventricular outflow tract and severe tricuspid regurgitation, both of which impeded forward blood flow.

## Discussion

Two-dimensional echocardiography has become established as an excellent noninvasive tool for the diagnosis of congenital heart disease. It is particularly useful in the recognition of altered ventricular anatomy, and it may be uniquely superior to angiography in visualizing altered anatomy about the internal "crux" of the heart (that is, the anatomic meeting point of the atrial and ventricular septa and the septal portion of the atrioventricular valves).[13] Two-dimensional echocardiography is less applicable for the complete assessment of extracardiac anatomy such as pulmonary artery distribution, coronary anatomy, mediastinal vascular anomalies, or atypical coarctation. To this end, Doppler[18–20] and contrast-assisted[16,17] echocardiography have played an important role in the assessment of certain extracardiac congenital cardiac anomalies.

Cardiac catheterization remains the standard means of diagnosing most congenital heart diseases. In addition to anatomic delineation, flow and pressure hemodynamics can be appreciated qualitatively and quantitatively. Over the past 10 years, M-mode and 2-D echocardiography have become accepted as excellent in diagnosing many structural (acquired or congenital) and hemodynamic cardiac abnormalities. It is logical that certain functions heretofore obtained invasively with angiography would be supplanted by a noninvasive echocardiographic technique. Because angiography entails the use of radiation[21] and contrast medium and is associated with morbidity and mortality, a technique that provides much of the same information with no ionizing radiation or contrast medium and little or no morbidity would be preferred. In our institution and others, there has been a shift toward the noninvasive technique either to supplement or to replace cardiac catheterization in selected situations. This has been particularly noticeable in critically ill infants. This shift in utilization appears to permit a more goal-oriented approach to both procedures. There is an impression that as fewer catheterizations are performed, there is more selective utilization of angiography and more dependence on echocardiography as the diagnostic procedure of choice from which clinical decisions regarding further management, medical or surgical, can be made. With the introduction of high-resolution, 2-D sector echocardiography, this impact has been very noticeable in infants, in whom altered hemodynamic function is often clinically predictable. Most sick newborns presenting with cyanosis or heart failure previously underwent diagnostic cardiac catheterization. The only common exception was in patients with patent ductus arteriosus, in which the clinical examination was often diagnostic. In a review of 15 newborns undergoing cardiac surgery (excluding patent ductus arteriosus) before sophisticated 2-D echocardiography was available, all had preoperative cardiac catheterization. In this study, 35% (6 of 17) of such patients went directly to surgery without cardiac catheterization. We attribute this change in great part to the introduction of high-resolution 2-D echocardiography.

In our 40 newborns, 5 were immediately recognized as having noncardiac problems on echocardiography, and they were managed accordingly. The most impressive feature is that in 27 (68%), the clinician used the echocardiogram and not cardiac catheterization as the primary imaging tool with which to direct further management. Nineteen (54%) of 35 patients with congenital heart disease required surgery in the neonatal period. Eight (42%) of these 19 patients went directly to surgery after 2-D echocardiographic examination and without preoperative cardiac catheterization. Fourteen (40%) of the 35 patients had cardiac catheterization in the neonatal period. These catheterizations were requested for 3 primary reasons: therapeutic balloon septostomy, anatomic assessment, and hemodynamic evaluation. To these ends, the echocardiographer must perform a complete examination of the intra- and extracardiac anatomy. In this series the most common request for cardiac catheterization was for further delineation of extracardiac anatomy (that is, pulmonary and aortic arch anatomy). Confident echocardiographic recognition of a transposition complex permits the clinician to proceed directly to atrial septostomy without previous angiography.

At our institution, both the clinicians and the surgeons have had confidence in the echocardiographic data obtained. The physician doing the echocardiographic examination must be expertly trained and knowledgeable. If this procedure is undertaken to replace portions of the cardiac catheterization, the echocardiographic examination must be performed with comparable expertise. There must be a strong working relation among clinician, echocardiographer, angiographer, and surgeon to bring about such a change in practice. When achieved, such use of the echocardiographic techniques appreciably expedites management of the critically ill newborn and reduces the need for cardiac catheterization.

# Rest and Exercise Ventricular Function in Adults With Congenital Ventricular Septal Defects

GEORGE JABLONSKY, MD, J. DAVID HILTON, MD, PETER P. LIU, MD, JOHN E. MORCH, MD, MAURICE N. DRUCK, MD, BEN-ZION BAR-SHLOMO, MD, and PETER R. McLAUGHLIN, MD, *With the technical assistance of* KATHY M. WINTER, BSc (N)

**Rest and exercise right and left ventricular function were compared using equilibrium gated radionuclide angiography in 19 normal sedentary control subjects (mean age 28 years, range 22 to 34) and 34 patients with hemodynamically documented congenital ventricular septal defect (VSD) (mean age 27 years, range 20 to 40). The 34 patients with VSD were divided into 3 groups: those in Group 1 (17 patients) had pulmonary to systemic blood flow ratios of less than 2 to 1; those in Group 2 (12 patients) had prior surgical closure of VSD (mean interval from surgery 17 years, range 9 to 22), and those in Group 3 (5 patients) had Eisenmenger's complex. Gated radionuclide angiography was performed at rest and during each level of graded supine bicycle exercise to fatigue. Heart rate, blood pressure, maximal work load achieved, and right and left ventricular ejection fractions were assessed. The control subjects demonstrated an increase in both the left and right ventricular ejection fractions with exercise (0.70 ± 0.07 to 0.79 ± 0.05 and 0.46 ± 0.06 to 0.57 ± 0.04; $p < 0.001$ for left and right ventricles, respectively). All study groups failed to demonstrate an increase in ejection fraction in either ventricle with exercise. Furthermore, resting left ventricular ejection fraction in Groups 2 and 3 was lower than that in the control subjects (0.59 ± 0.09 and 0.54 ± 0.06 versus 0.70 ± 0.07; $p < 0.001$) and resting right ventricular ejection fraction was lower in Group 3 versus control subjects (0.30 ± 0.07 versus 0.46 ± 0.06; $p < 0.001$). Thus (1) left and right ventricular function on exercise were abnormal in patients with residual VSD as compared with control subjects; (2) rest and exercise left ventricular ejection fractions remained abnormal despite surgical closure of VSD in the remote past; (3) resting left and right ventricular function was abnormal in patients with Eisenmenger's complex; (4) lifelong volume overload may be detrimental to myocardial function.**

Few data are available on the effects of long-term volume overload on right and left ventricular function.[1] However, patients with patent congenital VSD reaching adulthood provide an ideal opportunity to assess this effect because of chronic biventricular volume overload. Rest and exercise gated equilibrium radionuclide angiography has become a widely accepted noninvasive technique for the evaluation of ventricular performance. Wackers et al[2] and Maddahi et al[3] validated the reliability and reproducibility of this technique for the left and right ventricles, respectively.

This study was undertaken to evaluate ventricular performance in adult patients with isolated VSD using gated radionuclide angiography. The result is then compared with (1) age-matched normal control subjects, (2) patients with VSD who had previously undergone surgical closure, and (3) patients with Eisenmenger's complex.

## Methods

**Patient population:** Thirty-four patients with previous angiographically proven isolated VSD were selected for study from our adult congenital heart clinic follow-up population. All patients were aged 20 to 40 years with no known history of coronary artery disease or other concurrent forms of heart disease. The patients were divided into 3 groups.

Cath = catherization; Ex = exercise; LV = left ventricle; RV = right ventricle; SBP = systolic blood pressure.

*Group 1:* This group included 17 patients (9 male and 8 female) who had persistent small left to right shunts without the necessity of surgical correction (Table I). Their mean age was 25 years (range 20 to 39). All had undergone at least 1 cardiac catheterization. The mean time lapse from the last catheterization to the present was 12 years (range 0 to 18). The mean pulmonary to systemic blood flow ratio at the time of the last catheterization was 1.4 to 1. Mean pulmonary artery pressure was normal at 16.7 ± 3.5 mm Hg (mean ± standard deviation [SD]). All patients were in New York Heart Association (NYHA) functional class I. Thirteen of 17 patients were physically active in sports on a regular basis, whereas 4 were considered sedentary. None of the patients was participating in any physical fitness training program. On physical examination all patients had findings typical of VSD.

*Group 2:* This included 12 patients (5 male and 7 female) who had undergone surgical closure of VSD 9 to 22 years (mean 17 years) before the study (Table II). Their mean age was 26 years (range 20 to 33 years). The operation was performed before the advent of present-day techniques of cardioplegia and myocardial protection. All patients were also in NYHA class I. However, only 5 of 12 patients were active physically. The remainder led voluntarily sedentary lives without participation in regular sports activities.

*Group 3:* This included 5 patients (1 male and 4 female) with Eisenmenger's complex documented at previous cardiac catheterization. Their mean age was 33 years (range 24 to 40). All were variably symptomatic with dyspnea on exertion. Two patients were in NYHA class II, the remainder in class III.

*Control:* The control group consisted of 19 healthy volunteers (15 male and 4 female) with a mean age of 28 years (range 22 to 34). This was comparable to the mean age of 27 years (range 20 to 40) in our overall study group. All of the volunteers had a normal cardiac history and normal results on physical examination.

**Protocol:** All patients had a complete history, physical examination, standard 12-lead electrocardiogram, posteroanterior and lateral chest X-ray, and supine multiple-gated equilibrium cardiac blood pool scintigrams both at rest and with graded bicycle exercise to fatigue.

**Radionuclide angiograms:** Equilibrium gated radionuclide angiograms were obtained by imaging the cardiac blood pool in the 45° left anterior oblique position with a 10° cranial

tilt, after in vivo labelling of red blood cells with 25 mCi of technetium-99m.

Patients were imaged in the supine position using a portable gamma camera (Ohio Nuclear, Series Sigma 420) equipped with a general purpose parallel-hole collimator. The camera and an electrocardiographic gate (Ohio Nuclear) were interfaced to a dedicated computer (Digital Equipment Corporation 11/40 or 11/60).

Rest studies were acquired for 200 cardiac cycles. Graded exercise studies were performed using a Quinton supine bicycle ergometer as previously described from our laboratory.[4,5] Exercise was started at a work load of 200 kpm and increased in 200 to 300 kpm increments every 3 minutes to patient exhaustion. At each level of exercise, a stable heart rate was attained before a 2-minute acquisition period. Heart rate, blood pressure, and a single lead electrocardiogram (lead II) were monitored throughout the study. All control subjects and patients were encouraged to achieve peak exertion to the limit of symptoms in the supine posture.

**Data analysis:** All radionuclide angiographic analysis was performed on an 11/40 or 11/60 computer (Digital Equipment Corporation) using Gamma II software. Data were initially viewed in an endless loop format to visually define the borders of both the right and the left ventricles throughout the cardiac cycle. The right and left ventricular end-diastolic and end-systolic frames were determined from time-activity curves generated from regions of interest surrounding both ventricles. Four regions of interest were assigned to both end-systolic and end-diastolic frames; the 2 ventricles and a left and right paraventricular background region as previously described.[4,5]

Two experienced observers independently analyzed the studies, and the reproducibility of the data analysis was assessed by comparing their results. Interobserver correlation for both left and right ventricular ejection fractions in VSD patients as well as control subjects was excellent ($r = 0.88$).[4,5]

Ejection fractions (EF) were calculated by the following equation: $EF = EDC_{bc} - ESC_{bc}/EDC_{bc}$, where $EDC_{bc}$ = background corrected end-diastolic counts and $ESC_{bc}$ = background corrected end-systolic counts.

Statistical analysis of the change from rest to exercise in each group was carried out with the 2-tailed paired $t$ test. Comparisons among the 4 groups were carried out with the 2-tailed unpaired Student's $t$ test.

## Results

**Heart rate and systolic blood pressure response (Table III):** The resting heart rates (mean ± SD) were similar in Groups 1 and 2 compared with control subjects (81 ± 15 and 76 ± 15 versus 72 ± 14; p = not significant [NS]). However, Group 3 patients had a slightly higher resting heart rate (96 ± 5; $p < 0.05$ compared with control subjects, Groups 1 and 2).

All study groups demonstrated an increase in heart rate with exercise. However, Group 3 patients had the lowest peak exercise heart rate (121 ± 9; $p < 0.001$ compared with control subjects and Group 1).

Resting systolic blood pressure was similar in the 4 study groups (Table IV). Peak exercise systolic blood pressure (systolic BP ± SD) was again similar in Groups 1, 2, and 3 but was significantly higher in the control subjects (158 ± 27; 158 ± 25; 146 ± 23 versus 197 ± 32; $p < 0.001$).

**Work load:** The mean maximal work load achieved by control subjects (14 kpm/kg) was much higher than that in any of the groups with VSD. The mean maximal work loads in Groups 1 and 2 were moderately reduced at 9.3 and 8.6 ($p < 0.001$ versus control subjects) and markedly depressed in Group 3 at 4.1 kpm/kg ($p < 0.001$ compared with control subjects; $p < 0.05$ compared with Groups 1 and 2). As may be expected, patients who were active were able to reach significantly higher peak work loads than sedentary patients ($p < 0.01$ in Group 1 and $p < 0.003$ in Group 2).

**Ejection fractions (Table V):** *Normal subjects:* The mean left ventricular ejection fraction at rest (mean ejection fraction ± SD) was 0.70 ± 0.07 and increased to 0.79 ± 0.05 at peak exercise ($p < 0.001$). The mean

**TABLE V Mean Ejection Fractions (± Standard Deviation)**

| | Control Subjects | | Group 1 | | Group 2 | | Group 3 | |
|---|---|---|---|---|---|---|---|---|
| | Rest | Exercise | Rest | Exercise | Rest | Exercise | Rest | Exercise |
| LV | 70 ± 7 | 79 ± 5* | 70 ± 7 | 67 ± 6 | 59 ± 9† | 58 ± 14 | 54 ± 6† | 49 ± 2 |
| RV | 46 ± 6 | 57 ± 4* | 44 ± 8 | 46 ± 7 | 43 ± 6 | 43 ± 8 | 30 ± 7† | 34 ± 9 |

* $p < 0.001$ change in ejection fraction rest → peak exercise. † $p < 0.001$ ejection fraction rest versus control rest. LV = left ventricle; RV = right ventricle.

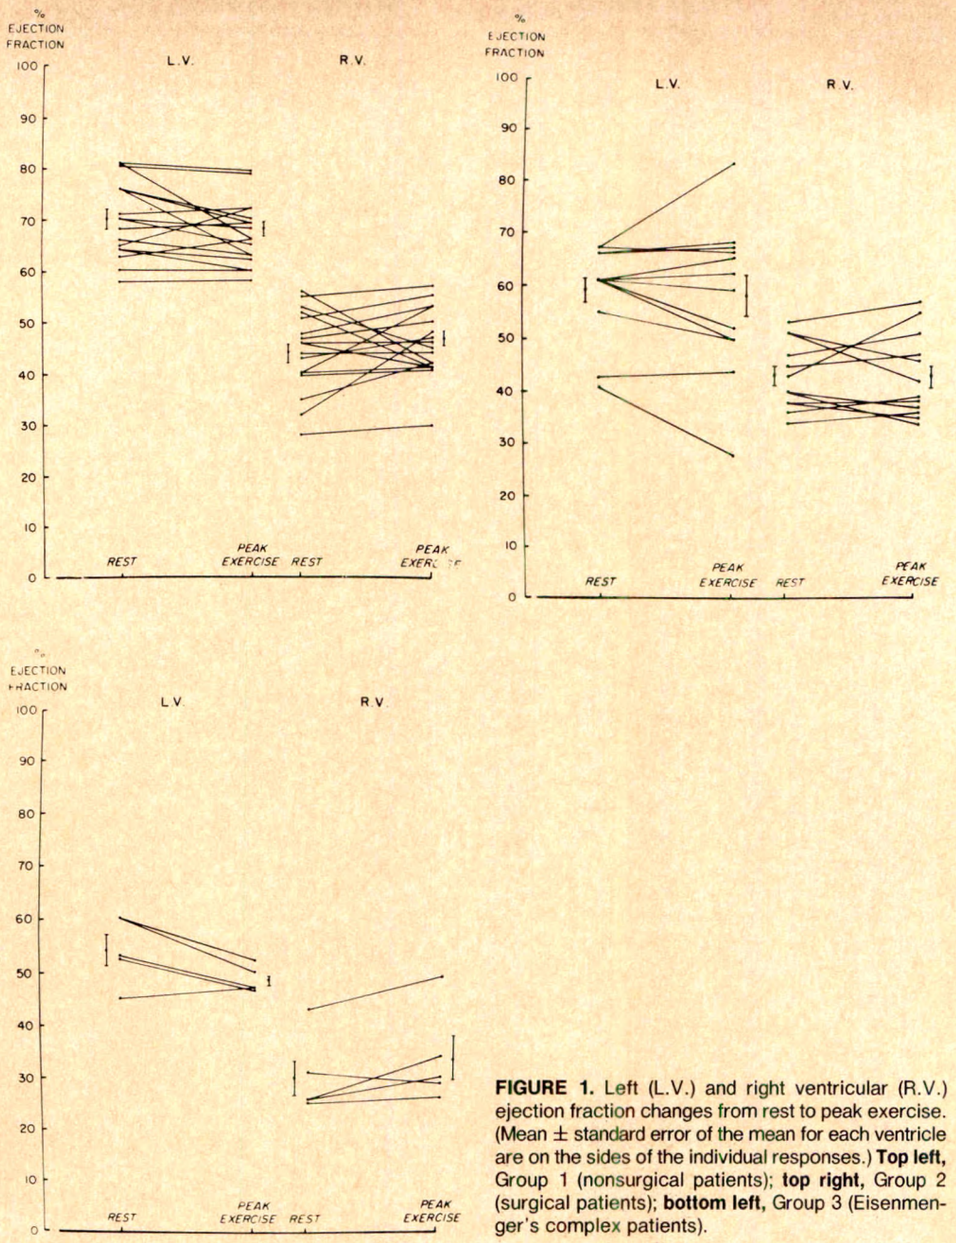

**FIGURE 1.** Left (L.V.) and right ventricular (R.V.) ejection fraction changes from rest to peak exercise. (Mean ± standard error of the mean for each ventricle are on the sides of the individual responses.) **Top left,** Group 1 (nonsurgical patients); **top right,** Group 2 (surgical patients); **bottom left,** Group 3 (Eisenmenger's complex patients).

right ventricular ejection fraction at rest was 0.46 ± 0.06 and increased to 0.57 ± 0.04 at peak exercise ($p < 0.001$).

*Group 1 (Fig. 1, top left):* Both left and right ventricular ejection fractions were similar to those in the control subjects at rest; however, both ventricles demonstrated a flat response to exercise, with a mean left ventricular ejection fraction of 0.70 ± 0.07 at rest and 0.67 ± 0.06 at peak exercise, and a mean right ventricular ejection fraction of 0.44 ± 0.08 at rest and 0.46 ± 0.07 at peak exercise ($p < 0.001$ versus control subjects at peak exercise for both left and right ventricles).

When physical conditioning was taken into account, this trend was still found to exist (Table I). The left ventricular ejection fraction at rest was 0.72 ± 0.05 for sedentary and 0.70 ± 0.08 for active individuals. On exercise, both decreased to 0.71 ± 0.02 for sedentary and 0.66 ± 0.07 for active patients ($p$ = NS between sedentary and active patients). Physical conditioning also did not account for an abnormal right ventricular ejection fraction response to exercise.

*Group 2 (Fig. 1, top right):* The resting left ventricular ejection fraction was lower than that for control subjects (0.59 ± 0.09 versus 0.70 ± 0.07; $p < 0.001$), whereas the right ventricular ejection fraction was similar to that of control subjects (0.43 ± 0.06 versus 0.46 ± 0.06; $p$ = NS). There was again a flat response to exercise for both ventricles, with a left ventricular ejection fraction at peak exercise of 0.58 ± 0.14 and a right ventricular ejection fraction at peak exercise of

0.43 ± 0.08 ($p < 0.001$ for both ventricles compared with the control subjects). Physical conditioning again did not account for the marked deviation from the normal exercise response (Table II).

*Group 3 (Fig. 1, bottom left):* Patients with Eisenmenger's complex had lower resting values for both left and right ventricles compared with control subjects (left ventricular ejection fraction 0.54 ± 0.06 versus 0.70 ± 0.07 and right ventricular ejection fraction 0.30 ± 0.07 versus 0.46 ± 0.06; $p < 0.001$). The ejection fraction response to exercise for both ventricles was similarly flat or decreased (left ventricular ejection fraction 0.49 ± 0.02 and right ventricular ejection fraction 0.34 ± 0.09 at peak exercise; $p < 0.001$ compared with control subjects). The mean ejection fraction response for both ventricles in all groups is displayed in Figure 2.

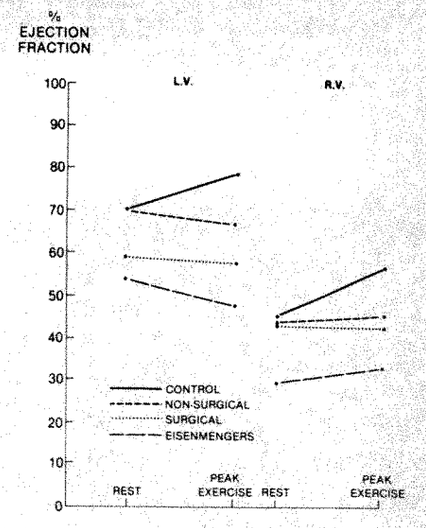

**FIGURE 2.** Mean left (L.V.) and right ventricular (R.V.) ejection fraction changes from rest to peak exercise in all groups compared with the control subjects. All study groups demonstrated a flat exercise response for both ventricles, whereas the ejection fraction increased with exercise in both ventricles in the control subjects. Control group, **unbroken line;** Group 1, **short dashes;** Group 2, **dotted line;** Group 3, **long dashes.**

## Discussion

**Group 1:** Patients with a small VSD (less than 2 to 1 pulmonary:systemic blood flow ratio with normal pulmonary vascular resistance) are believed to have a good overall prognosis with a functional status comparable to that of the general population.[6,7] In fact, a significant proportion may undergo spontaneous closure, and so far there is no evidence to suggest that an increase in shunt size can occur in these patients.[6–11]

Our results show that patients with small shunts had normal resting values for left and right ventricular ejection fraction, but they significantly failed to increase with exercise. The exercise response could not be predicted on the basis of history, physical examination, electrocardiogram, or chest roentgenogram, as all patients were in NYHA class I and had essentially normal electrocardiograms and chest X-rays.

The mean maximal work load attained was significantly lower than that of the control group; however, systolic blood pressure and heart rate response were normal in these patients. This finding could not be explained by a sedentary level of physical conditioning, which was present in only a small number of patients (4 of 17). This decrease in ejection fraction also did not correlate with age of patients, size of shunt, physical conditioning, or peak work load.

Several explanations for these findings are possible. The ventricles may respond to exercise by dilating and increasing their end-diastolic volumes during exercise with a constant ejection fraction. The stroke volume would increase during exercise as the end-diastolic volume increased; however, this increase could indeed represent previously unsuspected myocardial dysfunction secondary to chronic volume overload.

**Group 2:** All operated patients in our study had surgery through a right ventricular approach. All operations were performed before the advent of cardioplegia and modern myocardial protection, which may well be a significant factor influencing postoperative myocardial function. Furthermore, 10 of 12 patients had surgery after the age of 2 years, and the duration of uncorrected hemodynamic insult in patients with VSD may also be an important factor in predicting outcome.[12,13] The level of physical conditioning again did not appear to explain the abnormalities in exercise ejection fraction (Table V).

Several investigators have previously commented on impaired ventricular function after surgical repair of a congenital VSD. Jarmakani et al[14] looked at the velocity-pressure relation as a measure of left ventricular contractility in postoperative patients an average of 1.3 years after successful surgical closure. The ejection fraction was slightly depressed at rest in all patients studied. The same investigators looked at pre- and postoperative catheterization data in 23 patients to study the effect of VSD closure on left heart volume, mass, and contractility.[15] The postoperative catheterizations were performed 1 to 5 years after surgery, with a mean time lapse of 2 years. They found that although there had been significant regression in left ventricular volume and mass postoperatively, the results were still significantly higher than the normal values. Furthermore, postoperative resting left ventricular ejection fraction was lower than both the preoperative left ventricular ejection fraction and that of their normal control subjects (0.54 versus 0.60 and 0.63, respectively). They speculated that partially irreversible changes may be present in the myocardium associated with the hemodynamic effects of VSD.

Maron et al[16] studied the cardiac output and pulmonary arterial pressure response to upright exercise in 11 asymptomatic postoperative patients. Exercise studies were carried out 3 to 15 years (mean 9.5) after operative closure of isolated VSD. Ten of the 11 patients had had routine postoperative catheterizations within the first years after surgery and none had had evidence of residual shunt. Postoperative mean pulmonary arterial pressure was normal or mildly elevated at rest in

10 patients. During upright exercise sufficient to lower pulmonary arterial oxygen saturation to 30%, cardiac output was below the normal range in 5 patients, each of whom had been operated on after the age of 10 years. The investigators suggested that late cardiovascular function may be abnormal after repair of VSD and that the abnormalities may be related to age at operation.

Ahmad and Hallidie-Smith[17] found no abnormality of ejection fraction at rest in the early postoperative period in their study patients, and they speculated that abnormalities of postoperative myocardial function suggested by earlier studies may be related to the unavailability of currently used intraoperative myocardial preservation techniques. Further follow-up data on this group of patients will be necessary before this controversy can be settled. However, this finding is still clinically important, as a large number of these patients are being followed up by cardiologists. Therefore, baseline myocardial function determinations are important for future comparison if any change in clinical status occurs.

**Group 3:** At one extreme of the spectrum of population with chronic ventricular volume overload is the patient with Eisenmenger's complex. These patients had an extremely poor resting and exercise response as measured by all variables including heart rate and blood pressure response, maximal work load attained, and ejection fractions of both ventricles. These patients represent the end-stage of biventricular volume overload and pressure overload on the right ventricle as well as the added detrimental effect of right to left shunting of desaturated blood supplying hypertrophied viable myocardium.

In summary, with the aid of nuclear angiography, these data suggest the following: (1) The response of blood pressure, work load, and ejection fraction of both left and right ventricles to exercise in all patients with residual persistent VSD is abnormal compared with that of control subjects. (2) Rest and exercise left ventricular ejection fractions may be impaired postoperatively, and surgical closure does not appear to normalize ventricular function in patients operated on in the remote past or after the age of 2 years, or both. (3) Resting left and right ventricular function are abnormal in patients with Eisenmenger's complex. (4) Lifelong chronic volume overload, even to a small degree, may be detrimental to myocardial function.

# Prognosis of Symptomatic Coarctation of the Aorta in Infancy

PETER S. HESSLEIN, MD, FRCP(C), HOWARD P. GUTGESELL, MD, and DAN G. McNAMARA, MD

**Medical and surgical advances have improved the outlook for infants with symptomatic coarctation of the aorta. To help predict the clinical course of individual patients and to aid in individualizing their treatment, a 10-year experience with this condition was reviewed. Of 97 infants with symptomatic coarctation, 10 had isolated defects. In these patients, medical treatment was successful and surgical intervention could be postponed to allow for growth. The 87 other patients with associated cardiac defects were generally sicker at presentation and required earlier operation. Eleven of these died before surgical correction, 10 died at the time of repair, and 13 died later. The overall survival rate after 8 years was 62%, with most deaths occurring in the first 6 months of life. Late surgical results are flawed by a 32% rate of residual coarctation. Late postoperative hypertension is uncommon, and is usually attributable to a residual coarctation.**

The natural history of coarctation of the aorta in children and adults has been well described in clinical[1] and autopsy studies.[2,3] Early studies specifically excluded infants. Surgical techniques to repair coarctation have so improved the course of this disease in older children and adults that the natural course can no longer be determined for this age group. In contrast, the management of symptomatic infants with coarctation remains problematic, despite substantial medical and surgical advances during the last decade. The report of the 11-center New England Regional Infant Cardiac Program (NERICP)[4] has provided some useful information on the mortality of this lesion in infancy. In the present study we have reviewed our own recent experience with coarctation in infants, placing emphasis on the role of associated intracardiac anomalies in determining mortality and morbidity.

## Methods

We examined the records of 97 infants with aortic coarctation and congestive heart failure who presented to Texas Children's Hospital between January 1, 1970 and January 1, 1980. The criterion for entry into this series was that coarctation be documented at cardiac catheterization during the first 6 months of life. All patients received initial intensive medical therapy consisting of digoxin and furosemide, and 75 patients subsequently underwent surgical repair of coarctation. Eleven infants with complicated defects died before repair was attempted, and 11 others were awaiting repair at the time of this survey. Surgical treatment consisted of Dacron® patch aortoplasty as described by Reul et al[5] in 34 patients, classic primary resection with end-to-end anastomosis in 38 children, and repair employing the left subclavian artery (Blalock-Park[6] or Waldhausen-Nahrwold[7] technique) in 3 children.

To ascertain the prognosis of coarctation in this group of patients, we performed a clinical follow-up with emphasis on mortality, continued symptoms, the need for other surgical intervention, and the occurrence of unrelieved coarctation or systemic hypertension after initial repair. The mean duration of follow-up, excluding the patients who died, is now 62.6 months (5.2 years).

Because these patients manifest a broad range and combination of associated cardiac defects, they were classified into 4 subgroups. Group I consisted of 10 patients with isolated coarctation of the aorta. The mean follow-up for this group was 73.8 months. Group II included 43 patients with coarc-

AS = aortic stenosis; ASD = atrial septal defect; DORV = double outlet right ventricle; ECD = endocardial cushion defect; EFE = endocardial fibroelastosis; LV = left ventricular; MR = mitral regurgitation; MS = mitral stenosis; MV = mitral valve; PAPVD = partial anomalous pulmonary venous drainage; PDA = patent ductus arteriosus; PFO = patent foramen ovale; TGA = transposition of the great arteries; VSD = ventricular septal defect.

tation and a left-to-right shunt lesion. The mean follow-up for Group II patients (excluding deaths) was 57.9 months. Group III consisted of 15 patients with associated left heart obstructive lesions (but no intracardiac shunts) who were followed up for an average of 81.3 months. Group IV included 29 patients with coarctation associated with both obstructive and shunt lesions. The mean follow-up for Group IV survivors was 56.0 months. Table I lists the specific associated lesions for each group. Bicuspid aortic valve without obstruction was not included in this tabulation.

The surgical and follow-up data were analyzed for each subgroup as well as for the entire group, using actuarial and chi-square or Student's $t$ test statistical methods whenever appropriate.

**Presentation:** Table II summarizes the presentation and clinical course in infancy of our patients. Because inclusion in the study required that the infants have signs and symptoms of congestive heart failure and have undergone cardiac catheterization in the first 6 months of life, they were all by definition sick infants. However, the patients with associated left-to-right shunt lesions (Groups II and IV) tended to have more florid symptoms of pulmonary congestion than those with single or multiple left heart obstructions alone (Groups I and III), and they were therefore studied and repaired at an earlier age.

For 76 patients, repair of the coarctation was the first (and sometimes only) surgical procedure performed. In the patients with associated left-to-right shunts (Groups II and IV), incidental ligation and division of the ductus arteriosus were performed during 43 (75%) of 57 repairs of coarctation, whereas pulmonary artery banding was carried out during 24 (42%) of 57 operations. Twenty-three of these infants had both

DIC = disseminated intravascular coagulation syndrome; postcath = postcatheterization; SVT = supraventricular tachycardia. Other abbreviations as in Table I.

pulmonary banding and ductal division concurrent to the repair of coarctation.

Later operations were often required, most commonly closure of the ventricular septal defect and debanding of the pulmonary artery. To date 11 ventricular septal defects have been surgically closed, and 12 of 24 pulmonary bands have been removed. Four patients underwent aortic valvotomy, 2 had subaortic resection, and 1 each had a mitral commissurotomy, subpulmonary resection, atrial septal defect closure, repair of the atrioventricular canal, and Blalock-Hanlon atrial septectomy. Three patients required revision of the original repair of coarctation.

**Mortality:** Cumulative mortality is expressed in tabular form (Table II) and as an actuarial survival curve (Fig. 1). Uncomplicated coarctation carried no mortality over the mean follow-up period of 73.8 months (median 72). Eleven children with complicated defects died before any surgery was attempted. Their course is summarized in Table III. All but 1 of these children are believed to have died in a low-output state and congestive heart failure as a direct result of their cardiac disease; the remaining patient (Case 2) died from overwhelming infection. Five of these patients (Cases 2, 4, 6, 7, and 10) were not offered surgery because of the severity of associated cardiac and extracardiac defects. Three other infants died in the catheterization laboratory, and 2 more died within 1 day of cardiac catheterization. One child with coarctation and multiple sites of left-to-right shunting died as a result of refractory supraventricular tachycardia.

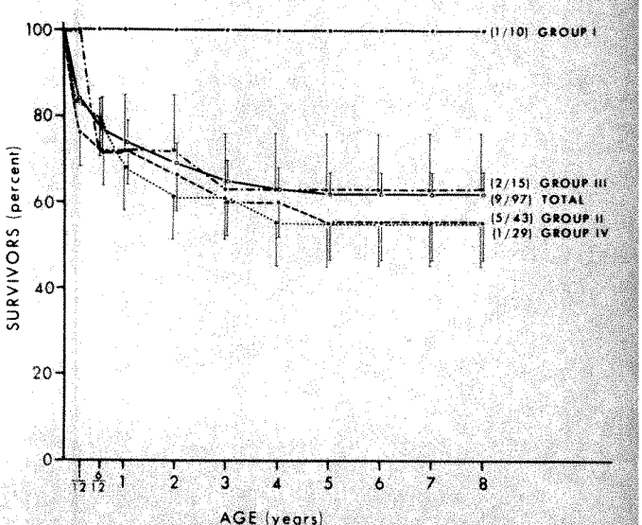

**FIGURE 1.** Survival of infants with symptomatic coarctation of the aorta. Data points represent mean actuarial survival, ±1 standard error of the mean. There were no deaths in Group I. The other 3 groups had similar survival curves, although the circumstances of death varied. The overall 8-year survival rate was 62%. Numbers in parentheses refer to the patient population in each group at the beginning and end of the actuarial survival curves. See text for more detailed explanation.

**TABLE IV Late Postoperative Morbidity**

| Group | Persistent CHF | Residual Coarctation (Gradient 10 torr) | Systemic Hypertension |
|---|---|---|---|
| I (n = 10) | 0 | 3 | 1 |
| II (n = 26) | 0 | 9 | 1 |
| III (n = 6) | 1 | 3 | 1 |
| IV (n = 14) | 5 | 3 | 0 |
| Total (n = 55) | 6 | 18 | 3 |

CHF = congestive heart failure.

There were 13 late deaths after surgical repair of coarctation, 5 of which were related to subsequent surgical intervention for associated lesions. Of the 8 late nonsurgical deaths, 3 occurred for reasons clearly related to associated cardiac anomalies, 2 were the result of overwhelming infection, and in 3 patients (1 each from Groups II, III, and IV) the cause of death is unknown.

Although there was some variability in the mode and timing of deaths among the postoperative groups with complicated lesions, the cumulative mortality for each of these groups was statistically comparable with the others. In actuarial terms, this translates to an overall 38% mortality rate over 8 years, with 42% of deaths occurring in the first month and 82% within 2 years.

**Postoperative morbidity:** Follow-up data at least 1 year after repair is available for 56 (75%) of 75 patients (Table IV). No patient in Group I or II had refractory congestive heart failure after repair, and more than three fourths of patients with other left-sided obstructions were relieved of symptoms after repair. Eighteen patients (32%) had continued evidence of coarctation after repair, defined as a gradient between arm and leg cuff pressures, or between proximal and distal intraaortic pressures, >10 torr. To date, 3 patients required revision of the coarctation repair, and these were all successful.

We evaluated for the presence of systemic hypertension, defined as a systolic blood pressure obtained in the right arm with an appropriate-sized cuff, which exceeded the normal mean for age and sex by >2 standard deviations.[8] Three patients (5%) met this criterion, 2 of whom also had evidence of a residual coarctation. The presence or type of associated cardiac defects did not appear to influence the occurrence of late postoperative hypertension.

## Discussion

The management of symptomatic infants with coarctation of the aorta remains problematic because of the high rate of mortality and morbidity in both surgically and medically treated patients. An update of the natural and unnatural course of these infants can be helpful in predicting the clinical course for individual patients and individualizing their treatment.

Patients with uncomplicated coarctation and congestive heart failure have recently become a subject of controversy. This combination is uncommon, comprising only 10% of the present series. In our experience and in that of others,[9–11] congestive symptoms could be controlled medically without incident until elective repair later in infancy or beyond. All 10 of our patients in this category were successfully treated medically without congestive failure. Five had later repair in the first year of life: 3 for systolic hypertension >200 mm Hg, and 2 because of social considerations. Overall, our 10 patients with uncomplicated coarctation underwent repair at a median age of 10.5 months (mean 20.2). However, Waldhausen et al[12] cited 2 cases of acute medical decompensation (including 1 death) as justification for their recommendation of immediate surgical repair in infancy. Although repair of uncomplicated coarctation carries a low risk at any age, we are concerned that early repair will increase the likelihood of a suboptimal result in terms of residual gradient. In our own experience, both the end-to-end anastomosis technique and the Dacron patch aortoplasty procedure have a significantly greater risk of a poor result if performed in infancy.[13] Several studies have been cited[14–17] as evidence that the subclavian flap technique effectively eliminates the effect of young age on surgical outcome. However, the follow-up period of these studies is brief, and data concerning the occurrence of residual gradient are scant or absent. At least 1 recent study, although not intended to be a comparative evaluation of surgical techniques, reported a higher rate of residual coarctation after subclavian flap repair than for either primary anastomosis or patch aortoplasty.[18] Until the effect of age is conclusively shown to be minimized by the subclavian flap technique, we continue to recommend medical management and elective surgical repair during childhood for most patients with isolated coarctation.

Complicated defects including coarctation present a different problem, where symptoms can be intractable and death a very real possibility. Although recent improvements in medical and surgical care have resulted in a reduced mortality compared with older series,[10] the 26% infant mortality reported in this series remains formidable. The fact that 10 infants died a cardiac death before operative treatment not only underscores the serious nature of this disease complex, but also suggests that we have relied too much on medical treatment alone in the past. However, the equal number of surgical deaths serves as a reminder that, for some infants, no currently available treatment may be sufficient. The cumulative mortality and morbidity figures for the 3 groups with complex defects are nearly identical, regardless of whether the associated defects consist primarily of a shunt, additional obstruction, or both. There is a difference between groups, however, in the circumstances of death: 9 of 10 surgical deaths occurred in Group II, whereas 9 of 13 late deaths occurred in Groups III and IV. When we compared our series with the earlier multicenter NERICP[4] group there was a striking similarity in the proportion and type of associated cardiac and extracardiac anomalies, as well as in the mortality risk of cardiac catheterization. Our more favorable early mortality experience probably reflects improvements in medical therapy as well as a trend toward earlier and more effective surgical intervention. In any event, coarctation in the form of a complex remains a dangerous condition requiring vigorous medical stabilization followed shortly thereafter by surgical repair. The specific technique of repair should depend on the preference and proficiency of the surgeon. Although some reports claim a superiority of patch aor-

toplasty to primary anastomosis,[19,20] we have found no significant difference in the effectiveness of these 2 procedures.[13] Many centers now prefer the subclavian flap technique for repair of infant coarctation, but our limited experience does not allow us to judge this technique. Simultaneous pulmonary artery banding for patients with ventricular septal defect should be considered on an individual, patient-by-patient basis, recognizing that isolated ventricular septal defect is often amenable to medical management and has the potential to close spontaneously. Pulmonary artery banding, on the other hand, commits the patient to a second surgical procedure. We therefore recommend that the size of the ventricular septal defect be assessed, either angiographically or echographically, as an aid in deciding whether or not a pulmonary band is needed. In this series, 24 patients received a pulmonary artery band out of 53 with associated ventricular septal defect. Six children had ventricular septal defects that closed spontaneously, and 5 of these 6 avoided a second thoracotomy because they had not received a pulmonary band. The 6th child required repeat operation to remove the pulmonary band and to resect a subaortic obstruction.

*Conclusion:* For infants with isolated coarctation of the aorta, the prognosis is excellent. For those with coarctation and associated cardiac anomalies, mortality remains high despite improved medical and surgical treatment. Early surgical intervention is both lifesaving and effective in reducing the symptoms of congestive heart failure, but surgical mortality is high and postoperative results remain flawed by a high rate of residual coarctation. Late systemic arterial hypertension occurs infrequently and is usually related to a residual coarctation. If an infant with complex coarctation receives early and vigorous management, the long-term prognosis depends primarily on the specific associated defects.

**ADDRESS MANUSCRIPTS TO:** William C. Roberts, MD, Editor-in-Chief, THE AMERICAN JOURNAL OF CARDIOLOGY, 6935 Arlington Road, Suite 406, Bethesda, Maryland 20814. The *covering letter* should state precisely and concisely the significance and uniqueness of the work in the authors' view. The authors might delineate the extent of any concessions they are readily prepared to make: for example, the elimination of 1 or more figures or tables or a portion of the text to increase the likelihood of publication of their work in the *Journal.* Several names and addresses should be provided of nonlocal experts who, in the authors' view, could provide objective and informed reviews of their work. The suggested reviewers will be carefully considered along with other experts in the field. Additionally, the editor would listen if the authors provided the names of any investigators they consider unlikely to give nonbiased reviews of their work.

Submit 3 copies (1 original and 2 xerographic copies) of the entire manuscript including text, references, figures, legends, and tables. Study recent past issues of the *Journal* for format. Arrange the paper as follows: (1) title page consisting of the article's title, the names of the authors, and the institution from which the work originated, (2) a second title page including only the article's title, (3) summary, (4) text, (5) references, (6) acknowledgment, (7) figure legends, and (8) tables. Number all pages in the above sequence, beginning with the title page as 1, the summary as 2, and so on (leave the second title page unnumbered). Type on 22 × 28 cm (8.5 × 11 inch) paper, only on 1 side of each sheet, double-spaced (including references) with at least 25 mm (1 inch) margins.

The second title page, the one which omits the names of the authors and the institution, will permit the Editor-in-Chief the option of acquiring blinded or nonblinded reviews. References to the institution in the text or to the author's previous work in the Reference section must be deleted or written in a manner that prevents identification of the authors and the institution. Label figures with the manuscript title rather than the authors' names so that blinded reviews can be obtained. The authors may state which type of review they wish in the covering letter.

**TITLE PAGE, SUMMARY, AND ABSTRACT:** Include the first or middle and last names with other initials of all authors. Provide a short *running title* of 3 to 6 words. Insert at the bottom the name and address of the institution from which the work originated, and information about grant support if necessary. Add at the bottom the phrase "*Address for reprints:*" followed by full name and address with zip code. Limit the **summary** to 250 words. Also, submit an **abstract** of 150 words or less to be used in the Table of Contents. List 2 to 6 **key words** for subject indexing at the end of the summary.

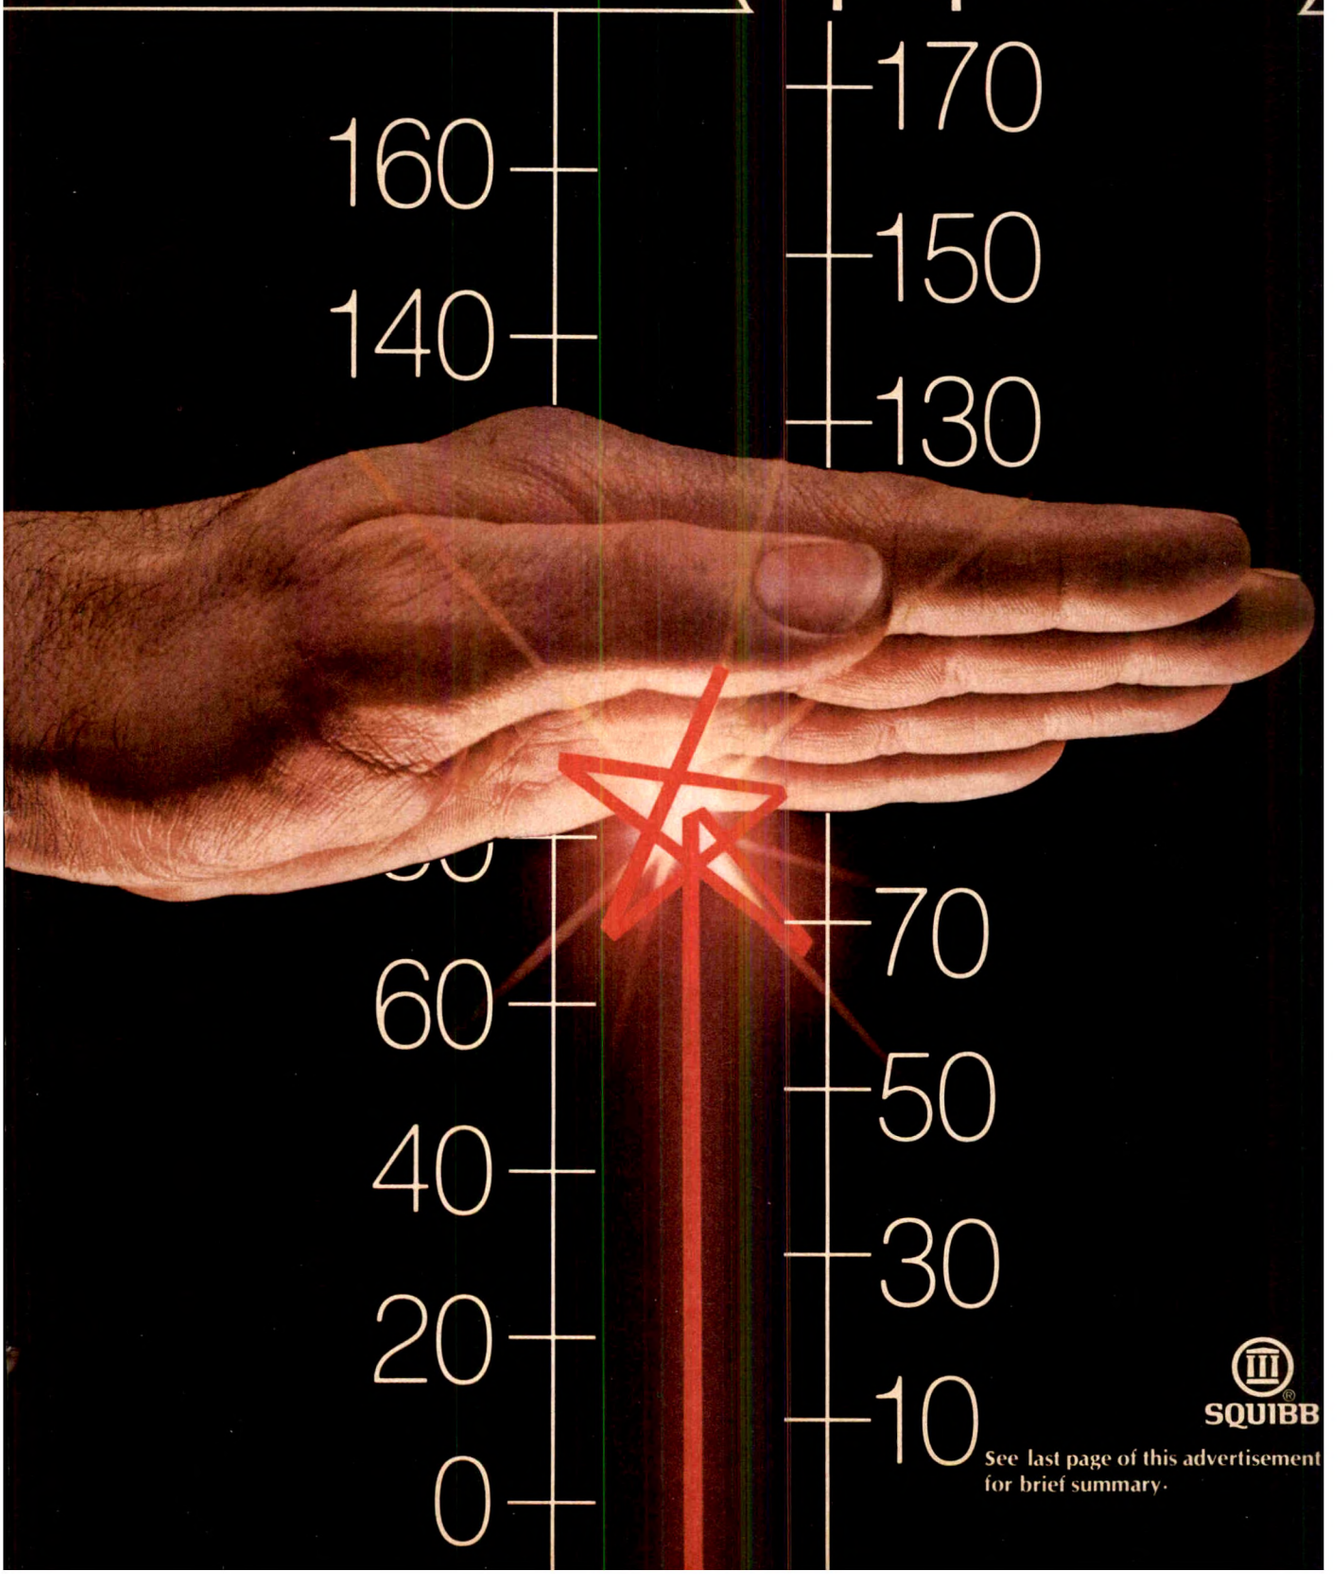
**STYLE:** Use appropriate **subheadings** throughout the body of the text, such as in the Methods, Results, and Comments sections. **Abbreviations** are permitted, but no more than 2 or 3 per manuscript. Spell out the first time they appear in the text followed by the abbreviation in parentheses. Consult the *Uniform Requirements for Manuscripts Submitted to Biomedical Journals* published in the *Annals of Internal Medicine* June 1982; 96: 766–771, and also the *Stylebook/Editorial Manual of the American Medical Association* for current usage. Use generic names of drugs. Do not spell out any number, including those less than 10, except when used for opening a sentence.

**REFERENCES:** In references, list **all authors,** inclusive pages for all journal references, and specific page numbers for all book references as shown below. Avoid referencing abstracts if possible, but indicate by the abbreviation (*abstr*) when doing so. Do not use periods after authors' initials. Check *Index Medicus* or *Annals of Internal Medicine* (June 1982) as cited above for journal titles and abbreviations. Personal communications do not constitute references. In referring to a manuscript that has been submitted but not yet published, use the phrase "unpublished observations" in parentheses.

**Journal:** Vismara LA, Vera Z, Miller RR, Mason DT. Efficacy of disopyramide phosphate in the treatment of refractory ventricular tachycardia. Am J Cardiol 1977; 39:1027–1034.

**Chapter in Book:** Schiebler GL, Van Mierop LHS, Krovetz LJ. Diseases of the tricuspid valve. In: Moss AJ, Adams F, eds. Heart Disease in Infants, Children and Adolescents. Baltimore: Williams & Wilkins, 1968: 134–139.

**Book:** Berne E. Principles of Group Treatment. New York: Oxford University Press, 1966:26.



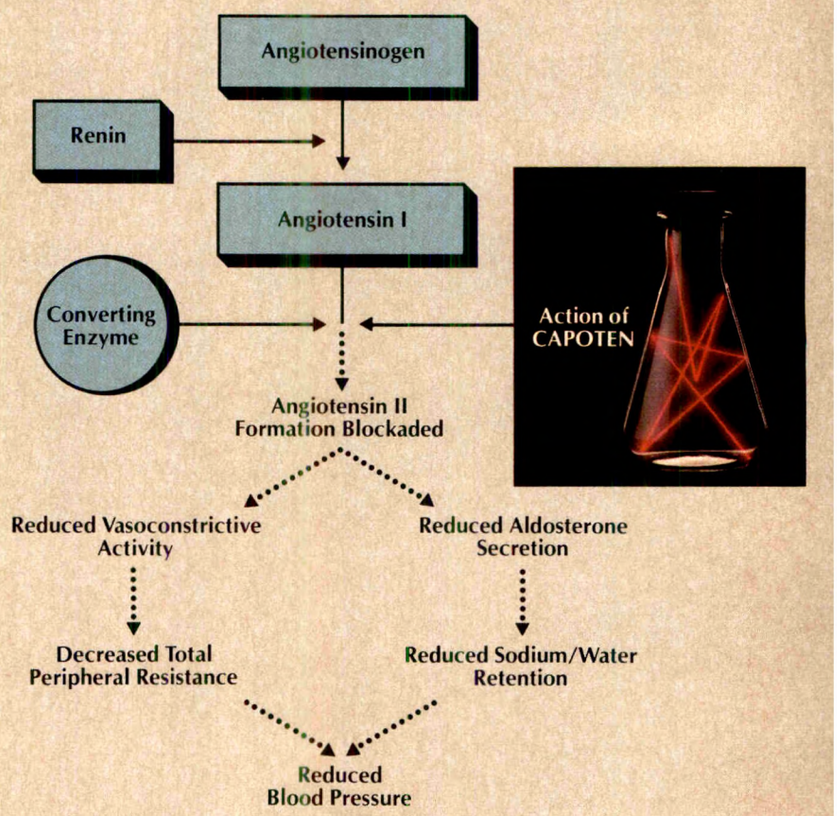
**FIGURES:** Submit 3 glossy nonmounted *prints* of each photograph and drawing. Artwork of published articles will not be returned unless requested. Use black ink for all *charts* (line drawings). Make decimals, broken lines, etc. strong enough for reproduction. Use arrows to designate special features. Crop photographs to show only essential fields. Identify figures on back by number and title of the article (omit the authors' names so that blinded reviews can be obtained). Number figures in the order in which they are mentioned in the text. Indicate the top of each figure. Submit written permission from the publisher and author to reproduce any previously published figure. Limit figures to the number necessary to present the message clearly. Type each figure legend on a separate page, double-spaced. Identify at the end of each legend and in alphabetical order all abbreviations in the figure. The cost of color reproduction must be paid by the author. If color figures are submitted, identify in the covering letter who should be billed for the color charges.

**TABLES:** Place each table on a separate page, double-spaced. Number each table in Roman numerals (Table I, II, etc.) and title each table. Identify in alphabetical order at the bottom of the table all abbreviations used. When tabulating patients, use no more than 2 lines, preferably only 1 line, per patient. Use a plus sign (+) to indicate positive or present; a zero (0) for negative or absent, and a dash (—) for "no information available" or "not done."

**REPRINTS:** Price schedules and order cards for reprints will be mailed to the author on publication of the article. Individual reprints must be obtained through the author.

# Designed to achieve your therapeutic goals in hypertension

# CAPOTEN® (captopril tablets)



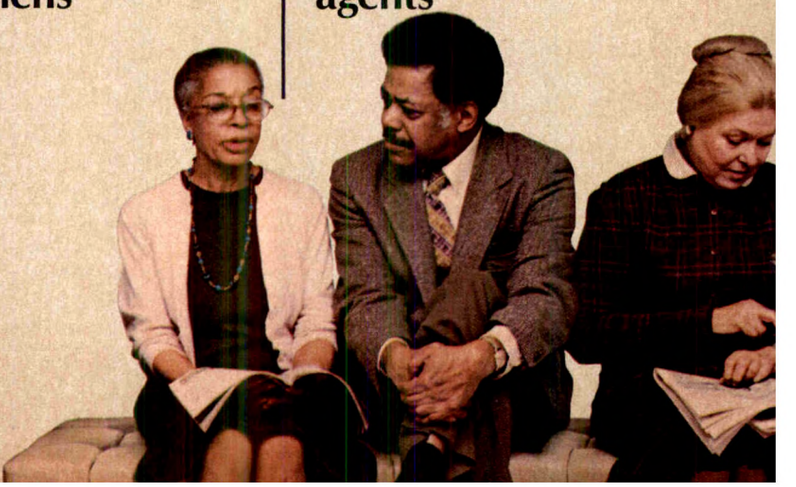
SQUIBB®

See last page of this advertisement for brief summary.

ACE* INHIBITOR

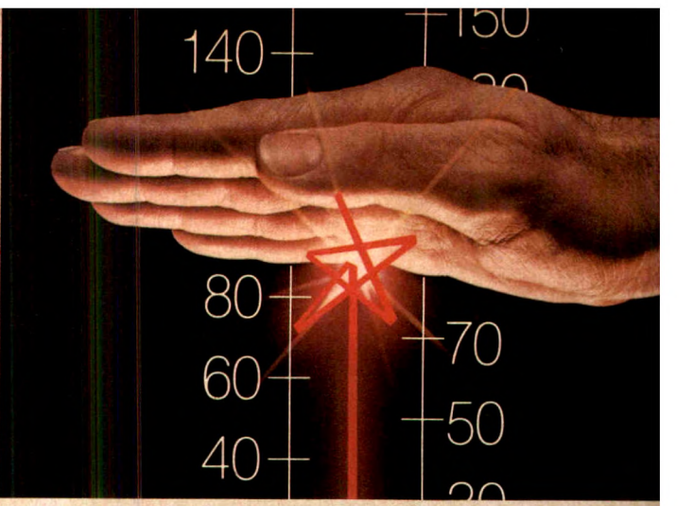
# CAPOTEN® (captopril tablets)

Because of its specific action within the renin-angiotensin-aldosterone (RAA) system, CAPOTEN enables you to reliably control blood pressure in a diverse group of hypertensive patients.



## For hypertensive patients:

**who experience unacceptable side effects with beta blockers, antiadrenergic agents, or vasodilators**



**whose blood pressure is uncontrolled by standard multidrug regimens**

**who have concomitant conditions contraindicating use of other antihypertensive agents**

*Angiotensin Converting Enzyme

SQUIBB

# A design that controls blood pressure without the following usual antihypertensive side effects*

- ▶ No cardiac depression
- ▶ No glucose intolerance
- ▶ No bradycardia
- ▶ No mental depression
- ▶ No sleep disturbances
- ▶ No nasal congestion
- ▶ No hypokalemia

- ▶ Rare impotence/loss of libido
- ▶ Rare bronchospasm
- ▶ Rare tachycardia
- ▶ Rare fatigue

ACE INHIBITOR

## CAPOTEN®
## (captopril tablets)

*Please see brief summary of prescribing information on the last page of this advertisement for INDICATIONS AND USAGE, WARNINGS, and ADVERSE REACTIONS.

ACE* INHIBITOR

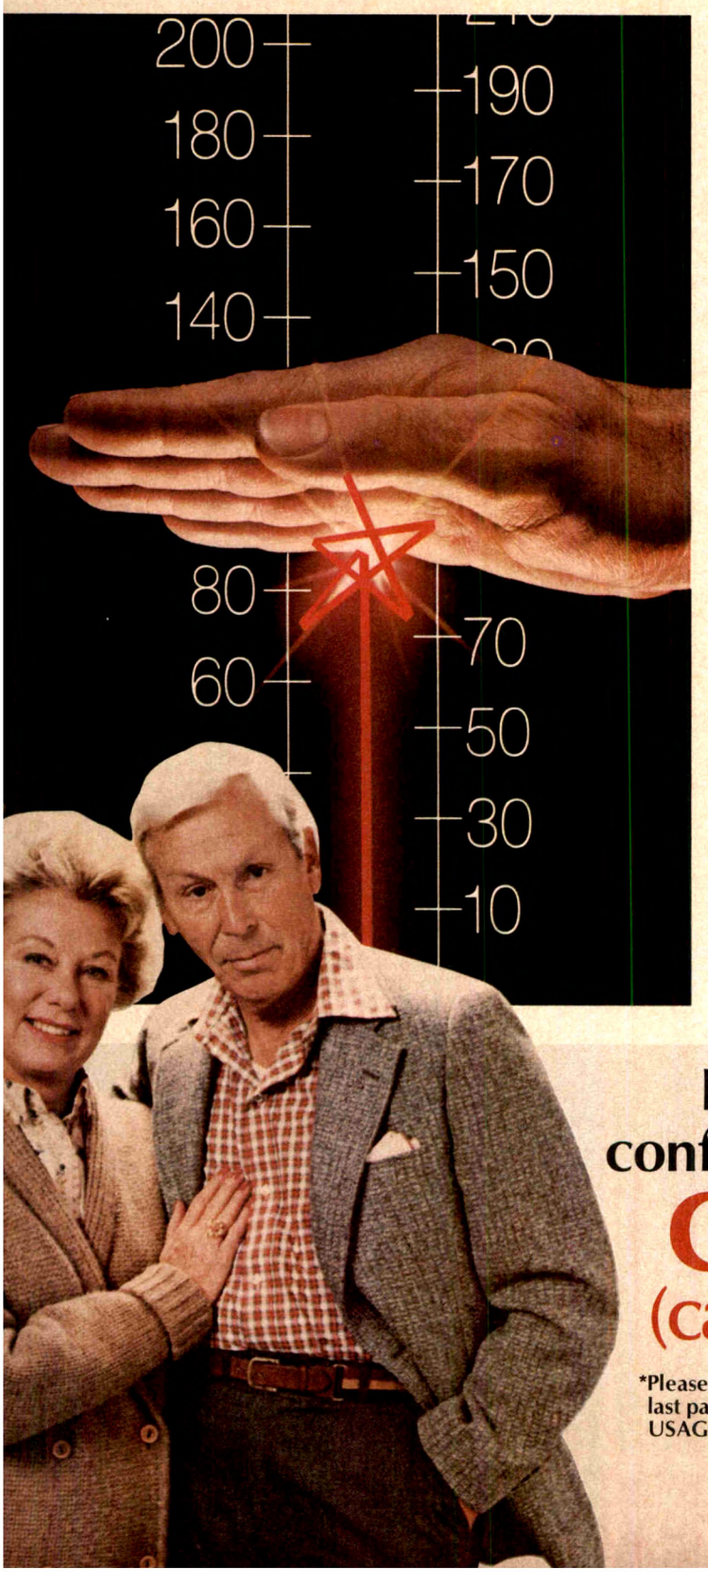
# CAPOTEN® (captopril tablets)

## Designed to control blood pressure even when coexisting disorders complicate hypertension management

Unlike some other antihypertensive agents, CAPOTEN is appropriate for use in the presence of a wide range of cardiovascular and metabolic disorders that often coexist with hypertension.

- ▶ **Bronchospastic disease**
- ▶ **Cardiac arrhythmias**
- ▶ **Congestive heart failure**
- ▶ **Diabetes mellitus**
- ▶ **Hepatic disease**

## Designed to control blood pressure when conventional multidrug regimens have proven inadequate



In scores of clinical studies, the effectiveness of CAPOTEN in lowering elevated blood pressure has been proven in many kinds of hypertension—even in those types that are most difficult to treat.

- ▶ **Essential hypertension**
- ▶ **Hypertension resistant to standard triple therapy (STT)**
- ▶ **Hypertension associated with low, normal, and high plasma renin levels**
- ▶ **Renovascular hypertension**

*Angiotensin Converting Enzyme

# Designed to achieve your therapeutic goals in hypertension

SQUIBB

## Effective blood pressure control

▶ Routine monitoring procedures are recommended because serious side effects (neutropenia/agranulocytosis, proteinuria) have been associated with CAPOTEN.*

▶ Obtain urinary protein level estimates prior to initiating therapy, at monthly intervals for the first nine months of treatment, and periodically thereafter.

▶ Obtain WBC counts at the initiation of therapy, at two-week intervals for the first three months of treatment, and periodically thereafter.

▶ Carefully review the WARNINGS and ADVERSE REACTIONS sections in the complete prescribing information, with particular attention to the patient at increased risk.

▶ The most frequently occurring adverse reactions are skin rash and taste alteration; both effects are generally mild, reversible, or self-limited.

## In hypertension... confidence comes with

# CAPOTEN®

## (captopril tablets)

*Please see brief summary of prescribing information on the last page of this advertisement for INDICATIONS AND USAGE, WARNINGS, and ADVERSE REACTIONS.

**Captopril Tablets**

**DESCRIPTION:** Capoten (captopril) is a specific competitive inhibitor of angiotensin I-converting enzyme (ACE), the enzyme responsible for converting angiotensin I to angiotensin II.

**INDICATIONS:** Because serious adverse effects have been reported (see WARNINGS), Capoten is indicated for treatment of hypertensive patients who on multidrug regimens have either failed to respond satisfactorily or developed unacceptable side effects. Usually, multidrug regimens include combinations of a diuretic, a sympathetic nervous system-active agent (such as a beta-blocker) and a vasodilator.

Capoten (captopril) is effective alone, but in the population described above, it should usually be used in combination with a thiazide-type diuretic. The blood pressure lowering effects of captopril and thiazides appear to be additive.

**WARNINGS: Proteinuria**—Total urinary proteins >1 g/day were seen in 1.2% of patients on captopril; the nephrotic syndrome occurred in about ¼th of these cases. Existence of prior renal disease increased the likelihood of development of proteinuria. About 60% of affected patients had evidence of prior renal disease; the remainder had no known renal dysfunction. In most cases, proteinuria subsided or cleared within 6 months whether or not captopril was continued, but some patients had persistent proteinuria. The BUN and creatinine were seldom altered in the proteinuric patients.

Membranous glomerulopathy was found in nearly all the proteinuric patients on captopril who were biopsied and may be drug related; this is uncertain since patients were not biopsied prior to treatment and membranous glomerulopathy may be associated with hypertension in absence of captopril therapy. Since most cases of proteinuria occurred by the 8th month of captopril therapy, patients on captopril should have urinary protein estimates (dip-stick on 1st morning urine, or quantitative 24-hr urine—the latter provides greater precision when proteinuria is persistent and/or at low levels) before therapy, at approx. monthly intervals for the 1st 9 months of therapy, and periodically thereafter. For patients who develop proteinuria >1 g/day, or increasing proteinuria, the benefits and risks of continuing captopril should be evaluated.

**Neutropenia/Agranulocytosis**—Neutropenia (<300/mm³) associated with myeloid hypoplasia (probably drug related) occurred in about 0.3% of captopril treated patients. About half of the neutropenic patients developed systemic or oral cavity infections or other features of agranulocytosis. Most of the neutropenic patients had severe hypertension and renal function impairment; about half had systemic lupus erythematosus (SLE), or another autoimmune/collagen disorder; multiple concomitant drug therapy was common, including immunosuppressive therapy in a few cases. Daily doses of captopril in the leukopenic patients were relatively high, particularly in view of their diminished renal function. The neutropenia appeared 3 to 12 weeks after starting captopril; it developed relatively slowly, taking 10 to 30 days to have white blood count fall to its nadir; neutrophils returned to normal in about 2 weeks (other than 2 patients who died of sepsis).

**Use captopril with caution in patients with impaired renal function, serious autoimmune disease (particularly SLE), or who are exposed to other drugs known to affect the white cells or immune response. In patients at particular risk (as noted above), perform white blood cell and differential counts prior to therapy, at about 2-week intervals for about the 1st 3 months of therapy, and periodically thereafter.**

The risk of neutropenia in patients who are less seriously ill or who receive lower dosages appears to be smaller, and it is sufficient in these patients to have white blood cell counts every 2 weeks for the 1st 3 months of therapy, and periodically thereafter. Perform differential counts when leukocytes are <4000/mm³ or the pretherapy white count is halved. All patients treated with captopril should be told to report any signs of infection (e.g., sore throat; fever); if infection is suspected, perform counts without delay. Since discontinuation of captopril and other drugs has generally led to prompt return of the white count to normal, upon confirmation of neutropenia (neutrophil count <1000/mm³) withdraw captopril and closely follow the patient's course.

**Hypotension**—Excessive hypotension was rarely seen in hypertensive patients but is a possible consequence of captopril use in severely salt/volume depleted persons such as those treated vigorously with diuretics, e.g., patients with severe congestive heart failure (see PRECAUTIONS [Drug Interactions]).

**PRECAUTIONS: General:** *Impaired Renal Function*—Some patients with renal disease, particularly those with severe renal artery stenosis, have developed increases in BUN and serum creatinine after reduction of blood pressure with captopril. It may be necessary to reduce captopril dosage and/or discontinue diuretic. For some of these patients, normalization of blood pressure and maintenance of adequate renal perfusion may not be possible (see DOSAGE AND ADMINISTRATION, ADVERSE REACTIONS [Altered Laboratory Findings]). *Surgery/Anesthesia*—During major surgery or anesthesia with agents that produce hypotension, captopril will block angiotensin II formation secondary to compensatory renin release; if hypotension occurs and is considered due to this mechanism, it is correctable by volume expansion.

**Drug Interactions:** *Hypotension: Patients on Diuretic Therapy*—A precipitous reduction of blood pressure may occasionally occur within the 1st 3 hours after administration of the initial captopril dose in patients on diuretics, especially those recently placed on diuretic therapy and those on severe dietary salt restriction or dialysis. The possibility of hypotensive effects can be minimized by either discontinuing the diuretic or increasing the salt intake about 1 week prior to initiation of captopril therapy. Alternatively, provide medical supervision for at least 3 hours after the initial dose. If hypotension occurs, place the patient in a supine position and, if necessary, administer an I.V. infusion of normal saline. This transient hypotensive response is not a contraindication to further doses which can be given without difficulty once the blood pressure has increased after volume expansion.

*Agents Causing Renin Release*—Captopril's effect will be augmented by antihypertensive agents that cause renin release.

*Agents Affecting Sympathetic Activity*—The sympathetic nervous system may be especially important in supporting blood pressure in patients receiving captopril alone or with diuretics. Beta-adrenergic blocking drugs add some further antihypertensive effect to captopril, but the overall response is less than additive. Therefore, use agents affecting sympathetic activity (e.g., ganglionic blocking agents or adrenergic neuron blocking agents) with caution.

*Agents Increasing Serum Potassium*—Since captopril decreases aldosterone production, elevation of serum potassium may occur. Give potassium-sparing diuretics or potassium supplements only for documented hypokalemia, and then with caution, since they may lead to a significant increase of serum potassium. If the patient has received spironolactone at any time up to several months prior to captopril therapy, determine the serum potassium frequently since the effect of spironolactone persists.

**Drug/Laboratory Test Interaction:** Captopril may cause a false-positive urine test for acetone.

**Carcinogenesis, Mutagenesis, and Impairment of Fertility:** Two-year studies with doses of 50 to 1350 mg/kg/day in mice and rats failed to show any evidence of carcinogenic potential.

**Animal Toxicology:** Chronic oral toxicity studies were conducted in rats (2 years), dogs (47 weeks; 1 year), mice (2 years), and monkeys (1 year). Significant drug-related toxicity included effects on hematopoiesis, renal toxicity, erosion/ulceration of the stomach, and variation of retinal blood vessels. Reductions in hemoglobin and/or hematocrit values were seen in mice, rats, and monkeys at doses 50 to 150 times the maximum recommended human dose (MRHD). Anemia, leukopenia, thrombocytopenia, and bone marrow suppression occurred in dogs at doses 8 to 30 times MRHD. The reductions in hemoglobin and hematocrit values in rats and mice were only significant at 1 year and returned to normal with continued dosing by the end of the study. Marked anemia was seen at all dose levels (8 to 30 times MRHD) in dogs, whereas moderate to marked leukopenia was noted only at 15 and 30 times MRHD and thrombocytopenia at 30 times MRHD. The anemia could be reversed upon discontinuation of dosing. Bone marrow suppression occurred to a varying degree, being associated only with dogs that died or were sacri-

©1982 E.R. Squibb & Sons, Inc. 522-508 Issued: June 1982

[illegible] 30 times MRHD, bone marrow suppression was found to be reversible upon continue drug administration. Captopril caused hyperplasia of the juxtaglomerular apparatus of th kidneys at doses 7 to 200 times the MRHD in rats and mice, at 20 to 60 times MRH in monkeys, and at 30 times the MRHD in dogs. Gastric erosions/ulcerations were i creased in incidence at 20 and 200 times MRHD in male rats and at 30 and 65 times MRH in dogs and monkeys, respectively. Rabbits developed gastric and intestinal ulcers whe given oral doses about 30 times MRHD for only 5 to 7 days. In the two-year rat study, irr versible and progressive variations in the caliber of retinal vessels (focal sacculatior and constrictions) occurred at all dose levels (7 to 200 times MRHD) in a dose-relate fashion. The effect was first observed in the 88th week of dosing, with a progressive increased incidence thereafter, even after cessation of dosing.

**Pregnancy: Category C**—Captopril was embryocidal in rabbits when given in doses 2 to 7 times (on a mg/kg basis) the maximum recommended human dose. The marked em bryocidal effect in rabbits was most probably due to the particularly marked decreas in blood pressure caused by the drug in this species. Captopril given to pregnant rats 400 times the recommended human dose continuously during gestation and lactatio reduced neonatal survival. No teratogenic effects (malformations) have been seen afte large doses of captopril in hamsters, rats, and rabbits.

There are no adequate and well-controlled studies in pregnant women. Captopr should be used during pregnancy only if the potential benefit justifies the potential ris to the fetus.

**Nursing Mothers:** Concentrations of captopril in human milk are about 1% of those maternal blood. The effect of low levels of captopril on the nursing infant has not bee determined. Exercise caution when administering captopril to a nursing woman, and, general, nursing should be interrupted.

**Pediatric Use:** Safety and effectiveness in children have not been established althoug there is limited experience with use of captopril in children from 2 months to 15 year of age with secondary hypertension and varying degrees of renal insufficiency. Dosage on a weight basis, was comparable to that used in adults. Captopril should be used i children only if other measures for controlling blood pressure have not been effective.

**ADVERSE REACTIONS:** Reported incidences are based on clinical trials involving abou 4000 patients.

*Renal*—One to 2 of 100 patients developed proteinuria (see WARNINGS). Renal in sufficiency, renal failure, polyuria, oliguria, and urinary frequency in 1 to 2 of 1000 patient but relationship to drug use is uncertain.

*Hematologic*—Neutropenia/agranulocytosis (probably drug related) occurred in abou 0.3% of captopril treated patients (see WARNINGS). Two of these patients develope sepsis and died.

*Dermatologic*—Rash (usually maculopapular, rarely urticarial), often with pruritus an sometimes with fever and eosinophilia, in about 10 of 100 patients, usually during the 1s 4 weeks of therapy. The rash is usually mild and disappears within a few days of dosag reduction, short-term treatment with an antihistaminic agent, and/or discontinuing the apy; remission may occur even if captopril is continued. Pruritus, without rash, in abou 2 of 100 patients. Between 7 and 10% of patients with skin rash have shown an eosino philia and/or positive ANA titers. A reversible associated pemphigoid-like lesion, an photosensitivity have also been reported. Angioedema of the face, mucous membrane of the mouth, or of the extremities in about 1 of 100 patients—reversible on discontinu ance of captopril therapy. One case of laryngeal edema reported. Flushing or pallor i 2 to 5 of 1000 patients.

*Cardiovascular*—Hypotension in about 2 of 100 patients. See PRECAUTIONS (Dru Interactions) for discussion of hypotension on initiation of captopril therapy. Tachycardia chest pain, and palpitations each in about 1 of 100 patients. Angina pectoris, myocardia infarction, Raynaud's syndrome, and congestive heart failure each in 2 to 3 of 100 patients.

*Dysgeusia*—About 7 of 100 patients developed a diminution or loss of taste percep tion; taste impairment is reversible and usually self-limited even with continued drug us (2 to 3 months). Weight loss may be associated with the loss of taste. Gastric irritation abdominal pain, nausea, vomiting, diarrhea, anorexia, constipation, aphthous ulcers peptic ulcer, dizziness, headache, malaise, fatigue, insomnia, dry mouth, dyspnea, an paresthesias reported in about 0.5 to 2% of patients but did not appear at increase frequency compared to placebo or other treatments used in controlled trials.

**Altered Laboratory Findings:** Elevations of liver enzymes in a few patients although n causal relationship has been established. A single case of hepatocellular injury wit secondary cholestasis has been reported in association with captopril use. A transien elevation of BUN and serum creatinine may occur, especially in volume-depleted or renc vascular hypertensive patients. In instances of rapid reduction of longstanding or severel elevated blood pressure, the glomerular filtration rate may decrease transiently, als resulting in transient rises in serum creatinine and BUN. Small increases in serum potas sium concentration frequently occur, especially in patients with renal impairment (se PRECAUTIONS).

**OVERDOSAGE:** Primary concern is correction of hypotension. Volume expansion with a I.V. infusion of normal saline is the treatment of choice for restoration of blood pres sure. Captopril may be removed from the general circulation by hemodialysis.

**DOSAGE AND ADMINISTRATION:** CAPOTEN (captopril) should be taken one hour befor meals. Dosage must be individualized.

Give consideration to recent antihypertensive drug therapy, extent of blood pressur elevation, salt restriction, and other circumstances before initiating therapy. If possible discontinue the patient's previous antihypertensive drug regimen for one week befor starting captopril. Initial dose of CAPOTEN (captopril) is 25 mg t.i.d. If satisfactory bloo pressure reduction is not achieved after 1 or 2 weeks, dose may be increased to 50 m t.i.d. If the blood pressure has not been satisfactorily controlled after another 1 to 2 weeks add a modest dose of a thiazide-type diuretic (e.g., hydrochlorothiazide, 25 mg daily) The diuretic dose may be increased at 1- to 2-week intervals until its highest usual anti hypertensive dose is reached. If further blood pressure reduction is required, CAPOTE (captopril) may be increased to 100 mg t.i.d. and then, if necessary, to 150 mg t.i.d (while continuing the diuretic). The usual dose range is 25 to 150 mg t.i.d. A maximum daily dose of 450 mg CAPOTEN (captopril) should not be exceeded.

For patients with accelerated or malignant hypertension, when temporary discontinua tion of current antihypertensive therapy is not practical, or when prompt titration to mor normotensive blood pressure levels is indicated, current antihypertensive medication ma be stopped and CAPOTEN (captopril) dosage promptly initiated at 25 mg t.i.d., under clos medical supervision. The daily dose of CAPOTEN (captopril) may be increased every 2 hours until a satisfactory blood pressure response is obtained or the maximum captopri dose is reached. In this regimen, addition of a more potent diuretic, e.g., furosemide may also be indicated. Beta-blockers may also be used in conjunction with captopri therapy (see PRECAUTIONS [Drug Interactions]), but the effects of the 2 drugs are less than additive.

**Dosage Adjustment in Renal Impairment**—Because CAPOTEN (captopril) is excreted primarily by the kidneys, excretion rates are reduced in patients with impaired renal func tion. These patients will take longer to reach steady-state captopril levels and will reac higher steady-state captopril levels for a given daily dose than patients with normal rena function. Therefore, these patients may respond to smaller or less frequent doses. Ac cordingly, for patients with significant renal impairment, initial daily dosage of CAPOTE (captopril) should be reduced, and smaller increments utilized for titration, which should be quite slow (1- to 2-week intervals). After desired therapeutic effect has been achieved dose should be slowly back-titrated to determine minimal effective dose. When con comitant diuretic therapy is required, a loop diuretic (e.g., furosemide), rather than thiazide diuretic, is preferred in patients with severe renal impairment.

For full prescribing information, consult package insert.

**HOW SUPPLIED:** Available in tablets of 25, 50, and 100 mg in bottles of 100, and i UNIMATIC® unit-dose packs of 100 tablets.

# Equilibrium Radionuclide Gated Angiography in Patients With Tricuspid Regurgitation

BRUCE HANDLER, MD, DAN G. PAVEL, MD, RAYMOND PIETRAS, MD, STEVEN SWIRYN, MD, ERNEST BYROM, PhD, WILFRED LAM, MD, and KENNETH M. ROSEN, MD

**Equilibrium gated radionuclide angiography was performed in 2 control groups (15 patients with no organic heart disease and 24 patients with organic heart disease but without right- or left-sided valvular regurgitation) and in 9 patients with clinical tricuspid regurgitation. The regurgitant index, or ratio of left to right ventricular stroke counts, was significantly lower in patients with tricuspid regurgitation than in either control group (range and mean ± standard error of the mean 0.4 to 1.0, 0.7 ± 0.1 versus 1.0 to 1.5, 1.3 ± 0.1 and 1.0 to 2.9, 1.5 ± 0.1, respectively, $p < 0.001$). Time-activity variation over the liver was used to compute a hepatic expansion fraction which was significantly higher in patients with tricuspid regurgitation than in either control group (1.4 to 11.4, 5.8 ± 1.0% versus 0.6 to 3.4, 1.9 ± 0.3% and 1.0 to 5.1, 2.3 ± 0.2%, respectively, $p < 0.001$). Fourier analysis of time-activity variation in each pixel was used to generate amplitude and phase images. Only pixels with values for amplitude at least 7% of the maximum in the image were retained in the final display. All patients with tricuspid regurgitation had >100 pixels over the liver automatically retained by the computer. These pixels were of phase comparable to that of the right atrium and approximately 180° out of phase with the right ventricle. In contrast, no patient with no organic heart disease and only 1 of 24 patients with organic heart disease had any pixels retained by the computer.**

**In conclusion, patients with tricuspid regurgitation were characterized on equilibrium gated angiography by an abnormally low regurgitant index (7 of 9 patients) reflecting increased right ventricular stroke volume, increased hepatic expansion fraction (7 of 9 patients), and increased amplitude of count variation over the liver in phase with the right atrium (9 of 9 patients).**

Tricuspid regurgitation can present a difficult clinical diagnosis, particularly when other cardiac lesions are present. Although first-pass radionuclide angiography was used to support the diagnosis in 1 case of traumatic tricuspid regurgitation,[1] equilibrium radionuclide gated angiography has not previously been employed to establish a diagnosis of tricuspid regurgitation. In this study, computer-processed results of equilibrium radionuclide angiography including Fourier analysis of time-activity variation in patients with clinically manifest tricuspid regurgitation were compared with results in 2 control groups, 1 consisting of patients with no organic heart disease and 1 consisting of patients with organic heart disease but no clinical evidence of right- or left-sided valvular regurgitation. Measurements of cardiac regurgitant index, hepatic expansion fraction, and amplitude and phase over the liver were abnormal in patients with tricuspid regurgitation.

## Methods

**Patient selection:** Three groups of patients were studied: those with no organic heart disease, those with organic heart disease but without right- or left-sided valvular regurgitation, and those with tricuspid regurgitation. Criteria for inclusion of patients with no organic heart disease were normal results on cardiovascular examination, normal heart size on chest X-ray, and normal left ventricular ejection fraction and wall motion on equilibrium gated angiography. Absence of demonstrable organic heart disease was supported by M-mode echocardiography and cardiac catheterization with angiography in some patients.

Criteria for inclusion of patients with organic heart disease were the presence of diagnosed heart disease without clinical evidence of right- or left-sided valvular regurgitation on history, physical examination, and noninvasive studies. All patients in the group had cardiac catheterization to confirm the diagnosis and all had equilibrium gated angiographic study.

Criteria for inclusion of patients with tricuspid regurgitation were the presence of at least 2 of the following 3 findings on physical examination: abnormal CV wave in the internal jugular venous pulse, a systolic murmur at the left lower sternal border that increased in intensity on inspiration, and a palpable expansile liver. An equilibrium radionuclide angiographic study was performed in each patient. Other independent data for the presence of tricuspid regurgitation were elevated right atrial pressures and large right atrial CV waves at cardiac catheterization, saline microbubbles visualized for at least 4 beats at the right atrial inferior vena caval junction on 2-dimensional echocardiography,[2,3] visible systolic bulging (of an enlarged right atrium and a palpable thrill over the right atrial wall) during cardiac surgery, regurgitation of contrast material into the right atrium during right ventricular angiography, surgical tricuspid valvectomy, and autopsy evidence of a grossly dilated right atrium, ventricle, and tricuspid valve anulus.

**Equilibrium gated radionuclide angiography:** Each study was performed with the patient in the supine position using in vivo red blood cell labeling with technetium-99m.[4] A large field of view camera (Siemens) was positioned to obtain the best septal left anterior oblique view of the heart with a 10 to 15° caudal tilt. Data were acquired (Informatek Simis 3 computer) using 64 frames per cardiac cycle with 250,000 to 300,000 counts per frame and stored on tape for processing.

Computer processing for calculation of left ventricular ejection fraction and assessment of left ventricular regional wall motion employed methods previously described.[5–8] The left ventricular regurgitant index was calculated as the ratio of left ventricular stroke counts to right ventricular stroke counts.[9] The stroke counts were obtained from left and right ventricular time-activity curves of the respective regions of interest by subtraction of the respective ventricular end-systolic from the end-diastolic counts for each patient studied. This allowed for right ventricular end-systole to occur during a different frame from left ventricular end-systole.

**Hepatic expansion fraction:** In each patient the entire field-of-view image at end-diastole was used to manually outline for computer processing a region of high activity below and to the right of the heart thought to correspond to the liver. The upper border of this region of interest was determined by following a trough of activity between the heart and the liver. This border was drawn tightly to avoid including the heart itself. Hepatic counts for each time frame were determined by the computer. A time-activity curve for the liver was then generated. A hepatic expansion fraction was calculated using the following formula: hepatic expansion fraction = (maximal counts − minimal counts)/minimal counts. Maximal and minimal counts were chosen by numerical value regardless of the frame in which they occurred during the cardiac cycle (see section on Fourier analysis). Interobserver variability in the measurement of hepatic expansion fraction was evaluated in 4 study patients. Independently calculated values by 2 of us differed by 0.1, 0.1, 0.2, and 0.3 percentage points, respectively.

**Fourier analysis:** Amplitude and phase analysis was performed using the first Fourier harmonic of time-activity variation in each pixel to generate amplitude and phase images. Each displayed pixel was color coded according to its value for amplitude and phase, respectively.[10–12]

**TABLE I Results of Equilibrium Gated Angiography**

| | No OHD | OHD, No TI | TI | p Value |
|---|---|---|---|---|
| LVEF (%) | 68 ± 2 | 48 ± 6 | 53 ± 5 | NS |
| RI | 1.3 ± 0.1 | 1.5 ± 0.1 | 0.7 ± 0.1 | <0.001 |
| HEF (%) | 1.9 ± 0.3 | 2.3 ± 0.2 | 5.8 ± 1.0 | <0.001 |
| Hepatic amplitude present/ total patients | 0/15 | 1/24 | 9/9 | . . . |

Values are the mean ± standard error of the mean. HEF = hepatic expansion fraction; LVEF = left ventricular ejection fraction; OHD = organic heart disease; RI = regurgitant index; TI = tricuspid insufficiency.

Organs that have large changes in blood volume during the cardiac cycle, such as the heart, have high amplitude and well defined areas of coherent phase. However, organs not exhibiting ordered variation of blood volume during the cardiac cycle, even though they may contain a large volume of blood, such as the spleen, have low amplitude values and random phase. The former accentuates the statistical uncertainty in the calculation of phase values in such organs. Therefore, to eliminate areas of low amplitude and uncertain phase, 2 steps were taken. An amplitude threshold of 7% (of the maximal amplitude value of the entire image) was used to eliminate all pixels of low amplitude. The specific value of 7% was chosen empirically to best separate the control and study groups. Isolated clusters of 4 or fewer pixels, which also may represent statistical uncertainty, were automatically eliminated from the final amplitude image. The final phase image was derived from the final amplitude image. Thus, pixels eliminated from the amplitude image were also eliminated from the final phase image.

The phase image depicts pixels according to their respective phase relative to a 0° phase reference[10,11] (with the entire cardiac cycle representing 360°) and represents the relative timing of count variation. Structures that fill and empty synchronously, such as the right and left ventricles, have similar phase. Structures that fill and empty in opposition, such as the left atrium and left ventricle, have a phase difference in the vicinity of 180°.

**Statistical analysis:** The left ventricular ejection fraction, regurgitant index, hepatic expansion fraction, and amplitude and phase images for the 3 groups of patients were compared. Statistical analysis was carried out using Scheffe's method for analysis of variance.

## Results

**Clinical characteristics:** Fifteen patients with no organic heart disease comprised the first control group. They were aged 15 to 58 years (mean ± standard deviation 31 ± 12). Six patients were women and 9 were men. The clinical diagnosis was supraventricular tachycardia in 6 patients, noncardiac chest pain in 3, primary conduction disease in 2, and pancreatitis, pneumonia, gastroenteritis, and vasovagal syncope in 1 patient each. By study design, each patient had essentially normal findings on cardiovascular examination and normal cardiac size on chest X-ray. Additional independent data for the absence of heart disease included no significant abnormalities on M-mode echocardiography (11 of 11 patients) and normal cardiac catheterization with angiography (8 of 8 patients).

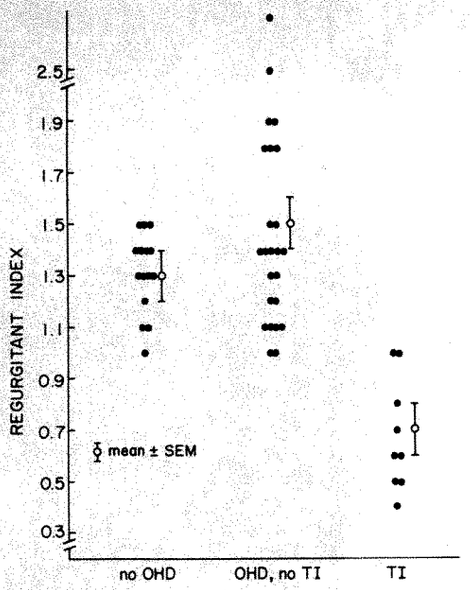

**FIGURE 1.** Regurgitant index is plotted on the ordinate. Each point represents 1 patient. **Left column,** values for patients with no organic heart disease (no OHD); **middle column,** values for patients with organic heart disease but without valvular insufficiency (OHD, no TI); **right column,** values for patients with tricuspid insufficiency (TI). Mean value for control patients is significantly higher than that of patients with tricuspid insufficiency ($p < 0.001$). SEM = standard error of the mean.

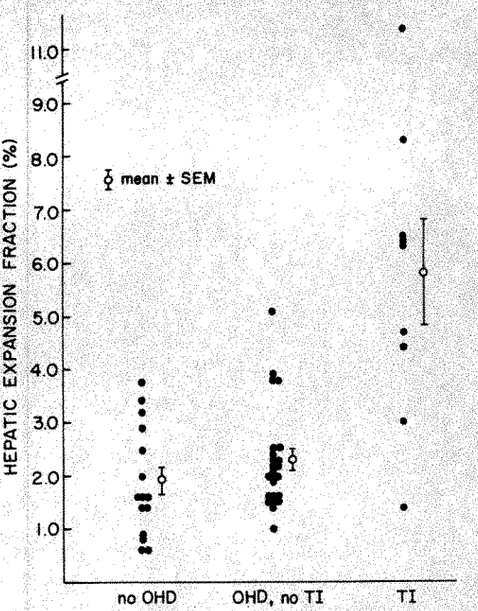

**FIGURE 2.** Hepatic expansion fraction in percentage is plotted on the ordinate. Each point represents 1 patient. **Left column,** values for patients with no organic heart disease (no OHD); **middle column,** values for patients with organic heart disease but without valvular insufficiency (OHD, no TI); **right column,** values for patients with tricuspid insufficiency (TI). Mean value for control patients is significantly lower than that of patients with tricuspid insufficiency ($p < 0.001$).

Twenty-four patients, aged 50 ± 14 years (range 14 to 69), with organic heart disease but without right- or left-sided valvular regurgitation comprised the second control group. There were 8 women and 16 men. The clinical diagnosis was atherosclerotic heart disease in 10 patients, cardiomyopathy in 8, mitral stenosis in 1, and miscellaneous cardiovascular diagnoses in the remaining 5. In each patient, the cardiovascular examination was appropriate for the clinical diagnosis and did not specifically suggest any right- or left-sided valvular regurgitation. The clinical diagnosis in each patient was confirmed by cardiac catheterization and angiography.

Nine patients, aged 41 ± 8 years (range 20 to 45), with tricuspid regurgitation comprised the study group. Five patients were women and 4 men. The clinical diagnosis was rheumatic heart disease in 5 patients, tricuspid valvectomy for bacterial endocarditis in 2, congenital heart disease in 1, and mixed-connective tissue disease with secondary pulmonary hypertension in 1. On physical examination, 7 patients had abnormal jugular venous CV waves, a positive Carvallo's sign, and an expansile liver. The remaining 2 patients had abnormal jugular venous CV waves and an expansile liver without documented Carvallo's sign to establish the presence of tricuspid regurgitation on clinical grounds. Independent data for the presence of tricuspid regurgitation were cardiac catheterization with elevated mean right atrial pressure and an increased right atrial CV wave (6 of 6 patients), positive contrast echocardiography (4 of 4 patients), positive findings at cardiac surgery (2 of 2 patients), positive contrast right ventricular angiography (1 of 1 patient), surgical tricuspid valvectomy in 2 patients, and postmortem evidence of a grossly dilated right atrium, ventricle, and tricuspid valve anulus in 1 patient.

**Equilibrium radionuclide angiography (Table I):** For patients with no organic heart disease, left ventricular ejection fraction ranged from 60 to 75% (mean ± standard error of the mean 68 ± 2%). For patients with organic heart disease without valvular regurgitation, left ventricular ejection fraction ranged from 19 to 82% (mean 48 ± 6%). For patients with tricuspid regurgitation, the left ventricular ejection fraction ranged from 22 to 74% (mean 53 ± 7%). Differences between each control group and the study group were not statistically significant.

For patients with no organic heart disease, the regurgitant index ranged from 1.0 to 1.5 (mean 1.3 ± 0.1). Normal in our laboratory is 0.9 to 1.7.[9] For patients with organic heart disease but without valvular insufficiency, the regurgitant index ranged from 1.0 to 2.9 (mean 1.5 ± 0.1). There was no significant difference in regurgitant index between these 2 control groups. In contrast, in patients with tricuspid regurgitation, the regurgitant index ranged from 0.4 to 1.0 (mean 0.7 ± 0.1), which was significantly lower than that in each control group ($p < 0.001$) (Fig. 1). Two patients with tricuspid regurgitation had a regurgitant index within the normal range. One of these patients had concomitant severe periprosthetic aortic regurgitation demonstrated by aortic root angiography. The other patient

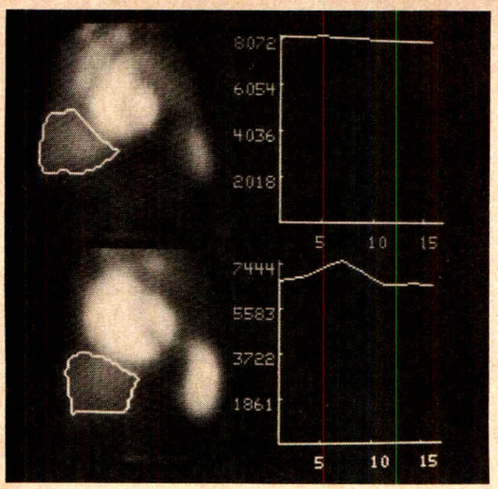

**FIGURE 3.** Hepatic expansion fraction. **Left,** end-diastolic image and outlined hepatic region of interest in a control patient (**above**) and a patient with tricuspid insufficiency (**below**). **Right,** corresponding time-activity curves for the hepatic regions of interest. Counts are represented on the ordinate and frame number on the **abscissa.** Note the ordered variation of hepatic activity during the cardiac cycle in the patient with tricuspid insufficiency.

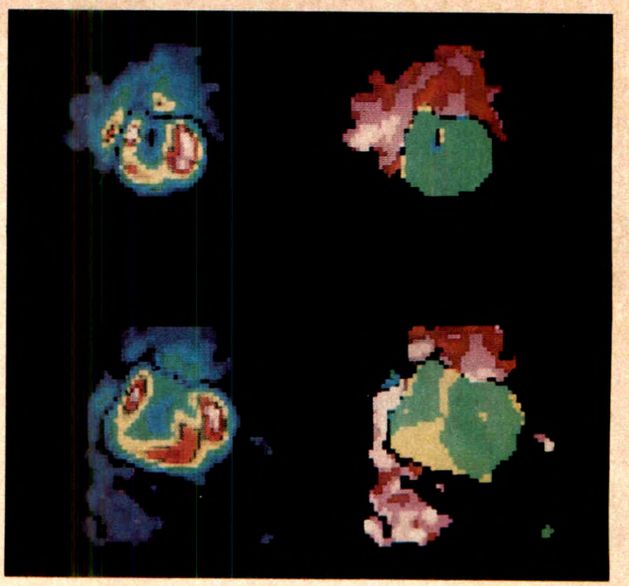

**FIGURE 4.** Final amplitude and phase images. **Left,** amplitude images in a control patient (**above**) and a patient with tricuspid insufficiency (**below**). **Right,** corresponding phase images. Note that in the control patient all pixels over the liver have been eliminated automatically (<7% maximal amplitude). In the patient with tricuspid insufficiency, pixels representing the liver have been retained (>7% maximal amplitude). The liver is of similar phase to the right atrium and of opposite phase to the right ventricle.

had concomitant severe mitral regurgitation demonstrated on left ventriculography.

**Hepatic expansion fraction (Table I):** For patients with no organic heart disease, the hepatic expansion fraction ranged from 0.6 to 3.4% (mean 1.9 ± 0.3%), reflecting the absence of substantial count variation over the liver during the cardiac cycle. For patients with organic heart disease without valvular regurgitation, the hepatic expansion fraction ranged from 1.0 to 5.1% (mean 2.3 ± 0.2%). There was no significant difference in the hepatic expansion fraction between these 2 control groups.

Four of 24 patients (17%) with organic heart disease without valvular regurgitation had values for hepatic expansion fraction that were above the range of those in patients with no organic heart disease. However, in none of these patients did the peak of hepatic activity occur simultaneously with or within 1 frame of the nadir of right ventricular activity (see later).

For patients with tricuspid regurgitation, the hepatic expansion fraction ranged from 1.4 to 11.4% (mean 5.8 ± 1.0%), which was significantly higher than that in each control group ($p < 0.001$) (Fig. 2). Two patients with tricuspid regurgitation had values for hepatic expansion fraction that were within the range of those in patients with no organic heart disease. Except in 1 of these patients, peak hepatic activity occurred simultaneously with or within 1 frame of the nadir of right ventricular activity in patients with tricuspid regurgitation. The outlined hepatic regions of interest and time-activity curves from representative patients with no organic heart disease versus those in the study group are illustrated in Figure 3.

**Amplitude and phase images (Fig. 4):** All patients with no organic heart disease and 23 of 24 patients with organic heart disease without valvular insufficiency had amplitude values for all pixels over the liver of <7% of the maximal amplitude in the image. Therefore, these pixels were automatically eliminated from the amplitude and phase images. In contrast, all patients with tricuspid regurgitation had at least 100 pixels over the liver with an amplitude >7% of the maximal amplitude in the image. Therefore, these pixels were automatically retained in the amplitude and phase images. Thus, substantial amplitude of hepatic blood volume variation with the cardiac cycle was present in all 9 patients with tricuspid regurgitation. On the phase images there is uniform phase for the atria and uniform (but 180° opposite) phase for the ventricles in all 3 groups of patients, reflecting that the atria fill when the ventricles empty (Fig. 4). Pixels over the liver in all patients with tricuspid regurgitation were in phase with the right atrium.

**Summary of data:** In summary, 3 variables were examined in each patient: regurgitant index, hepatic expansion fraction, and amplitude over the liver. All patients with no organic heart disease had a normal regurgitant index, low hepatic expansion fraction, and absence of significant amplitude over the liver. Of patients with organic heart without valvular regurgitation, all had a normal (17 patients) or increased (7 patients) regurgitant index. Twenty of 24 patients (83%) had low hepatic expansion fractions. Twenty-three of 24 (96%) had absence of significant amplitude over the liver.

In contrast, 7 of 9 patients (78%) with tricuspid regurgitation had a below-normal regurgitant index. Seven of 9 patients (78%) with tricuspid regurgitation had an above-normal hepatic expansion fraction. All 9

patients (100%) with tricuspid regurgitation had substantial amplitude over the liver. Looked at another way, in 5 of 9 patients with tricuspid regurgitation, all 3 measures gave abnormal values; 4 of 9 patients had abnormal values in only 2 measures.

## Discussion

Currently, the diagnosis of tricuspid regurgitation is established on the basis of physical findings. However, these findings may be obscured by multivalvular disease or after valve replacement for left-sided lesions. Right ventricular angiography and direct surgical evaluation are invasive and have been criticized as unreliable.[13] Contrast M-mode and 2-dimensional echocardiography,[2,3] sometimes with pulsed Doppler echocardiography,[14] has recently been useful in establishing the presence of tricuspid regurgitation. Intracardiac phonocardiography has also been useful when combined with right ventricular angiography.[15]

Equilibrium radionuclide gated angiography provides a noninvasive method for evaluating aortic or mitral insufficiency, or both.[9,16–19] However, there are no reports of a series of patients with right-sided valvular regurgitation. Patients with left-sided regurgitation have an increased left ventricular stroke volume and therefore an elevated regurgitant index. Patients with right-sided regurgitation would logically be expected to have an increased right ventricular stroke volume and consequently a decreased regurgitant index.

In the present study, 7 of 9 patients with tricuspid regurgitation had a low regurgitant index compared with that of patients without evidence of tricuspid regurgitation (Fig. 1). However, a low regurgitant index might be expected in many situations characterized by right ventricular volume overload. The physical findings of pulmonary regurgitation producing right ventricular volume overload are distinctive and usually not confused with those of tricuspid regurgitation. Intracardiac left to right shunting in atrial septal defect results in an increased Qp/Qs ratio because of right-sided volume overload.[20] However, concomitant left-sided regurgitation with increased left-sided stroke volume, depending on the degree, tends to normalize the ratio of left to right ventricular stroke counts. This was the case in 2 patients in the present series with tricuspid regurgitation whose values for regurgitant index were within the normal range.

To our knowledge, no reports have appeared analyzing the results of time-activity variation over noncardiac structures during equilibrium gated angiography. Eight of 9 patients with tricuspid regurgitation demonstrated ordered time-activity variation over the liver during the cardiac cycle (Fig. 2 and 3). Comparing the time-activity curves over the liver and the right ventricle, the peak of hepatic activity occurred within 1 frame or simultaneously with the nadir of right ventricular activity for 8 of 9 patients with tricuspid regurgitation. It seems doubtful that transmitted right ventricular, diaphragmatic, or abdominal aortic pulsations could result in an increased hepatic expansion fraction to the degree seen in patients with tricuspid regurgitation. A left ventricular to right atrial shunt as might occur in some patients with atrioventricular canal defects or ruptured sinus of Valsalva into the right atrium or right ventricle might mimic similar hemodynamic results and consequently an expansile liver. However, the clinical history and physical findings should allow differentiation of these patients.

At present, manual determination of a hepatic region of interest is somewhat subjective, depending as it does on outlining an area of high activity where the liver is located. The critical boundary of this region is found between the liver and the heart, especially in patients with right heart enlargement. Therefore, we made this border tight on the liver side. The finding that the apex of the hepatic time-activity curve corresponded to the nadir of the right ventricular time-activity curve (opposition of phase) is reassuring, because inclusion of a large area of right ventricle in the hepatic region of interest should obliterate this. Inclusion of the inferior vena cava within the hepatic region of interest seems probable, and this structure may also contribute to some of our findings.

Our group and others previously reported results of Fourier analysis in left ventricular regional wall motion abnormalities and in abnormal electrical activation including left bundle branch block and ventricular tachycardia.[10,12,21] In the present study, Fourier analysis was applied to each pixel from a large field-of-view image. The resulting amplitude image in all control patients had no pixels with substantial (>7% of maximum) amplitude over the liver. All patients with tricuspid regurgitation had ≥100 pixels with substantial amplitude over the liver. The maximal amplitude in the image should usually occur over the left ventricle. When a patient with tricuspid regurgitation has a low left ventricular ejection fraction, pixels over the liver may be included as having ≥7% of a low maximal amplitude and might not have substantial amplitude in an absolute sense. That the mean value of left ventricular ejection fraction in patients with organic heart disease without valvular regurgitation was lower than that in patients with tricuspid regurgitation argues against errors in resulting amplitude images.

Pixels corresponding to the right atrial and hepatic regions of interest were of similar phase to each other and of opposite phase to pixels corresponding to the right ventricular region of interest. Thus, pixels over the hepatic region of interest with substantial amplitude correspond to the physical finding of an expansile liver.

**Clinical significance:** We did not explore this technique in patients with severe right heart failure and hepatic congestion but without tricuspid regurgitation, although they would be an important control group. It would be very difficult to know conclusively that such patients did not have small degrees of tricuspid regurgitation. Because no strong standard is available for determining tricuspid regurgitation, no statement can be made about sensitivity or specificity of this method in such patients.

*In summary*, equilibrium gated angiography and Fourier analysis were used to distinguish patients with from those without clinical tricuspid regurgitation.

Characteristic findings of patients with tricuspid regurgitation included an abnormally low regurgitant index in 7 of 9 patients, an increased hepatic expansion fraction in 7 of 9 patients, and increased amplitude over the liver with pixels in phase with the right atrium in all 9 patients. These results imply that gated angiography can be used to confirm the presence of tricuspid regurgitation or to detect unsuspected tricuspid regurgitation. It is not known whether this method will allow quantification of the severity of this lesion.

# The Apex Impulse in Mitral Stenosis: Graphic Explanation Of the Palpable Movements at the Cardiac Apex

JON FLOYD, AB, PARK W. WILLIS, IV, MD, and ERNEST CRAIGE, MD

**Simultaneously recorded phonocardiograms and apexcardiograms of 39 patients with mitral stenosis (MS) were retrospectively analyzed. A notch on the upstroke of the apexcardiogram coincidental with the first heart sound ($S_1$) occurred in 18 (47%) of the patients. The notch ratio or vertical distance from the onset of the apical impulse to the notch ratio or vertical distance from the onset of the apical impulse to the notch as a percentage of the total upstroke was measured and compared with the mean mitral diastolic gradient obtained at cardiac catheterization. Statistical analysis showed a significant relation ($r = 0.61$; $p < 0.01$) between notch ratio and the mean mitral diastolic gradient. This study reaffirms that the complex palpable movements at the cardiac apex, consisting of a "tap" representing $S_1$ occurring perceptibly after the onset of the apex impulse itself, are a useful diagnostic sign of MS. Furthermore, a graphic measurement of the extent of delay of $S_1$ with respect to the onset of the apical thrust can provide a rough measure of the severity of the valvular obstruction.**

For almost 2 centuries, physicians have been interested in palpation of the chest wall movements of cardiac origin as an aid to cardiac diagnosis. Several palpable phenomena have been described in association with MS, such as the precordial heave of right ventricular hypertrophy and the accentuated pulmonary component of the second heart sound. The events at the cardiac apex are usually referred to as a tapping impulse—an empirical description which is not particularly helpful in physical diagnosis. Almost 40 years ago, however, Cossio[1] analyzed palpable phenomena at the cardiac apex in MS and found that these consist of a complex sequence of a thrust resulting from ventricular systole on which a shock representing the delayed and accentuated first heart sound is surmounted. Our studies seek to confirm the validity of Cossio's observations and to determine whether the extent of the delay of the palpable shock of $S_1$ with respect to the onset of the ventricular thrust might have utility in predicting the severity of MS.

## Methods

Phonocardiographic and apexcardiographic records from 39 patients with predominant MS and 4 normal subjects were analyzed. The patients were identified from the computerized files of the Cardiac Graphics Laboratory at North Carolina Memorial Hospital, and all patients had complete hemodynamic data obtained at cardiac catheterization close in time to the noninvasive studies. In some patients with MS minor degrees of mitral or aortic regurgitation, or both, were also present, but those with severe regurgitant conditions were excluded. The normal subjects were studied for chest pain but proved to have normal coronary arteries and normal ventricular function.

Phonocardiograms were recorded from Leatham-type suction microphones at the upper right sternal border and the lower left sternal edge. Simultaneous apexcardiograms were recorded from a hand-held piezoelectric transducer with the patient lying in the left lateral decubitus position. The phonocardiograms and apex pulse were recorded on an Irex Continutrace 101 or 102 Recorder (Irex, Ramsey, New Jersey) at 100 mm/s paper speed.

From the combined electrocardiogram and phonocardiogram, the Q-$S_1$ interval was measured to document the delay in $S_1$ known to occur in MS.[2–4] The graphic equivalent of the palpable shock resulting from $S_1$ was perceptible as a notch on the upstroke of the apexcardiogram.[5,6] The "notch ratio" was calculated as the vertical distance from the onset of the apical upstroke to the level of the notch, divided by the entire height of the apexcardiogram (Fig. 1). In cases of atrial fibrillation, where the diastolic filling time varied on a beat-to-beat basis resulting in a fluctuating Q-$S_1$ time, 5 successive cycles were measured and the average was taken. In a few instances, a distinct notch could not be appreciated on the upstroke of the apexcardiogram and a change in slope coincidental with the mitral component of $S_1$ was substituted. In the normal controls where no notch was present, a vertical line was drawn through the onset of the high frequency vibrations representing the mitral contribution to $S_1$ and the point of intersection of this line with the apexcardiogram was taken as the notch position (Fig. 2).

* Measurements collected from 18 patients with MS; data from normal subjects are included for comparison.

Hemodynamic studies were performed in the Cardiac Catheterization Laboratory, using standard methods in order to provide confirmation of the diagnosis as well as evidence of its severity. The mean mitral diastolic gradient was determined by planimetry of the area between the pulmonary capillary wedge pressure curve and the left ventricle.[7]

The mean mitral diastolic gradient was taken as the invasively obtained index of severity of stenosis. Care was taken to insure that heart rate and blood pressure were comparable, while both invasive and noninvasive records were obtained because of the profound effect of diastolic filling time on the Q-$S_1$ interval. To determine the relation between the mean mitral diastolic gradient and the notch ratio, univariant regression analysis was carried out.

## Results

A notch was present on the upstroke of the apexcardiogram in 18 of 39 patients, or 46%, of those with MS. The notch ratio and values for mean mitral diastolic gradient are listed in Table I. The notch ratios in the patients with MS ranged from 51 to 93%, reflecting the delay in mitral valve closure with respect to the onset of ventricular contraction. Regression analysis of the data from the patients listed in Table I indicated a sig-

nificant correlation ($r = 0.61$, $p < 0.01$) of notch ratio with the mean mitral diastolic gradient.

The 4 normal subjects are listed at the bottom of Table I. They had no mitral diastolic gradient and their notch ratios were low (0 to 15.3%).

## Discussion

Palpable events over the precordium in patients with MS have been appreciated since the early 19th century. In 1806, Corvisart[8] noted the thrust at the lower end of the sternum which we recognize as indicative of right ventricular hypertrophy. The accentuated and palpable first heart sound was described by Duroziez[9] in 1862, and the shock associated with an exaggerated second sound by Friedreich[10] in 1867. In 1898, Bard[11] studied the apex impulse in MS and concluded that it was made up of 2 almost simultaneous phenomena—the apical thrust resulting from ventricular systole on which is superimposed a palpable first heart sound. A detailed analysis of these palpable events at the cardiac apex in mitral stenosis was undertaken by Cossio[1] in Argentina. He recognized a relatively slow-rising impulse due to ventricular systole followed by a quick vibratory shock of $S_1$. Delay of the latter produced a complicated but informative palpatory sequence which he felt was almost pathognomonic of MS. Although Cossio's observations were made 40 years ago and are generally appreciated in Latin America,[12,13] there is only limited discussion of this physical sign in English textbooks,[14–17] and some authors do not mention it at all.[18,19]

The delay in the mitral component of the first heart sound in MS is due to the time required in early systole for left ventricular pressure to exceed that of the left atrium and to close the mitral valve. A measure of this delay ($Q\text{-}S_1$ time) has been used as an index of severity of stenosis.[2–4] This measurement requires a combination of phonocardiogram and electrocardiogram. The $Q\text{-}S_1$ time is affected by the duration of the electromechanical interval, the height of the ventricular pressure at the onset of systole, and the rate of rise of pressure. It is therefore only a crude index of severity and has been superseded by more accurate noninvasive methods. To exclude the effect of the electromechanical delay, Oreshkov[20] measured from the onset of the systolic wave in the apexcardiogram to the onset of the high frequency vibrations of $S_1$, termed the C-1 interval. He showed that duration of the C-1 interval correlated better with the diameter of the mitral orifice than did the $Q\text{-}S_1$ time. Similarly, the electromechanical interval does not interfere with our measurements which begin at the onset of the apical thrust, known to be synchronous with the beginning of the rise in pressure in the left ventricle.[21]

Although a significant correlation is demonstrated between the notch ratio (a measure of the delay of $S_1$ with respect to the onset of ventricular systole) and severity of stenosis, the relation is not linear. There are several possible reasons for this: the rate of rise of ventricular pressure is not uniform among the patients studied, the height of ventricular pressure at the onset

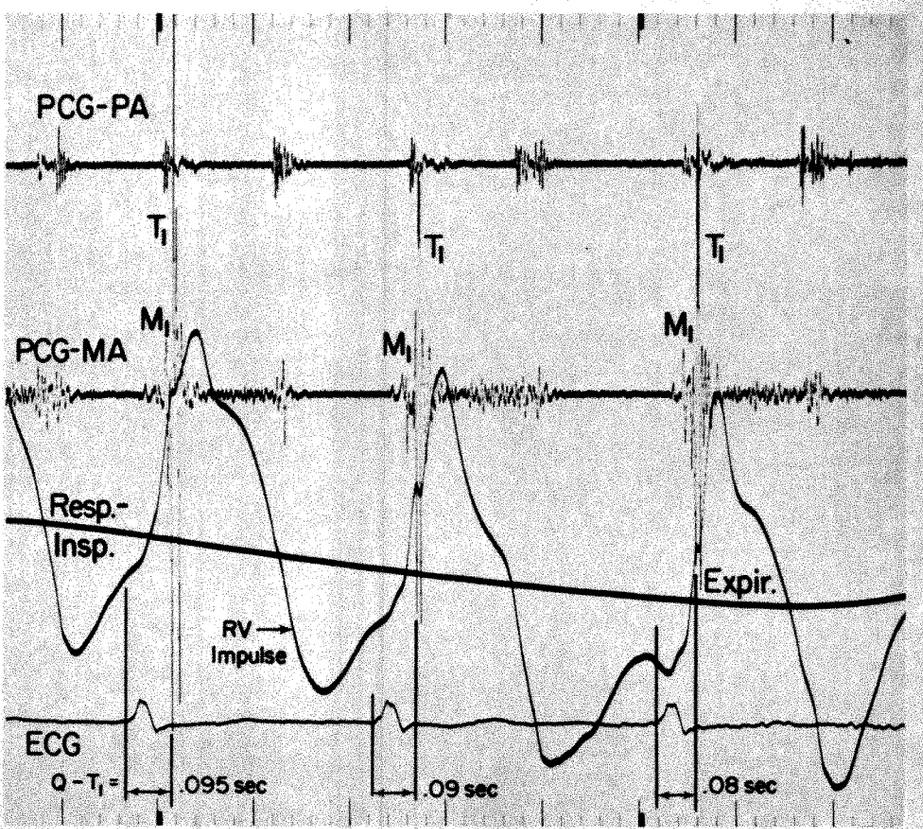

**FIGURE 3.** Simultaneous right ventricular (RV) impulse and phonocardiograms at pulmonary (PCG-PA) and mitral (PCG-MA) areas, with respiration (Resp.), from a 72-year-old woman who had an atrial septal defect and mild mitral regurgitation. The delayed, loud tricuspid valve closure ($T_1$) was palpable as a notch on the right ventricular impulse (see text). Expir. = expiration; ECG = electrocardiogram; Insp. = inspiration.

of systole varies, and there is known to be a variation in the rate of closure of the mitral valve after the left ventricle-left artery pressure crossover. In patients with atrial fibrillation there is a beat-to-beat change in all these parameters. Complicating conditions such as aortic regurgitation will alter ventricular diastolic pressure and further affect the timing of $S_1$ with respect to ventricular systole. The absence of a palpable $S_1$ or its graphic equivalent, the notch on the apexcardiogram, may be explained in severe MS by heavy calcification of the valve leaflets, a complication well known to result in a diminished intensity of $S_1$.

Although the delayed palpable $S_1$ can, as Cossio indicated, be strongly suggestive of MS, it is not possible to estimate at the bedside with any certainty the extent of the delay. The entire interval from the onset of the ventricular impulse to the palpable $S_1$ is usually <0.12 second. It is possible nevertheless to appreciate that the thrust and the palpable sound are occurring sequentially and not synchronously. This observation, although useful in suggesting the possibility of MS, is not specific for that condition since left atrial myxoma is also associated with an accentuated, delayed $S_1$ and, in graphic tracings, a deep notch on the apex resembling that described previously.[22] Fortunately, myxoma is usually excluded by echocardiography without difficulty. We have also found that tricuspid valve closure may be palpable in certain conditions. Recently, we studied a patient who had an atrial septal defect and mild mitral regurgitation (Fig. 3). The right ventricular impulse was prominent and there was a loud, palpable tricuspid valve closure sound ($T_1$). In this case, the notch ratio showed inspiratory variation; it was quite high (approximately 75%) at peak inspiration but diminished, as did $T_1$ amplitude, when Q-$T_1$ interval decreased from 0.095 to 0.080 second during expiration.

*Conclusion:* Palpable events at the cardiac apex are useful as a bedside physical sign of MS. The manifestation strongly suggestive of this diagnosis consists of an apical thrust due to left ventricular systole upon which is superimposed a delayed tap representing $S_1$. This sign is not present in all instances of MS since some patients lack a palpable apical impulse and some have an inaudible or very soft $S_1$ due to calcification of the valve.

A graphic equivalent of the palpable events described above can be obtained by combining phonocardiograms and apexcardiograms with an electrocardiogram. Delay in $S_1$ results in the appearance of a coincidental notch on the apexcardiogram high on the systolic upstroke. The notch ratio, an index of the extent of this delay, has a significant relation with the severity of stenosis as obtained at cardiac catheterization.

# Coronary Vascular Reserve in Left Ventricular Hypertrophy Secondary to Chronic Aortic Regurgitation

AUGUSTO D. PICHARD, MD, HARRY SMITH, PhD, JAMES HOLT, MA, JOSE MELLER, MD, and RICHARD GORLIN, MD

**Coronary vascular reserve was studied in 11 patients with severe chronic aortic regurgitation (AR). Nineteen patients with the chest pain syndrome and normal findings on cardiac catheterization served as control subjects. Resting coronary sinus flow and contrast-agent–induced hyperemia were measured by continuous thermodilution. Left ventricular (LV) dimensions and mass were obtained echocardiographically. All patients had normal coronary arteries. Resting coronary flow was increased and coronary reserve was decreased in patients with AR compared with the control subjects: 310 ± 38 versus 121 ± 13 ml/min and 56 ± 9 versus 86 ± 7.5%, respectively. The decrease in coronary vascular reserve correlated with the increase in LV mass ($r = -0.86$, $p = 0.001$) and LV wall thickness ($r = -0.83$, $p = 0.002$) and with the decrease in LV volume/mass ratio ($r = 0.761$, $p = 0.007$). There was no significant correlation between the decrease in coronary vascular reserve and LV volume ($r = 0.255$), LV peak wall stress ($r = 0.292$), LV systolic pressure ($r = -0.495$), aortic or LV diastolic pressure ($r = 0.322$ and $-0.318$, respectively), or aortic-LV diastolic gradient, nor with the voltage on the electrocardiogram (limb leads $r = -0.60$, precordial leads $r = -0.118$). Thus, coronary vascular reserve is decreased in proportion to the degree of left ventricular hypertrophy in patients with chronic AR. Patients with angina pectoris tended to have a lower coronary vascular reserve than those without angina (median 26 versus 76%, difference not significant). LV wall thickness and not LV volume is the critical component of left ventricular mass related to coronary reserve. No significant correlation between the decrease in coronary vascular reserve and the presence of angina pectoris was demonstrated.**

Aortic regurgitation (AR) imposes a load on the left ventricle, which, if applied gradually, is well tolerated for many years. During this period a number of reserve mechanisms enter into play, the most important being an increase in end-diastolic volume and an increase in stroke volume. These reserve mechanisms allow near-normal effective cardiac performance until late in the course of the disease, when progressive LV dilatation occurs and a gradual course toward end-stage disease or death follows even in the absence of overt clinical manifestations.[1] Some patients have angina pectoris at this stage, often in the presence of normal coronary arteries. The exact mechanism for the failure of these reserve mechanisms has not yet been clarified. We previously demonstrated[2] that patients with pressure overload LV hypertrophy due to aortic stenosis have a decreased coronary vascular reserve. This decrease may be related to the pathogenesis of LV decompensation and may potentiate angina pectoris. This study analyzes coronary flow dynamics and coronary flow reserve in patients with volume overload LV hypertrophy from chronic AR.

## Methods

Eleven patients (9 men and 2 women) with chronic AR referred for diagnostic cardiac catheterization were evaluated. Their ages ranged from 24 to 63 years (mean 48). All patients had normal coronary arteriograms. All patients had 3 to 4+ (moderate to severe) or 4+ (severe) AR defined angiographically: that is, 3+ indicates that during aortography the entire left ventricle is opacified with regurgitant contrast medium but does not reach the same radiologic density as the aorta; 4+ indicates that the entire ventricle is opacified with regurgitant contrast medium and reaches the same contrast as the aorta.[3] These patients had no aortic stenosis or other valvular lesions. Two patients were taking digitalis and 9 were taking diuretics. No patient was taking beta-blocking drugs or dilators. Ten of 11 patients had symptoms.

Nineteen patients with a chest pain syndrome referred for cardiac catheterization and found to have normal coronary arteries served as control subjects. These patients had no other known cardiac disease (valvular, myocardial, or the like). Three patients were taking beta-blocking agents, 3 patients long-acting nitrates, 2 patients nitroglycerin whenever needed, and 1 patient Norpace®. Twelve patients were taking no medication.

History of angina pectoris, syncope or presyncope, and symptoms or signs of congestive heart failure including dyspnea, orthopnea, rales, and peripheral edema were recorded. LV hypertrophy on the electrocardiogram was evaluated by adding the voltage of the R wave in lead I plus the S wave in lead III and the voltages of the S wave in $V_1$ and the R wave in $V_5$.[4] S-T segment depression with asymmetric T-wave inversion, so-called strain pattern,[4] was noted when present.

Right heart catheterization with a Swan-Ganz catheter and P23D Statham transducers were used to determine right heart pressures. LV and aortic pressures were determined with a fluid-filled catheter and P23D Statham transducers. The heart rate was measured at the time of coronary blood flow determination. LV mean diastolic pressure was calculated as an average of 3 points in diastole: initial, mid, and late diastole. LV end-diastolic pressure was measured at the top of the R wave. Aortic diastolic pressure was measured as end-diastolic pressure. The aortic to LV diastolic gradient was calculated as the difference between aortic diastolic pressure and LV mean diastolic pressure. All medications were withheld at least 12 hours before catheterization.

Echocardiography was performed just before catheterization or the day before. If high quality recordings were not obtainable, the patient was not entered into the study. Dimensions of the septum, LV posterior wall and LV internal diameter were performed in diastole, before the *a* wave. They were measured in millimeters, using the standard convention.[5] LV mass was calculated using the following formula[6]: LV mass (g) = $0.77 \times 10^{-3}$ [(LVID + LVPW + IVS)$^3$ − LVID$^3$] + 2.4, where LVID = LV internal dimension in diastole, LVPW = LV posterior wall dimension in diastole, and IVS = interventricular septal dimension in diastole.

The LV volume/mass ratio was calculated by dividing the echocardiographic end-diastolic LV internal dimension by the sum of the posterior and septal wall thicknesses at end-diastole.[7] LV wall stress was evaluated as peak systolic stress by the formula[8–10]: Peak stress = (SBP × LVID) (h × [1 + (h/LVID)]), where SBP = systolic blood pressure, LVID = LV internal dimension, and h = (IVS + LVPW)/2. We used the end-diastolic h/R (mass/volume) ratio, which is quite similar to the h/R ratio at peak systolic stress.[9] Although the systolic pressure is less than the peak LV systolic pressure,[9,10] the correlation between true peak systolic stress and peak stress estimated by the foregoing formula is acceptable.[10] Echocardiographic dimensions were measured by 2 investigators who had no knowledge of the results of the coronary sinus flow measurement.

Coronary sinus blood flow was determined by the continuous thermodilution technique of Ganz et al[11] using a preshaped coronary sinus catheter with 2 thermistors and 2 pacing electrodes (Wilton Webster Laboratories). Resting coronary sinus flow was obtained before any intervention. Hyperemic flow was defined as the maximal flow recorded after contrast medium injection into the left coronary artery (5 to 10 ml). Hyperemic flow was determined 3 to 6 times in each patient. Coronary reserve was defined as the percentage of increase in coronary sinus flow and was calculated as follows: (Hyperemic flow − resting flow):(resting flow) ×100. Because resting coronary blood flow as determined by this technique represents an unknown fraction of the total LV venous outflow, primarily the percent change in flow with hyperemia was used for analysis in this study. Data from coronary sinus flow measurements were recorded at a paper speed of 2.5 or 5 mm/s with an Electronics for Medicine DR 12 recorder, and entered into a minicomputer (Texas Instruments TI 59) for calculation of flow. Flow measurements obtained by the thermodilution technique and the evocation of a constant hyperemic response with a given dye volume were previously validated in our laboratory.[2]

**TABLE I Summmary of Clinical and Hemodynamic Data (Mean ± Standard Error of the Mean)**

| | AR | Control |
|---|---|---|
| Patients (n) | 11 | 19 |
| Age (yr) (NS) | 47.4 ± 4 | 47.1 ± 1 |

| LV peak systolic stress* | 895.8 ± 51 | 701.2 ± 22.9 |

* $p < 0.01$; † $p < 0.05$.

Ao = aorta; CHF = congestive heart failure; CSF = coronary sinus flow; IVS = interventricular septum; LV = left ventricle; LVID = left ventricular internal diameter; LVPW = left ventricular posterior wall; NS = not significant; $R_1 + S_3$ = sum of voltages of R in lead I and S in lead III; $S_{V_1} + R_{V_5}$ = sum of voltages of S in lead $V_1$ and R in lead $V_5$.

Means and standard errors were recorded for each measurement by groups. Comparisons between the groups for all continuous measurements were made using a 2-tailed *t* test. Pearson's product moment correlation coefficients were calculated to determine the association of all continuous measurements with the percent change in coronary sinus flow. For the frequency data, Fisher's exact test and the chi-square test were used. When each group was divided into subgroups, that is, those with and those without angina, comparisons of coronary reserve among the 4 groups were made using the Kruskal-Wallis nonparametric test.

## Results

Table I summarizes the clinical and hemodynamic data on the 30 patients by patient groups: the control subjects and those with AR. The age was similar in both groups. There was a predominance of men. Typical angina pectoris (classic, effort-induced) was present in 4 of 11 patients with AR and in 4 of 19 control subjects. Fifteen control subjects had atypical chest pain syndrome. Signs or symptoms of congestive heart failure were elicited by history or physical examination in 9 of 11 patients with AR and in none of the control subjects. No patient had syncope. Voltage in the limb leads (17.2 ± 2.6 mm) and precordial leads (46.8 ± 2 mm) of the

electrocardiogram suggested LV hypertrophy in patients with AR and not in the control group (9.4 ± 1.4 and 25.6 ± 2.1 mm, respectively). ST-T strain pattern was present in 9 of 11 patients with AR and in none of 19 control subjects. Heart rate was similar in both groups (77.6 ± 2.4 versus 72 ± 1.9 beats/min, difference not significant [NS]). LV and aortic pressures were different in both groups; those with AR had a higher LV systolic pressure (152 ± 7.1 versus 123.2 ± 4.4 mm Hg, $p < 0.01$), a higher LV mean diastolic pressure (11.6 ± 1.3 versus 7.4 ± 0.9 mm Hg, $p < 0.01$), a higher LV end-diastolic pressure (19.1 ± 2.5 versus 12.5 ± 0.9 mm Hg, $p < 0.05$), a higher aortic systolic pressure (145.8 ± 61 versus 123.2 ± 4.4 mm Hg, $p < 0.01$), and a lower aortic diastolic presure (64.9 ± 4.1 versus 72.9 ± 1.9 mm Hg, $p < 0.05$). The diastolic gradient between the aorta and the left ventricle was lower in those with AR (52.3 ± 4 versus 65.5 ± 1.9 mm Hg, $p < 0.01$).

Echocardiographic dimensions of the LV wall and LV internal diameter were larger in patients with AR (13.3 ± 0.7 and 59.9 ± 1.3 versus 9.8 ± 0.2 and 42.5 ± 0.8 mm, respectively; both $p < 0.01$). The LV mass was significantly increased in the group with AR (338.9 ± 19.4 versus 128.6 ± 5.4 g, $p < 0.01$). The LV volume/mass ratio was not significantly different in both groups (2.31 ± 0.15 versus 2.2 ± 0.06). The LV peak systolic wall stress was significantly higher in patients with AR (895.8 ± 51 versus 701.2 ± 22.9, $p < 0.01$). Coronary sinus flow at rest and during hyperemia was significantly higher in patients with AR (309 ± 38.4 and 459.7 ± 45.9 versus 120.6 ± 13 and 218.7 ± 21.9 ml/min, respectively; both $p < 0.01$); no further analyses of these values were performed, given the expected variability of the total flow measurement by the coronary sinus thermodilution technique. The percent change in coronary flow during hyperemia (coronary reserve) was significantly lower in the group with AR (55.6 ± 9.2 versus 85.8 ± 7.5%, $p < 0.0187$).

Table II indicates the correlation between the percent change in coronary sinus flow with hyperemia and 11 variables that may influence the coronary vascular reserve in patients with AR. There was a strong negative correlation between coronary reserve and left ventricular mass ($r = -0.86$) (Fig. 1). A strong negative correlation was also found between coronary reserve and LV wall thickness in diastole ($r = -0.83$). A positive correlation was found between coronary reserve and LV volume/mass ratio ($r = 0.76$). No significant correlation was found between coronary vascular reserve and LV volume in diastole ($r = 0.25$), LV peak wall stress ($r = 0.292$), and LV systolic ($r = -0.495$) or diastolic pressure ($r = -0.32$). No significant correlation was found either between coronary reserve and aortic diastolic pressure ($r = 0.32$) or the aortic-LV diastolic gradient ($r = 0.45$). The correlation between coronary vascular reserve and voltage was $r = 0.604$, $p = 0.064$ in the limb leads and $r = -0.118$, $p = 0.745$ in the precordial leads.

Four of 11 patients with AR had angina pectoris. Their coronary reserve was 20, 28, 25, and 107%. The median coronary reserve was 26% in patients with AR and angina pectoris and 66% in those with AR without angina pectoris. The median for the control patients with and without angina pectoris was 72 and 74%, respectively. Although the median coronary reserve was at least 40% lower in patients with AR and angina pectoris, the Kruskal-Wallis test ($k = 5.75$, $p < 0.07$) for testing differences in locations (medians) did not reach the alpha = 0.05 significance level. Patients with AR with and without angina pectoris had similar values for all other variables ($p > 0.05$).

**TABLE II Correlations of Percent Change in Coronary Sinus Flow (Coronary Reserve) and 11 Other Variables**

| | r | p |
|---|---|---|
| Heart rate | 0.071 | <0.834 |

| Resting coronary flow | −0.640 | <0.0338* |

* Statistically significant ($p < 0.05$). r = correlation factor.

## Discussion

**Coronary vascular reserve:** Experimental studies show that volume overload LV hypertrophy is associated with decreased coronary vascular reserve. Feldman et al,[12] who studied the peak reactive hyperemic flow after 10-second coronary occlusion in dogs with acute, reversible AR, found it reduced. In addition, and of great interest, Feldman et al[12] showed that coronary reserve was further reduced by the presence of moderate (50%) coronary narrowing. Karp and Roe[13] studied the effects of chronic (2 to 6 weeks) aortic insufficiency on coronary blood flow; they showed that after temporary coronary occlusion, the overshoot flow repaid an average of 75% (range 0 to 180%) of the calculated flow debt, as compared with 365% in the control subjects. Heiss et al[14,15] studied the coronary reserve in patients with AR and other cardiomyopathies and reported a lower reserve in patients with aortic insufficiency and aortic stenosis than in control subjects. Heiss also showed a positive correlation between coronary reserve and the coronary arteriovenous oxygen difference.

In this study of patients with AR we found an increase in resting coronary sinus flow and a decrease in coronary vascular reserve as compared with those in control subjects (Table I). The decrease in coronary reserve correlated negatively with the increase in resting coronary flow, suggesting that the coronary circulation can adapt to the increased myocardial oxygen requirements of LV hypertrophy by increasing the resting flow, but that it is unable to modify its capacity for maximal coronary flow, so that the increase in resting flow is obtained at the expense of the coronary reserve.

To determine whether the decrease in coronary vascular reserve was the result of LV hypertrophy per se or the result of the specific hemodynamic alterations of chronic AR, the correlation between the decrease in coronary vascular reserve and all other variables measured in this study was analyzed. Table II presents a

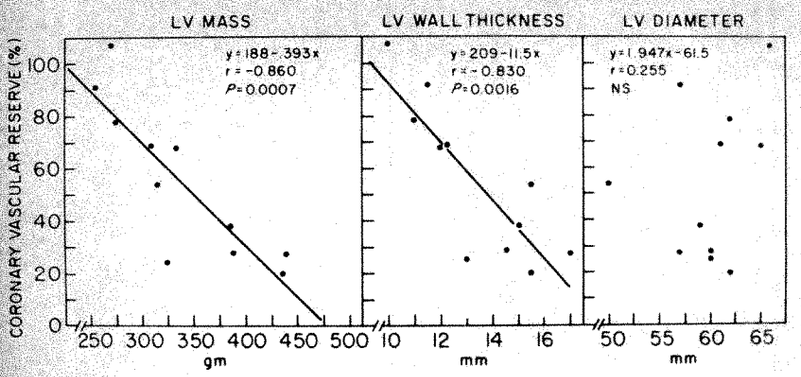

**FIGURE 1.** Correlation between coronary vascular reserve and LV mass in patient with AR.

summary of the most important variables in determining or limiting coronary flow and their correlation with coronary vascular reserve. We found that the LV mass was negatively correlated with the coronary reserve ($r = -0.86$, $p < 0.001$), the patients with the largest mass having the lowest coronary reserve. The increase in LV mass (weight) in aortic insufficiency is the result of a thickened LV wall, encompassing a dilated LV chamber. When analyzing these 2 components separately (Fig. 1), we found a strong negative correlation between coronary reserve and LV wall thickness ($r = -0.83$, $p < 0.001$), but no significant correlation between coronary reserve and LV internal dimension ($r = 0.26$, $p = NS$), suggesting that wall thickness is more important than LV volume in determining coronary vascular reserve in patients with LV hypertrophy secondary to chronic AR.

The ratio between LV diameter and thickness (volume/mass ratio) was similar in the group with AR and the control group (Table I). When analyzed as a continuous function, volume/mass ratio correlated positively with coronary vascular reserve (Table II), the patients with the lowest volume/mass ratio having the lowest coronary vascular reserve. This finding can be explained by the predominant role played by wall thickness in reducing coronary vascular reserve.

Peak systolic stress is a major determinant of myocardial oxygen consumption[16] and hence of coronary blood flow. In asymptomatic or compensated AR, peak systolic stress remains normal[8-10] and end-systolic stress increases.[10] In symptomatic or decompensated AR, peak systolic stress is increased.[14-17] In our study, peak systolic stress was increased in the group with AR as compared with the control group but no strong correlation was found between the increase in peak systolic stress and the decrease in coronary vascular reserve ($r = 0.45$, $p = NS$). This inability to increase coronary vascular reserve along with the increase in peak systolic stress is consistent with our finding of impaired coronary vascular reserve in LV hypertrophy.

Aortic and LV diastolic pressures as well as the aortic-LV diastolic gradient are major determinants of diastolic coronary blood flow. These pressures were significantly different in the group with aortic insufficiency from those in the control group, but we found no significant correlation between the decrease in coronary vascular reserve and the increase in LV diastolic pressures, the decrease in aortic diastolic pressures, or the decrease in the aortic-LV gradient (Table II). Experimentally it has been observed[10,18,19] that a change in the diastolic/systolic ratio of coronary flow occurs with aortic insufficiency: with increasing degrees of AR the systolic component of coronary blood flow becomes more important and the diastolic component decreases; in acute severe AR, all coronary blood flow becomes systolic, with reversal of coronary flow (retrograde flow) during diastole. We could not evaluate the contribution of systolic coronary flow to total coronary blood flow in this study. The lack of significant correlation between coronary vascular reserve and diastolic pressures may be related to the independence of this systolic component from the diastolic pressures, or the result of the predominant effect of LV mass on coronary vascular reserve.

The LV systolic pressure was significantly higher in the group with AR than in the control group (Table I), but we found no significant correlation between the increase in LV systolic pressure and the decrease in coronary reserve, suggesting that other variables outweighed its effect on myocardial oxygen consumption and coronary blood flow.

Of the variables analyzed then, the LV mass, wall thickness, and volume/mass ratio were the only significant determinants of coronary vascular reserve.

**Chest pain:** The mechanism of angina pectoris is a subject of great interest, especially in patients with aortic valvular disease. It has been shown[2,20,21] that patients with aortic stenosis and LV hypertrophy have a decreased coronary vascular reserve. We propose that this decrease in coronary vascular reserve may be related to the pathogenesis of angina pectoris in these patients. Bertrand[22] evaluated the supply/demand ratio in AR by measuring the diastolic pressure-time index over the systolic pressure-time index (DPTI/SPTI)[23] and found it significantly decreased in those with angina pectoris but found no relation between exercise-induced angina and the DPTI/SPTI ratio. The value of the DPTI/SPTI ratio is controversial,[24] making these observations difficult to interpret.

In this study of severe symptomatic AR, the median coronary reserve was 26% in those with angina pectoris and 66% in those without angina pectoris (NS). The

median for the control patients with and without angina was 72.3, and 73.8% respectively. We also compared the clinical data, hemodynamic values, and echocardiographic dimensions in those with and without angina pectoris and found no statistically significant differences. Perhaps with a larger patient population statistical significance will be achieved. Interestingly, 3 of the 4 patients with angina pectoris had the lowest values for coronary vascular reserve, that is, 20, 25, and 28%; these patients had the highest resting coronary blood flow, suggesting that they had undergone vasodilation at rest and had lost the capacity to increase coronary flow appropriately in situations of increased demand.

## Limitations of the Study

**Determination of LV mass by echocardiography:** There is no precise method to measure LV mass in vivo with absolute accuracy. In our study, LV mass was determined echocardiographically. Studies by Devereux and Reichek[5] in normal hearts and hearts with LV hypertrophy validated the echocardiographic calculation of LV mass in patients who later came to autopsy, finding a correlation of 0.92 for LV mass by echocardiography versus LV mass at autopsy. Grossman et al[9] reported good agreement between dimensions determined by echocardiography and by angiographic methods. Abdulla et al[25] failed to find a good correlation between angiographic and echocardiographic determination of LV mass in AR, but they did not use biplane angiography in all cases. Even if the determination of LV mass in our study did not represent accurately the true anatomic LV mass, the directional changes observed and their relation to coronary vascular reserve should remain a valid conclusion.

**Coronary sinus flow measurement may not represent total LV venous outflow:** In the human heart, coronary sinus flow is highly representative of the total LV efflux.[26,27] Also, coronary sinus flow as determined by the continuous thermodilution technique accurately represents total LV coronary flow.[28,29] A possible source of error in estimating total coronary sinus flow stems from the fact that in some cases the posterior ventricular vein drains very near the ostium of the coronary sinus, so that its flow is not included in the measurements obtained.[11] The flow measured may decrease artifactually if the thermodilution catheter is advanced too far into the coronary sinus or may increase artifactually if it is too close to the right atrium, especially in cases of elevated right atrial pressure.[30]

These considerations would not influence the conclusions of our study, because our analysis was based not so much on the total flow per se, but rather on the percent change in flow seen during contrast-agent–induced hyperemia. The percent change should be the same for total or less than total coronary sinus flow.

**Contrast agents may not induce maximal coronary vasodilation:** A major limitation in our study could exist if the contrast agent produced less than a maximal increase in coronary conductance, because in that case the total coronary vascular reserve could not be evaluated by this method. Existing information is controversial in this respect. In the experimental situation, the increase in coronary conductance produced by contrast agents is equivalent to a 10 to 15 second occlusion of the coronary artery ($r = 0.86$),[31,32] similar to the effect of an intracoronary bolus injection of adenosine triphosphate (ATP) or papaverine, but lower than the effect of a prolonged infusion of ATP or papaverine.[31] This comparison has not been made in human beings. The hyperemic reaction to contrast agent injection is greater than the increased flow necessary to repay the oxygen debt, as proved by an increase in coronary sinus oxygen saturation without a change in myocardial oxygen consumption[33] and a concomitant increase in the forearm flow,[34] suggesting an important reflex component in the contrast-agent–induced hyperemia.

Although the effect of contrast agents on the coronary conductance may be to produce near-maximal vasodilation, the effects of contrast agents on cardiac and circulatory hemodynamics[35,36] may influence qualitatively and quantitatively the hyperemic reaction, and maximal coronary flow may not be obtained. Agents that increase coronary conductance without major changes in hemodynamic variables seem better suited for the study of coronary reserve in human subjects. We have currently started a study with such an agent, that is, intravenous dipyridamole.

Even if contrast agents had not induced maximal increase in coronary sinus flow in our study, analysis of the directional changes observed, as well as analysis of the factors determining such changes, such as LV dimensions and hemodynamic variables may remain valid.

**Dose response to contrast agent:** If the hyperemic response is dose related, patients with LV hypertrophy could have a reduced response because they get a lower amount of contrast agent applied per gram of myocardium. We previously demonstrated that this is not the case when $\geq 5$ ml of contrast agent is injected.[2]

**Effect of drugs on coronary blood flow:** Although all drug therapy was discontinued at least 12 hours before the study, some drugs may have a residual effect on coronary blood flow and this effect may influence our results.

**The control group may not be truly normal:** This group of patients had chest pain syndrome with normal coronary arteries. None of them had clinical or laboratory findings that would suggest the presence of underlying coronary artery spasm. Patients in whom coronary artery spasm was suspected had provocative testing with ergonovine maleate and were not included in this study. However, we did not evaluate dynamic changes in coronary tone, myocardial biopsy, blood elements physiology, and hormonal or other variables that could alter coronary blood flow and explain the cause of the chest pain. If such an alteration in coronary blood flow were demonstrated, a better control group would be necessary.

*Conclusions:* Patients with chronic AR and LV hypertrophy seem to have an increased resting coronary flow and a decreased coronary vascular reserve. The decrease in coronary vascular reserve was significantly

correlated with the degree of LV hypertrophy, represented in our study by LV mass, LV wall thickness, and LV volume/mass ratio. The decrease in coronary vascular reserve had no significant correlation with the hemodynamic changes attributable to AR, suggesting that LV hypertrophy per se was the principal determinant of the restricted coronary reserve found in this study.

Although not proven, it seems reasonable to propose that the limitation in the coronary vascular reserve may be one of the underlying mechanisms responsible for the clinical deterioration of patients with advanced AR. Whether the altered capacity to appropriately increase coronary blood flow participates in the pathogenesis of the syndrome of angina pectoris in patients with AR and normal coronary arteries remains unanswered. Our study shows a trend that supports the hypothesis of a limited coronary vascular reserve being a cause of angina pectoris, but the population size and limitations of the methods do not allow for a definite conclusion.

# Regurgitation of Prosthetic Heart Valves: Dependence On Heart Rate and Cardiac Output

KEVIN C. DELLSPERGER, PhD, DAVID W. WIETING, PhD, DEBRA A. BAEHR, BS, ROBERT J. BARD, BS, JEAN-PIERRE BRUGGER, PhD, and EARL C. HARRISON, MD

**Prosthetic heart valves exhibit closure and leakage backflow; however, no well-controlled study to evaluate the influence of factors such as cardiac output and heart rate on backflow has been reported to date. Four clinically used prosthetic aortic valves (size 27 mm)—St. Jude Medical, Björk-Shiley Spherical Disc, Björk-Shiley Convexo Concave, and Starr-Edwards model 1260—were studied in the aortic chamber of a pulse duplication system at heart rates of 50, 80, 110, and 140 beats/min, cardiac output of 2, 4, 6, and 8 liters/min, and mean aortic pressure of 100 mm Hg. Regurgitation was calculated in percentage and found to vary directly with heart rate and inversely with cardiac output. The range of values obtained were 5.5% for the Starr-Edwards model 1260 valve at 110 beats/min and 8 liters/min, to 37.5% for the Björk-Shiley Convexo Concave valve at 140 beats/min and 2 liters/min. Regurgitation was also calculated in milliliters/stroke and ranged from 3.4 ml/stroke for the Starr-Edwards model 1260 valve at 140 beats/min and 2 liters/min, to 17.3 ml/stroke for the Björk-Shiley spherical disc valve at 50 beats/min and 2 liters/min. Regurgitation associated with prosthetic heart valves may present a problem clinically, particularly under conditions of low cardiac output and tachycardia.**

Since the pioneering work of Hufnagel and Harvey[1] in 1952, and Harken et al[2] and Starr and Edwards[3] in 1960, considerable effort has been devoted to the design, development, and testing of prosthetic heart valves.[4] The goal continues to be a heart valve which functions with the efficiency of a normal human heart valve. Major problems associated with tissue and mechanical prosthetic heart valves include thromboembolism, hemolysis, tissue overgrowth, infection, calcification, valve wear, and excessive pressure gradients.[5–10]

One problem not generally considered when selecting a prosthetic heart valve is the volume of backflow (regurgitation) associated with the particular design. For the patient with poor cardiac performance, the amount of backflow may be critical when heart rates and cardiac outputs differ from the norm. Backflow associated with prosthetic heart valves is composed of 2 categories: (1) closure backflow (which is required to close the valve), and (2) leakage backflow (which occurs after the valve is closed) (Fig. 1).

Although studies of backflow associated with prosthetic heart valves under various test conditions have been reported, a detailed analysis of the interrelationship of backflow, heart rate, and cardiac output has heretofore not been performed.

## Methods

Four different currently used clinical prosthetic aortic valves were employed in this study. All valves were equivalent to a 27 mm mounting diameter. The study included the following valves: a Björk-Shiley spherical disc, Björk-Shiley Convexo Concave disc, St. Jude Medical, and Starr-Edwards model 1260. Each valve was independently studied in the aortic chamber of a pulse duplication system which models the left heart as described by Wieting et al[5] in 1966 (Fig. 2.)

The chamber geometry was obtained by sectioning room temperature vulcanizing (RTV) silicone rubber injection molded castings. The aortic sinuses are modeled as an axisymmetric bulge due to ease of manufacturing. A schematic diagram of the aortic valve test chamber is shown in Figure 3. A Björk-Shiley spherical disc 29 mm mitral valve was used

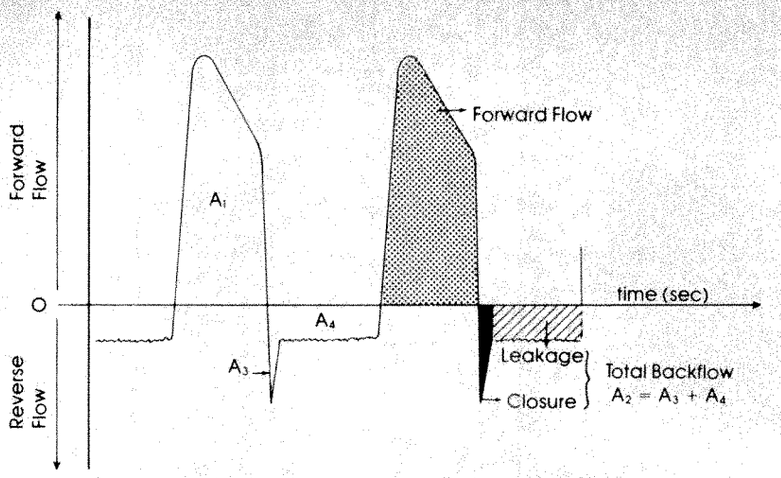

**FIGURE 1.** Typical aortic flow versus time tracing, illustrating categories of backflow.

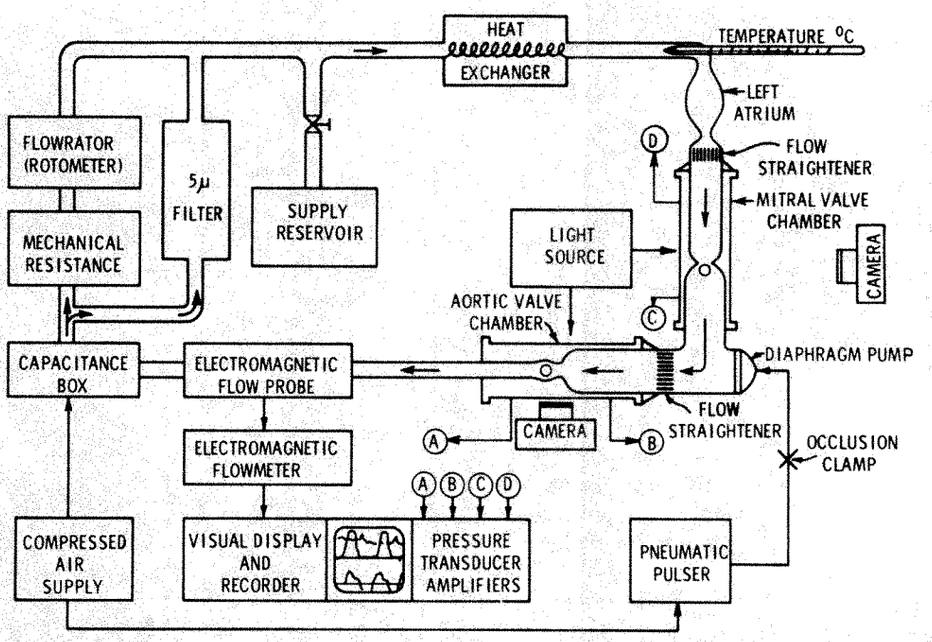

**FIGURE 2.** Schematic diagram of the pulse duplication system as designed by Wieting et al[5] in 1966.

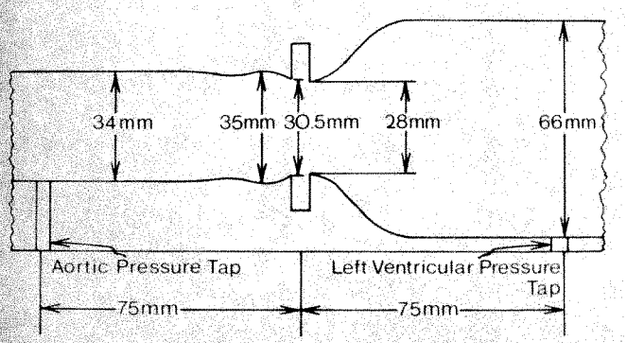

**FIGURE 3.** Schematic diagram illustrating cross-sectional flow areas of the aortic valve testing chamber.

in the mitral chamber for all studies. The valves were tested in an aqueous glycerol blood analog fluid composed of 36.7% glycerol by volume. The specific gravity of this solution at 25°C is 1.1 with a viscosity of 3.5 centipoise. The pulse duplication system was adjusted until the left atrial, left ventricular, and aortic pressures resembled physiologic waveforms. These pressures were measured with 3 Ailtech MS20 physiologic pressure transducers. Aortic flow was measured with a Carolina square wave electromagnetic flowmeter, model 501, using a 26 mm diameter cannulating iron-core flow probe, model EP 695. The pressure and flow signals were filtered at 30 Hz and monitored and recorded on a Honeywell Electronics for Medicine VR-6 Simultrace recorder using paper speeds of 100 mm/s.

Heart rates and cardiac outputs used were as follows: heart rate 50 beats/min, cardiac output 2 and 4 (liters/min); rate 80 beats/min, output 2, 4, and 6 liters/min; rate 110 beats/min,

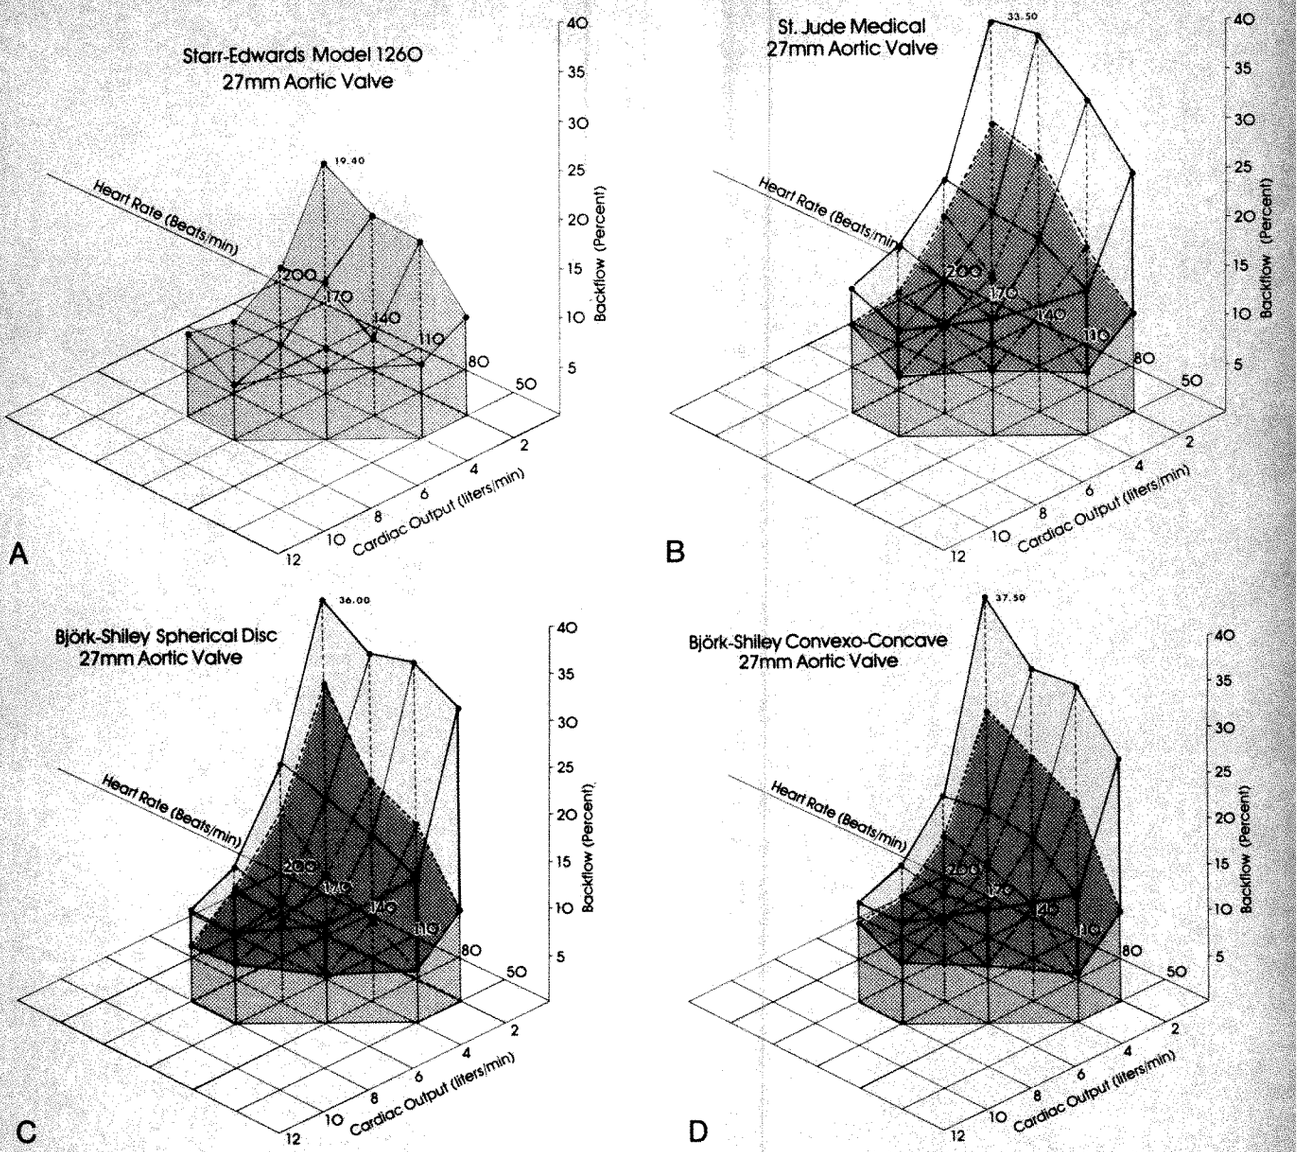

**FIGURE 4.** Three-dimensional graphic representation of backflow expressed in percentage as dependent upon cardiac output and heart rate for the following aortic valve prostheses: **A**, Starr-Edwards model 1260; **B**, St. Jude Medical; **C**, Björk-Shiley spherical disc; and **D**, Björk-Shiley Convexo Concave. In each graph, the upper surface represents the total backflow. The lower surface in **B, C,** and **D** represents closure backflow. The volume of backflow shown between the 2 surfaces in **B, C,** and **D** is the backflow that occurs while the valve is closed (leakage backflow). Since the Starr-Edwards model 1260 valve has no leakage backflow, the closure backflow is the total backflow.

output 2, 4, 6, and 8 liters/min; and rate 140 beats/min, output 2, 4, 6, and 8 liters/min. Systolic durations, corresponding to the Q-T interval of the electrocardiogram for each heart rate setting, were selected as reported by Burton.[11] The resulting values are as follows: heart rate 50 beats/min, systolic duration 420 ms; rate 80 beats/min, duration 350 ms; rate 110 beats/min, duration 290 ms; and rate 140 beats/min, duration 260 ms.

Throughout the range of simulated heart rates and cardiac outputs, the mean aortic pressure was maintained at 100 ± 2 mm Hg; mean left atrial pressure was maintained at physiologic levels, not exceeding 18 mm Hg at the rapid heart rate and high cardiac output settings.

Backflow results were analyzed by planimetry techniques in 2 major categories: (1) percent backflow, and (2) backflow measured in milliliters/stroke. In each major category, total backflow was divided into closure and leakage backflow (Fig. 1.) The percent backflow was measured using the following formula[5]: Percent backflow = $(A_n/A_1) \times 100\%$ (n = 2, 3, 4) where $A_1$ is the area under the forward flow versus time curve, $A_2$ is the area of total backflow, $A_3$ is the area of backflow during valve closure, and $A_4$ is the area of backflow during valve leakage. Backflow in milliliters/stroke is obtained from the following formula: Backflow (ml/stroke) = $[A_n/(A_1 - A_2)] \times (CO/HR)$ (n = 2, 3, 4), where $A_1$, $A_2$, $A_3$, and $A_4$ are as just described, CO is the mean flow rate in milliliters/minute, and HR is the pulse rate in beats/minute.

## Results

The percent backflow results are shown graphically in Figure 4. The upper surface represents the total percent backflow at each setting. The lower surface in Figure 4 (B, C, and D) illustrates the percent backflow

required to close the valve or closure backflow. The volume between the lower and upper surfaces in these figures represents backflow occurring while the valve is closed—leakage backflow. It is obvious that under conditions of low cardiac outputs and high heart rates, backflow greatly increases, reaching 37.5% for the Björk-Shiley Convexo Concave aortic valve. The Starr-Edwards prosthesis exhibited the lowest percent backflow of the valves studied at a heart rate of 140 beats/min and a cardiac output of 2 liters/min, having a total backflow of 19.3%. The valves generally have percent backflow which varies directly with heart rate and inversely with cardiac output.

The actual values for percent backflow are presented in Tables I and II. The valve which exhibited the highest percent backflow at each setting is summarized in Table III. The Starr-Edwards model 1260 aortic valve has the lowest total percent backflow at each setting.

A graphic representation of the backflow in milliliters/stroke is shown in Figure 5. The backflow in milliliters/stroke remains relatively constant along a plane of constant heart rate. This analysis suggests that there is a true inverse relation between percent backflow and cardiac output: that is, the amount of backflow in volume remains constant with constant heart rates, but the denominator becomes smaller, leading to larger percent values. The actual values for backflow in milliliters/stroke are presented in Tables IV and V.

## Discussion

**In vitro studies:** Natural human heart valves have net backflows which are not measurable.[5,12,13] The anatomic configuration of these valves takes advantage of flow inertia to promote rapid closure. After closure, natural human heart valves seal tightly and do not allow retrograde flow.

By their nature, however, all prosthetic heart valves require a certain amount of backflow to effect closure.[14,15] One major consideration for closure backflow is the drag force exerted on the occluder by the retrograde flow. As shown in Figure 4, the closure backflow is greater for the Björk-Shiley Convexo Concave valve than for the Björk-Shiley spherical disc valve. Leakage

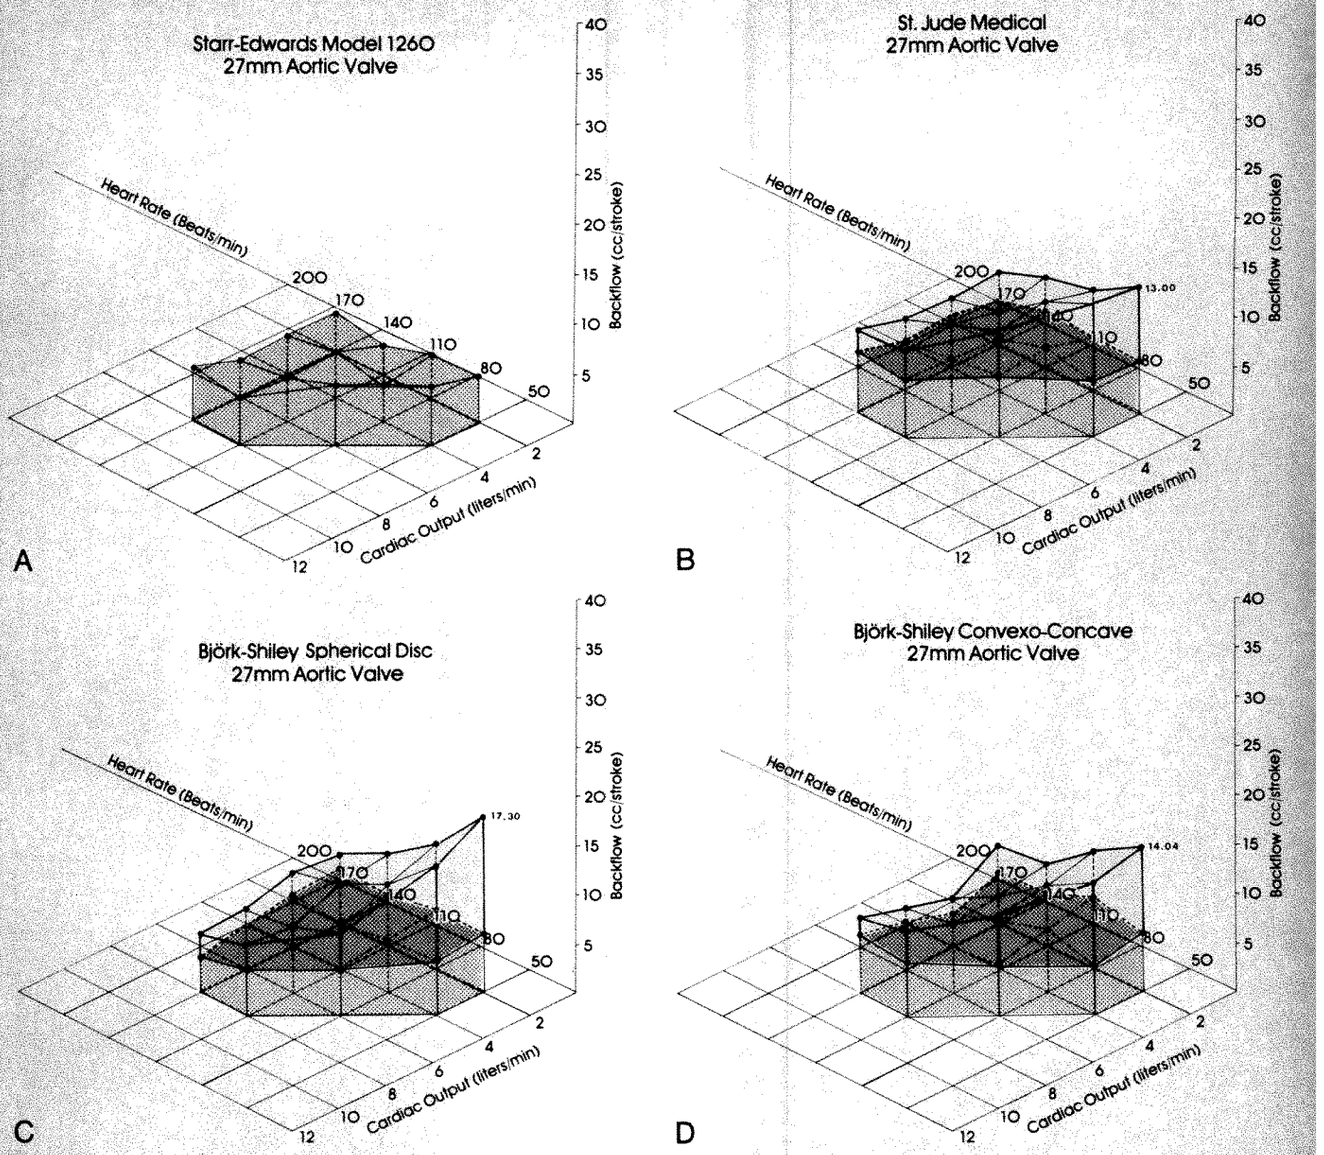

**FIGURE 5.** Three-dimensional graphic representation of backflow expressed in milliliters/stroke (cc/stroke) as dependent upon cardiac output and heart rate for the following aortic valve prostheses: **A,** Starr-Edwards model 1260; **B,** St. Jude Medical; **C,** Björk-Shiley spherical disc; and **D,** Björk-Shiley Convexo Concave. In each graph, the upper surface represents total backflow. The lower surface in **B, C,** and **D** represents closure backflow. The volume of backflow shown between the 2 surfaces in **B, C,** and **D** is the backflow that occurs while the valve is closed (leakage backflow). Since the Starr-Edwards model 1260 valve has no leakage backflow, the closure backflow is the total backflow.

backflow, however, is slightly greater in the Björk-Shiley spherical disc valve than in the Convexo Concave model. One possible explanation for the higher closure backflow is that the Björk-Shiley Convexo Concave occluder presents less drag to the reverse flow and therefore closes slower. Drag forces during closure are greater when the occluder presents a concave surface to the reverse flow, similar to a sail in the wind. Drag forces during closure are least when the occluder is streamlined in the direction of retrograde flow.

The results of this study indicate much lower backflows for the Starr-Edwards model 1260 valve than for the other prostheses studied. The major reason for this finding is the absence of leakage. The absence of leakage backflow stems from the orifice seating design of this prosthesis. Other prostheses studied—the St. Jude Medical, Björk-Shiley spherical disc, and Björk-Shiley Convexo Concave—have built into their design a "controlled leakage" which tends to increase total backflow.

Total backflow results obtained are consistent with those reported by Wright[14] at varying heart rates with a constant stroke volume. Although valves sizes in this study were larger than those used by Wright in the simulated mitral valve position, the values obtained are within the range of experimental error. Work by Baehr (unpublished data) in the aortic position of a similar test apparatus with size 25 mm aortic valves supports these

findings of markedly increased backflows at low cardiac output and fast heart rates.

Although most investigators have not divided backflow analysis into the 2 types of backflow, several studies have been carried out on the leakage component. Bellhouse and Bellhouse[16] found that a leakage of 5.7% at a cardiac output of 5 liters/min associated with the Björk-Shiley spherical disc mitral valve, which is consistent with the results obtained in this study. On the other hand, Björk and Henze[17] evaluated leakage through a Björk-Shiley spherical disc prosthesis using a column of test fluid (human blood) with variable height. They found that the leakage flow rate at a pressure of 100 mm Hg was 7.5 ml/s for a 27 mm valve. This leakage flow rate when converted into leakage backflow is 5.9 ml/stroke at a heart rate of 50 beats/min and 1.3 ml/stroke at a heart rate of 140 beats/min. The values obtained by Björk and Henze are lower than those obtained in this study in a pulse duplicator system with a blood analog test fluid.

**In vivo results:** Many investigators have stated that an obligatory closing backflow exists in mechanical prosthetic heart valves[13,15,16,18,19]; however, few have reported the magnitude of this backflow.[13,15,19] Levang et al[20] studied the transvalvular regurgitation of Björk-Shiley spherical disc aortic valves after implantation in humans using 2 techniques. One technique employed an electromagnetic flow probe placed around the ascending aorta perioperatively. This technique, however, lacks specificity in assessing transvalvular regurgitation. Reverse flow due to coronary blood flow was estimated and subtracted from the overall reverse flow waveform. The transvalvular regurgitant fraction was found to be 7% for a size 27 mm Björk-Shiley spherical disc aortic valve. They divided the backflow into closure and leakage components and found that

approximately half of the total backflow occurs during each phase at a heart rate of 72 beats/min. In addition to the perioperative flow recordings, postoperative cineaortography was performed and the transvalvular leakage was graded from 0 to IV according to the degree of contrast filling of the left ventricle. Used clinically, however, this technique lacks the quantitative measure that a well-controlled in vitro study would yield. In Levang's series of 47 patients with Björk-Shiley spherical disc prostheses, 42 patients had a grade I transvalvular regurgitation, 4 patients had a grade II transvalvular regurgitation, and 1 patient had a grade III transvalvular regurgitation. The patient with the grade III transvalvular regurgitation was found to have a 30% regurgitation during the perioperative flow measurement.

Williams et al,[13] using an electromagnetic flow probe placed upstream from the normal mitral valve, found that in dogs, regurgitation associated with normal valve closure was negligible when compared to the approximate 4% associated with a Starr-Edwards mitral valve prostheses at low heart rates. Nolan and co-workers[19,21,22] reported that closure backflow in calves varied from 1.3 to 3.6 ml for disc and ball-type mitral valve prostheses as measured with an electromagnetic flow probe attached to the orifice of the prosthesis. These figures are slightly lower than the 4.5 ml measured in this study for a Starr-Edwards prosthesis in the aortic position. In vivo studies reported by Frater[23] indicated the obligatory closing backflow was approximately 3.1 ml for eccentrically opening mitral valve prostheses, such as the Björk-Shiley spherical disc valve. In Frater's work the amount of obligatory backflow did not vary significantly as the heart rate was increased, while the percentage of backflow increased as the heart rate increased. The 3.1 ml obtained by Frater for an eccentrically opening mitral valve is lower than the 5.1 to 5.5 ml found for the Björk-Shiley valves in this study. The amount of fluid required, however, in order to close a prosthetic valve in the mitral position is lower than that required for the closure of an aortic prosthetic valve (unpublished data).

**Clinical significance:** When evaluating a valvular lesion hemodynamically, both the decrease in pressure and the regurgitation should be assessed. Clinically significant incompetence occurs at regurgitant flows as low as 20 to 30% of the forward stroke volume.[24] In this study, all prostheses exhibited some degree of backflow at all pulse duplicator settings. The backflow in the "normal" range of operation was approximately 10%, which is not considered clinically significant. However, the hinged leaflet valves have total regurgitant fractions >20% once cardiac output is <4 liters/min and heart rate is >110 beats/min. At rates equivalent to clinical tachycardia, closure backflow is the major component of regurgitation, while the leakage backflow is the major component of regurgitation at rates equivalent to clinical bradycardia.

The physician should be aware of the possible problems which may be associated with prosthetic valves with high regurgitant fractions. Specifically, for a patient with tachycardia and low cardiac output, backflow may present an enormous demand on the cardiac energy supply. In this case, the valve which has a low closure backflow would be hemodynamically favorable. However, a patient with bradycardia presents a different type of problem. In this patient, the obligatory closure backflow is small compared with the large volume of leakage backflow. At these rates, leakage backflow may represent as much as 65 to 75% of the total backflow. For this patient, a prosthesis which possesses little or no leakage backflow would be hemodynamically favorable.

It is reasonable to speculate that diastolic augmentation with an intraaortic balloon pump may be associated with excess backflow in patients with prosthetic valves which have a large amount of leakage backflow. From this study and others,[17,24] the slower the heart rate and the higher the closing transvalvular pressure, the greater the amount of leakage backflow.

**Conclusion:** Regurgitation of the 4 prosthetic valves studied is dependent on heart rate and cardiac output. During tachycardia, closure backflow dominates, whereas, during bradycardia leakage backflow dominates. Regurgitation also varies inversely with cardiac output. Regurgitation of prosthetic valves does not appear to be significant for the patient with heart rates and cardiac outputs in the normal range. Mean aortic pressures were maintained at a constant level in this study. Because mean aortic pressure fluctuates in vivo, further analysis of the regurgitation of prosthetic aortic valves should be made with varying mean aortic pressures.

Total backflows >30% were measured for the 3 hinged leaflet valves (St. Jude Medical, Björk-Shiley spherical disc, and Björk-Shiley Convexo Concave). These high percent backflows measured in vitro could be clinically significant, particularly at increased heart rates and low cardiac outputs.

The Starr-Edwards model 1260 ball valve had the smallest backflow measured both in percentage and in milliliters/stroke. A major factor responsible for the lower backflow is the absence of leakage backflow with this orifice seating ball valve; however, the closure backflow for the Starr-Edwards valve was also less than that associated with the hinged leaflet valves.

Based on the results of this study, backflow associated with prosthetic heart valves may be a matter of even greater concern when surgically replacing more than 1 diseased or malfunctioning cardiac valve. Backflow associated with 2 or more prosthetic valves could result in an increased work load of >50% on the heart in order to maintain suitable cardiac output. For this reason, it is imperative that future prosthetic heart valves be designed to minimize backflow.

# Noninvasive Detection of Active Pericardial Bleeding Using Cardiac Blood Pool Scintigraphy

TIMOTHY M. BATEMAN, MD, RASHID MASSUMI, MD, RICHARD J. GRAY, MD, AURELIO CHAUX, MD, MICHELE A. DeROBERTIS, RN, DAVID E. BROWN, CNMT, JACK M. MATLOFF, MD, and DANIEL S. BERMAN, MD

**The diagnosis of active pericardial bleeding has traditionally depended on an invasive documentation by needle aspiration, angiography, or direct inspection. Blood pool scintigraphy performed in 2 patients just before and after the development of hemopericardium revealed unique images in which acute pericardial bleeding manifested itself by an additional blood pool adjacent to the cardiac chambers. With appropriate attention to technical factors, such distinctive images should be highly specific for active bleeding into the pericardial sac.**

Active pericardial bleeding is a described complication of blunt or sharp cardiac trauma,[1,2] pacemaker or catheter perforation,[3] open heart surgery,[4] acute myocardial infarction,[5] rupture of the heart or aorta,[6,7] neoplastic disease of the pericardium,[8] drugs that alter clotting mechanisms,[9] and pericarditides of viral, tubercular,[10] or uremic[11] origin. When bleeding accompanies inflammatory conditions of the pericardium, no special management is usually needed beyond an awareness of its possibility and an avoidance of medications that may exacerbate the hemorrhage. In other cases, however, active pericardial hemorrhage may be life-threatening. Situations of this type may arise secondary to pacemaker or catheter perforation, early after cardiac surgery, early after infarction, or with retrograde aortic dissection, where the detection of bleeding may presage impending cardiac tamponade. Traditionally, the diagnosis has depended on a strong clinical suspicion followed by invasive documentation by needle aspiration, angiography, or direct inspection.

Nuclear techniques may be useful for the detection of bleeding, in that red blood cells are labelled with a radionuclide, thereby allowing their localization to various intra- or extravascular spaces. In active pericardial bleeding, an additional blood pool encircling all or part of the myocardium may be expected. However, this finding has not yet been reported and in our experience is an uncommon observation. Because this may simply reflect the infrequent application of blood pool imaging in suspected hemopericardium, we believe it important to draw attention to scintigraphic findings when cardiac blood pool imaging is performed in patients with active pericardial bleeding.

## Reports of Patients

**Patient 1:** A 76-year-old man was referred for exercise radionuclide ventriculography because of recent onset of typical angina. Results of physical examination were within normal limits. As the patient was being prepared for the exercise test, chest pain accompanied by a heart block typical of the Mobitz II pattern occurred. After injection of 25 mCi of technetium-99m–labelled red blood cells, a resting radionuclide ventriculogram was normal (Fig. 1A). The exercise study was deferred in view of the ischemia-induced heart block, and the patient underwent temporary pacemaker insertion. Difficulty in obtaining regular capture required numerous repositionings of the electrode within the right ventricle. Approximately 1 hour after pacemaker insertion, a sharp pleuritic anterior chest pain suddenly developed that was quite unlike the angina. The pacing threshold of the ventricular demand pacemaker concomitantly increased, and there was intermittent loss of ability to capture. A 2-dimensional echocardiogram revealed a small anterior and posterior pericardial effusion and also suggested that the tip of the pacemaker wire was outside the right ventricular chamber, as described previously.[3,12,13] A diagnosis of pacemaker perforation was made, and the wire was repositioned inside the right ventricle. Four hours after injection of the technetium-99m–labelled red blood cells, repeat scintigraphic images revealed a halo of increased radioactivity around the entire heart (Fig. 1B). The subsequent course was uneventful.

**Patient 2:** A 59-year-old woman was referred for surgical therapy of mitral stenosis. Valvuloplasty and double aortocoronary saphenous vein bypass grafting were performed. The pericardium was left open

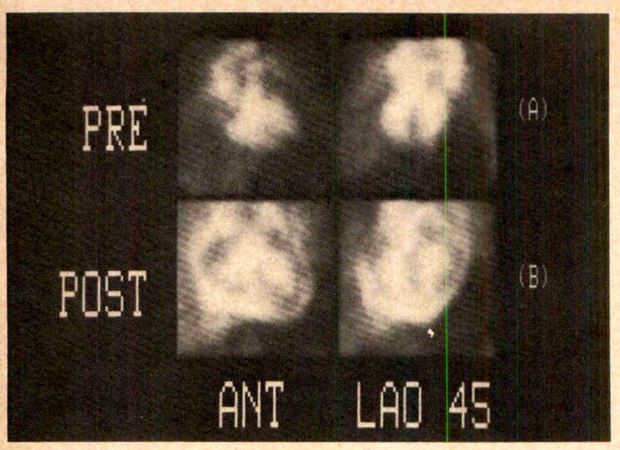

**FIGURE 1.** Patient 1. **A,** anterior (ANT) and left anterior oblique (LAO) 45° cardiac blood pool scintigrams taken at rest with patient supine. **B,** same views 4 hours later, after a temporary transvenous pacemaker tip had penetrated the right ventricular wall. A "halo" of activity surrounding the heart has developed, consistent with the presence of radioactively labelled red blood cells within the pericardial space.

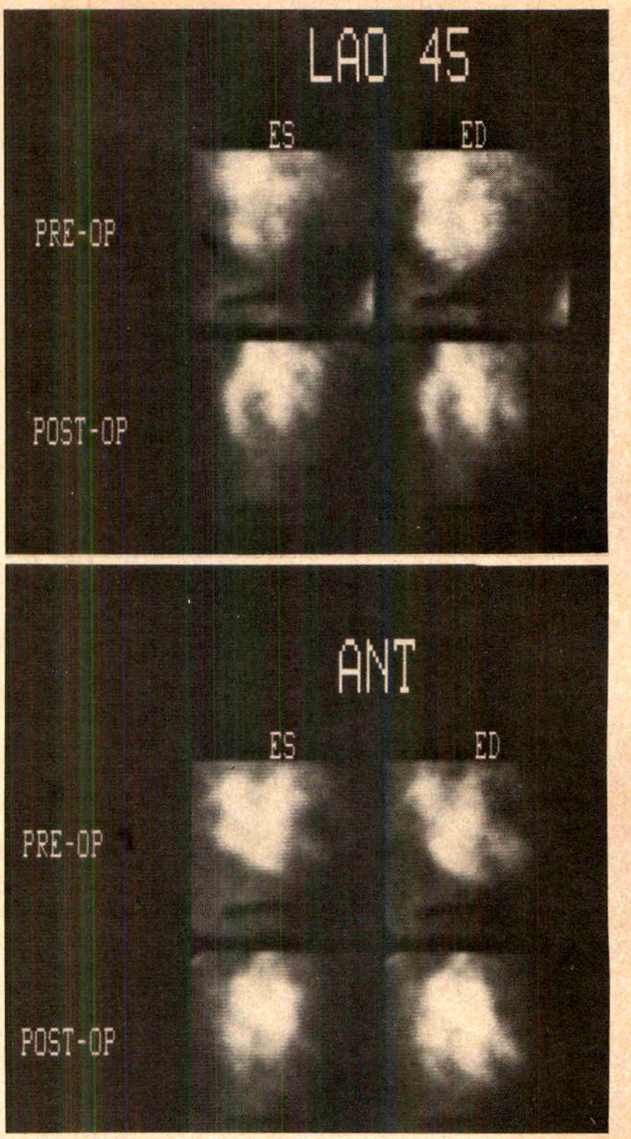

**FIGURE 2.** Patient 2. Cardiac blood pool scintigrams taken at rest with the patient supine, before open heart surgery (PRE-OP), and just before the development of tamponade (POST-OP). ES = end-systole; ED = end-diastole.

and 2 chest tubes were placed in the pericardial space. By 8 hours postoperatively, 1,100 ml of blood had been lost from the chest tubes. The neck veins were distended, and the cardiac index was only 1.9 liters/min/$m^2$ and the blood pressure 100/50 mm Hg. Because the pulmonary capillary wedge pressure was 12 mm Hg, blood, colloid, and plasma expanders were given, with a rapid increase in the right atrial pressure (to 24 mm Hg), and little change in the pulmonary capillary wedge pressure, cardiac index, or blood pressure. Chest X-ray showed a larger cardiac silhouette than preoperatively, with a prominent right heart border. A diagnosis of right atrial tamponade[14] was suspected and the patient returned to the operating room. On opening of the sternum, cardiac index and blood pressure increased and the right atrial pressure decreased precipitously, changing its waveform from a finely undulating line to a recognizable atrial pressure tracing with steep $x$ and $y$ descents. Fresh blood and well-formed clots were seen throughout the pericardial cavity, with a marked accumulation over the right coronary artery graft, clearly compressing the right atrium. The source of bleeding was a small area on the right atrium.

Equilibrium radionuclide ventriculography using technetium-99m–labelled red blood cells had been performed approximately 48 hours preoperatively and again about 3 hours postoperatively (Fig. 2). The postoperative wall motion study differed from the preoperative one in that the end-diastolic volume of the left ventricle was much smaller and a faint halo of increased radioactivity surrounded the entire heart, both findings probably representing blood outside of and compressing the cardiac chambers. There was a marked accumulation of radioactivity along the free border of the right ventricle and right atrium. In the preoperative anterior views, the right atrium virtually disappeared during ventricular diastole, as the labelled blood left it to fill the right ventricle. In the postoperative images, the area of the right atrium emitted a large number of counts that did not vary with the cardiac cycle, indicating a large volume of labelled blood lying outside the atrial chamber and compressing it to a fraction of its normal size. Post-reoperative images were similar to those taken before the first operation.

## Discussion

In equilibrium blood pool scintigraphy, red blood cells are labelled with a radiopharmaceutical agent that emits gamma rays detectable by a scintillation camera. A parallel-hole collimator is placed between the patient and the camera to allow localization of count origins and thus the development by a computer of an image of the blood pool within the region of viewing interest. In the usual situation in which cardiac imaging is performed, the labelled red blood cells remain within the vascular space and the resulting images are therefore of the cardiac chambers and the great vessels, with "background radioactivity" resulting from the pulmonary vascular bed and scatter from radioactivity contained within the cardiac chambers. The myocardium surrounding the cardiac chambers will not be as great a source of gamma rays and so will appear as a rim of relative darkness. With a large pericardial effusion, this rim of darkness will be thicker than expected.[15] If pericardial bleeding is active, an additional radioactive blood pool encircling all or part of the myocardium would be expected. If the blood is flowing into a closed and healthy pericardium with or without excessive

pericardial fluid, the blood should distribute rather uniformly throughout the pericardial space with a slightly greater concentration in the dependent areas, as in Patient 1. When the bleeding is brisk and the pericardium is diseased, absent, or open, the formation of blood clots may lead to an uneven distribution of blood, as in Patient 2.

In the detection of bleeding, the radionuclear label must be nearly completely bound to red blood cells, for unbound isotopes may distribute freely throughout extra- as well as intravascular spaces and may even accumulate in various serous cavities. Indeed, the differentiation of transudative from exudative pericardial effusions has been attempted on the basis of how fast an injected bolus of free technetium-99m diffused into the pericardial space of patients with known effusions.[16] Radioactivity emanating from the pericardium will not be specific for active pericardial bleeding if the technetium-99m has been labelled to albumin, because this bond is not stable and a large portion of the tracer will be free to redistribute throughout extravascular spaces within 1 hour of injection.[17] Moreover, there will be situations other than active bleeding in which albumin itself would extravasate into the pericardial space. Because in the absence of bleeding, red blood cells remain exclusively intravascular, tagged red cells are the ideal agent for blood pool imaging. At our institution, an in vitro method for labelling red blood cells with technetium-99m is employed.[18] This method routinely provides >95% labelling efficiency which persists at this high level for at least 30 minutes after injection.[19] It is not certain that this degree of binding will continue for a prolonged period, but preliminary studies here have established a comparable binding efficiency for at least 4 hours from the time of injection. An in vivo method[20] for labelling erythrocytes is more commonly employed for convenience and availability, but has a lower intravascular retention of activity at 30 minutes than does the in vitro method.[19] Therefore, we believe the in vitro method holds more promise if blood pool imaging is to become a reliable test for the detection of bleeding.

Blood pool scintigraphy is not yet a proven sensitive method for detecting pericardial bleeding. Also unknown is the amount of bleeding required before the described scintigraphic appearances may be anticipated. However, these are reasonable areas for investigation, because a reliable method of either detecting or ruling out pericardial bleeding would find clinical use if it even occasionally eliminated the need for a more invasive diagnostic approach. In addition, because technetium-99m has a half-life in excess of 6 hours, visualization of bleeding may be possible as late as 24 hours after injection of the labelled red blood cells. Therefore, repeated imaging may be of help in detecting slow or intermittent pericardial hemorrhage.

This present documentation should serve to direct attention to other possible uses of blood pool imaging in the detection of active bleeding. Recent reports have demonstrated its usefulness in the diagnosis and localization of acute gastrointestinal bleeding[21] and in the localization of active pulmonary hemorrhage.[22] Presumably, this procedure may also permit the noninvasive diagnosis of bleeding into joints, pleural spaces, and meninges.

# Assessment of the Cardiac Effects of Hemodialysis With Systolic Time Intervals and Echocardiography

ABRAHAM BORNSTEIN, MD, WILLIAM H. GAASCH, MD, and JOHN HARRINGTON, MD

**The acute effects of hemodialysis on left ventricular (LV) function were studied with the use of externally recorded LV systolic time intervals and echocardiography; 10 patients with normal or near-normal predialysis LV function and no circulatory congestion were studied. Hemodialysis significantly decreased the LV ejection time (LVET) from 270 ± 9 ms to 237 ± 10 ms ($p < 0.001$); no significant change was noted in the preejection period (PEP). The PEP/LVET ratio increased from 0.41 ± 0.05 to 0.45 ± 0.06 ($p < 0.05$). The LV end-diastolic dimension decreased from 5.3 ± 0.3 cm to 4.8 ± 0.3 cm ($p < 0.001$). Fractional shortening and ejection fraction did not change significantly, but hemodialysis slightly increased mean $V_{CF}$ from 1.2 ± 0.1 $s^{-1}$ to 1.4 ± 0.1 $s^{-1}$ ($p < 0.005$). Hemodialysis was associated with a 17% decrease (87 ± 8 ml to 72 ± 7 ml; $p < 0.001$) in LV stroke volume as calculated from echocardiographic data. Small changes in heart rate and blood pressure were insignificant. We conclude that the postdialysis reduction in stroke volume was due primarily to an acute decrease in LV preload; dialysis also appears to be associated with a small increase in the LV contractile state.**

The effect of chronic renal failure and hemodialysis on cardiac function has been the subject of several reports. Early studies primarily used the classic measurements of cardiac output and stroke volume,[1-3] but more recently the effect of hemodialysis on left ventricular function has been studied with noninvasive techniques.[4-6] The latter methods not only allow determination of LV end-diastolic volume or dimension, systolic ejection fraction, and cardiac output, but also provide information regarding changes in the LV contractile state.[7,8] Noninvasive methods have an obvious advantage over invasive techniques partly because they make it possible to monitor LV performance serially in chronically dialyzed patients during diagnostic or therapeutic intervention. The externally recorded systolic time interval and the echocardiographic LV study are complementary in that each provides information the other does not.[7-9]

Hemodialysis in patients with chronic renal failure is reported to cause a reduction in stroke volume as reflected by a decrease in LV ejection time. However, we were unable in those studies to estimate changes in ejection fraction or LV contractile state.[4] The purpose of the present study was to examine the effects of hemodialysis on LV function using both systolic time intervals and the echocardiographic (echo) LV study. Specifically, we wish to define the mechanisms responsible for the postdialysis reduction in LV stroke volume.

## Methods

Ten patients with chronic renal failure maintained by long-term hemodialysis at the Hemodialysis Unit of the New England Medical Center Hospital were studied. All 10 patients were active and ambulatory, and none had evidence of pulmonary congestion or more than a trace of peripheral edema. No patient was taking digitalis. The patients were studied immediately before and after hemodialysis (4 to 5 hours) in the recumbent position. Dialysis was performed using a 1.0 $m^2$ parallel plate kidney and a variable degree of positive pressure ultrafiltration. Blood flow was typically 250 to 300 ml/min.

Echocardiograms were obtained with a Smith Kline Ekoline 20A ultrasonoscope using a 2.25 MHz, 0.5 inch transducer focused at 7.5 cm. LV dimensions were measured at end-diastole and end-systole, and the fractional change in LV dimension (or circumference) was calculated as (DED − DES)/DED, where DED = dimension at end-diastole and DES = dimensions at end-systole. Mean normalized velocity of circumferential fiber shortening (mean $V_{CF}$ expressed in circumferences per second [circ/s]) was calculated as follows: Mean $V_{CF}$ = (DED − DES)/DED·LVET, where LVET = LV

BP = blood pressure; C = control (before dialysis); D = dialysis (after dialysis); DED = left ventricular dimension at end-diastole; FS = fractional shortening; HR = heart rate; LVET = left ventricular ejection time; NS = not significant; PEP = preejection period; SE = standard error; $V_{CF}$ = mean velocity of circumferential fiber shortening.

ejection time measured from the carotid pulse tracing recorded simultaneously with the echocardiographic study. Our methods, including the rationale for the normalized velocities and the limitations of these echocardiographic techniques, are detailed in previous reports.[7–9] LV volume was estimated from the method of Teichholz et al.[10]

Externally monitored LV systolic time intervals were recorded at a paper speed of 100 mm/s using standard methods.[11] Lead II of the electrocardiogram was recorded simultaneously with the phonocardiogram and the carotid pulse tracing. Electromechanical systole ($QS_2$) was measured from the onset of the QRS complex of the electrocardiogram to the first high-frequency component of the second heart sound; the LV ejection time was measured from the rapid upstroke to the incisural notch on the carotid pulse tracing; the preejection period (PEP) was derived by subtracting LVET from the $QS_2$ interval.

Echocardiographic and systolic time interval measurements were averaged over 12 cardiac cycles, and the heart rate was obtained from the average R-R interval of the 12 QRS complexes. Blood pressure was measured by cuff sphygmomanometer. All data are presented as the average ±1 standard error of the mean; statistical analyses were performed using a paired *t* test.

Patients were selected for this study only if they were free of clinical evidence of LV disease and had normal or near-normal echocardiographic and systolic time interval data before hemodialysis. Both the echocardiographic and systolic time interval data were clearly normal in 7 of the 10 patients. One patient (Patient 5) had left bundle branch block and abnormal systolic time intervals, in part secondary to conduction delay. Patients 8 and 10 had abnormal systolic time intervals and normal echocardiographic measurements.

## Results

The echocardiographic and systolic time interval data are presented in Table I, and a representative study is shown in Figure 1. Body weight and LV end-diastolic dimension decreased in every patient (both $p < 0.001$), but fractional shortening did not show a consistent tendency to increase or decrease; there was a small and statistically significant ($p < 0.005$) increase in circumferential fiber shortening velocity ($V_{CF}$). LV end-diastolic volume decreased from 143 ± 18 ml to 119 ± 17 ml ($p < 0.001$), and stroke volume decreased from 87 ± 8 ml to 72 ± 7 ml ($p < 0.001$).

The LV ejection time decreased in every patient ($p < 0.001$), but there was no significant change in the preejection period; the PEP/LVET ratio increased from 0.41 ± 0.05 to 0.45 ± 0.06 ($p < 0.05$). The heart rate tended to increase and arterial pressure tended to decrease, but these changes did not achieve statistical significance.

The average blood urea nitrogen level decreased from 89 ± 4 to 48 ± 7 mg/dl ($p < 0.001$); serum calcium increased from 8.9 ± 0.2 to 9.4 ± 0.1 mg/dl ($p < 0.02$); serum potassium decreased from 5.2 ± 0.3 to 4.0 ± 0.2 mEq/liter ($p < 0.005$).

## Discussion

The major hemodynamic change associated with hemodialysis was a decrease in stroke volume due to a reduction in LV preload; there was no change in fractional shortening, but our data indicate an increase in contractility after dialysis.

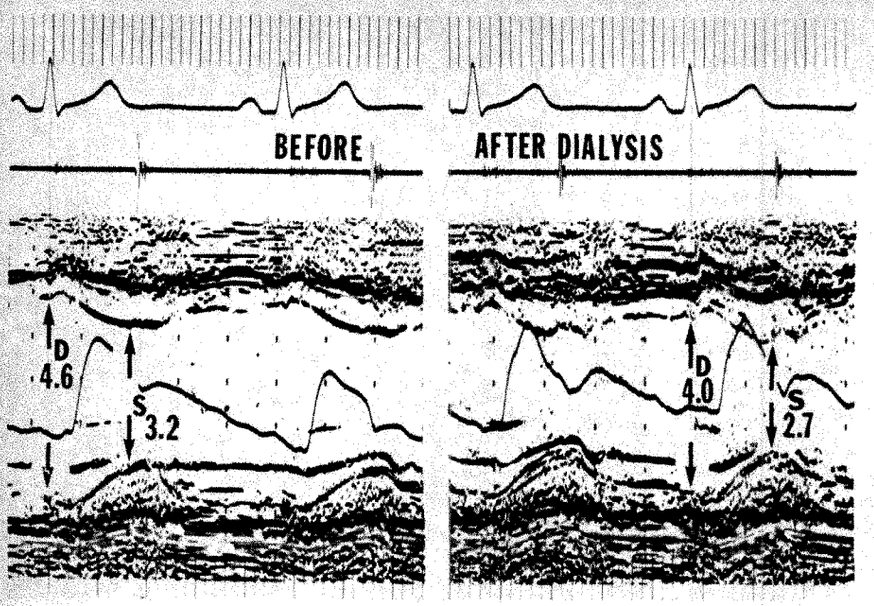

**FIGURE 1.** Echocardiographic LV studies before and after hemodialysis (Patient 1). With dialysis, the LV dimension at end-diastole (D) decreased from 4.6 to 4.0 cm and the systolic dimension (S) from 3.2 to 2.7 cm. See text for details.

Hemodialysis resulted in a highly significant decrease in LV ejection time, no change in the preejection period, and a small but significant increase in the PEP/LVET ratio. If these data were interpreted without the information provided by the echocardiographic LV study, it might be concluded that the decrease in LVET, which implies a postdialysis rejection in stroke volume,[4] was due to a decline in the systolic ejection fraction, because an increase in the PEP/LVET ratio suggests a decrease in the ejection fraction.[11] It is well known that decreased LV preload commonly accompanies hemodialysis, and although it might also contribute to a reduction in LVET, the relative contributions of these 2 factors (decreased preload and ejection fraction) are impossible to assess from systolic time interval data alone. The echocardiogram provides important information in this regard. The echocardiographic LV study confirmed a reduction in preload, but no change in fractional shortening indicates no change in the systolic ejection fraction. Thus, the suggestion that the ejection fraction decreased with dialysis (on the basis of an increase in the PEP/LVET ratio, as described earlier) is not supported by the measured echocardiographic fractional shortening. Not only does the echocardiographic LV study identify the basis for the postdialysis reduction in LVET, namely, a 17% decrease in LV end-diastolic volume and a 24% decrease in stroke volume, but also the combination of both techniques provides additional insight into the cardiac effects of hemodialysis.

LV mean circumferential fiber shortening velocity calculated from the echocardiographic dimension data and the LVET has been used as an index of LV contractile state, but it is well known that mean $V_{CF}$ is sensitive to acute alterations in LV afterload[8]: that is, an increase in LV contractile state or a decrease in afterload, or both, will result in an increase in mean $V_{CF}$. In our 10 patients, the decrease in LV systolic pressure was minimal (and statistically nonsignificant), but the decrease in LV systolic dimension and volume was highly significant. Because afterload (systolic wall stress) is directly related to systolic pressure and radius, a postdialysis reduction in afterload is apparent. For this reason the postdialysis increase in $V_{CF}$ must be interpreted with caution. The increase in $V_{CF}$ was likely due in part to a reduction in afterload, and perhaps to an increase in contractility, but we would not conclude, as have others,[5] that the increase in $V_{CF}$ can be taken as evidence of an increase in LV contractile state alone. However, there is some evidence of an increase in contractility which is not apparent on analysis of the echocardiographic LV study; the absence of a change in PEP is not consistent with a pure decrease in preload. The PEP is determined by the rate of development of LV isovolumic pressure (LV dP/dt) and the level of aortic diastolic pressure (aortic valve opening pressure); LV dP/dt increases with an increase in preload or an increase in contractile state (and vice versa), or both.[11] Arterial pressure did not change significantly, but with a decreased preload, the expected change in the PEP should have been an increase (if there were no change in contractility). The PEP did not change, and the lack of such a change is likely due to the opposing effects of a decrease in preload (which should increase the PEP) and an increase in contractility (which should decrease the PEP). Although this may be weak evidence for an increase in the LV contractile state, the acute increase in serum calcium as well as a potential reduction in uremic toxins or an improvement in electrolyte balance, or both, might be expected to augment LV contractility. Alternatively, a reflex increase in sympathetic tone as a consequence of the reduced stroke volume could have caused the increase in contractility.

The findings in our 10 patients complement those recently reported with radionuclide left ventriculography. Hung et al[6] found that the systolic ejection fraction remained unchanged in 15 patients with a

normal predialysis ejection fraction; their methods did not allow measurement of end-diastolic or stroke volume, but did suggest that the *combination* of an acute decrease in preload (which should reduce the systolic ejection fraction) and afterload (which should increase the systolic ejection fraction) might explain the absence of a change in the ejection fraction. Our findings of a postdialysis reduction in preload and afterload and no change in the ejection fraction confirm the hypothesis of Hung et al.[6] In contrast to the findings in patients with normal LV function, these investigators and others[5] showed that the systolic ejection fraction may increase in patients with a low predialysis ejection fraction.

It thus appears that the cardiac effects of hemodialysis in patients with normal LV function are primarily related to variations in LV preload and the Frank-Starling mechanism. In addition, dialysis appears to be associated with a small increase in LV contractile state. Both the externally recorded systolic time intervals and the echocardiographic LV study are influenced by hemodialysis and both provide useful information about the functional state of the left ventricle, especially when used together. It should be emphasized that any single assessment of LV function in patients with chronic dialysis may not be truly representative of the functional state of the left ventricle because of the lack of a steady state. Serial studies may be useful in this regard.

# Normal Left Atrial Function Determined by 2-Dimensional Echocardiography

JACK GUTMAN, MB, BS, FRACP, YIN SHI WANG, MD, DENNIS WAHR, MD, and NELSON B. SCHILLER, MD

**To obtain normal values for left atrial function noninvasively, volumes of the left atrium and ventricle were calculated in 52 volunteers by 2-dimensional echocardiography. A light pen digitizing and computation system, controlled by a microprocessor, was used to outline the left atrium and ventricle in orthogonal apical views. Then, to calculate end-systolic and end-diastolic atrial and ventricular volumes, a modified Simpson's rule formula was used. End-systolic left atrial volume (mean ± standard deviation) was 37 ± 11.7 ml or 21 ± 6.6 ml/m$^2$. The change in left atrial volume from end-systole to end-diastole was 24 ± 7.6 ml or 13.5 ± 4.3 ml/m$^2$, which represented 37 ± 12.9% of left ventricular stroke volume. The mean fractional emptying of the left atrium was 65 ± 8.9% and the conduit volume was 41 ± 14.0 ml or 23 ± 7.9 ml/m$^2$. These values are similar to those reported in studies in which left atrial function was calculated from contrast angiography.**

Harvey[1] first proposed that atrial function made an important contribution to ventricular filling. Although some denied this contribution,[2-4] later studies supported Harvey's proposal by demonstrating the influence of atrial function on ventricular filling and stroke volume.[5,6]

Levophase and transseptal contrast angiography have provided data about absolute left heart volumes, which were then used to determine left atrial function.[7-16] However, these techniques require cardiac catheterization, which precludes their routine clinical use. M-mode echocardiography, a noninvasive technique, has been a reliable indicator of angiographically determined left atrial size expressed as an area,[17,18] but can only imply left atrial function indirectly.[19,20] Gated radionuclide angiography also provides a noninvasive means of assessing normal left atrial function.[21] However, it provides information about relative and not absolute changes in atrial volume, and there are potential errors because of atrioventricular overlap, the technique for background correction, and the differential tissue attenuation of left atrial and ventricular photons. Bough et al[21] attempted to eliminate the last potential error by using M-mode echocardiography to determine the comparative depths of the left atrium and ventricle. Because patients are frequently referred for 2-dimensional echocardiography to assess valvular lesions or left ventricular performance, it would be preferable to derive information relating to left atrial function from these same echocardiograms rather than to perform an additional test.

Although previous studies have indicated that left atrial and left ventricular volumes measured from apical and parasternal 2-dimensional echocardiograms correlate with the respective angiographic volumes or radionuclide techniques,[22-24] routine clinical application of quantitative 2-dimensional echocardiography, a noninvasive technique, has been hampered by the lack of normal values.[25] To obtain normal values, we used this method to calculate absolute left atrial volumes. We then determined left atrial function expressed as the change in left atrial volume from end-systole to end-diastole, the ratio of this change to left ventricular stroke volume, the left atrial fractional emptying, and the left atrial conduit volume.

## Methods

Sixty-three subjects volunteered for the study. Eleven were excluded: 2 had hypertension, 2 chronic obstructive pulmonary disease, 4 mitral valve prolapse, and 3 left ventricular or atrial echocardiograms of suboptimal quality. Thus, 52 normal volunteers (29 male and 23 female) aged 20 to 66 years (mean 37 ± 11.0), none of whom had a history of cardiac disease or hypertension or any clinical evidence of cardiac abnormality, were included. The average subject's body surface area was

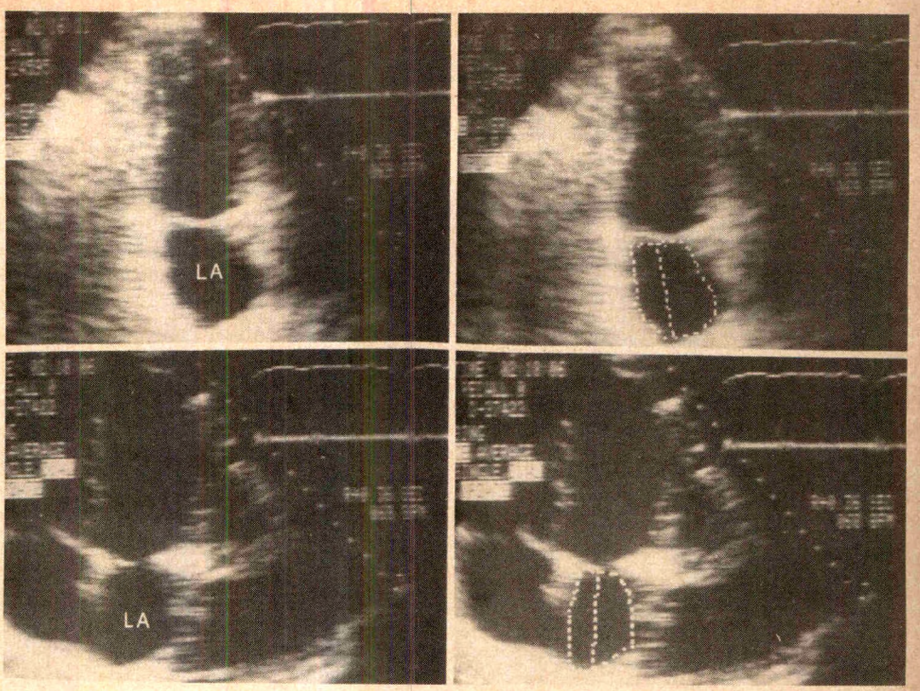

**FIGURE 1.** Determination of left atrial volumes in a normal subject from apical 2-chamber views (**above**) and 4-chamber views (**below**) at end-systole. The left atrial outlines, traced with a light pen, are **on the right.** LA = left atrium.

1.78 ± 0.21 $m^2$. Regional wall motion, wall thickness, and cardiac valves were normal as were blood pressure and the 12-lead electrocardiogram.

Two-dimensional echocardiograms were recorded with Varian 3000 or 3400 phased array 84° sector scanners and 2.25 MHz, 32 element transducers. The images were generated at 32 frames/second and recorded with standard video techniques at 64 fields/second for later playback and analysis in the stop-action mode. The 2- and 4-chamber views were used for end-systolic and end-diastolic volume measurements because they are orientated in 2 orthogonal planes. These views were obtained with the patient in the extreme left lateral recumbent position with respiration suspended at end expiration. This is important because changes in position and phase of respiration may affect the volume of the heart chambers. The transducer was angled to qualitatively maximize atrial or ventricular size separately and to obtain clear outlines of each chamber at end-systole and end-diastole. End-systole was defined by advancing the videotape, frame by frame, to obtain maximal atrial and minimal ventricular size (usually at the end of the T wave of the electrocardiogram just before the mitral valve opening). End-diastole was determined by obtaining minimal atrial and maximal ventricular size (usually at the peak of the R wave of the electrocardiogram just after closure of the mitral leaflet). After an optimal image was identified, volume measurements were repeated 3 times and averaged from a single cardiac cycle.

Left atrial volumes were obtained in the following way using a light pen digitizing and computation system controlled by a microprocessor.[26] The atrial outline was traced along the inner border of the atrial wall (Fig. 1). However, when dropout of the atrial septum occurred, the outline was completed by a straight line drawn between the 2 inner borders of the adjacent clear echoes. Instead of using the inner surface along the coapted leaflets of the mitral valve, a straight line connecting both sides of the leaflet attachments to the mitral valve anulus was taken as the border of the atrial outline. Care was taken to exclude both the pulmonary veins and the atrial appendage from the atrial perimeter. To calculate atrial end-systolic and end-diastolic volumes, a modified biplane Simpson's rule formula was used.[27] Change in left atrial volume was calculated from the difference between end-systolic and end-diastolic left atrial volume. Fractional emptying of the left atrium was then computed by dividing the change in left atrial volume by the left atrial volume at end-systole. Left atrial conduit volume was derived by subtracting the change in left atrial volume from the left ventricular stroke volume. To calculate left atrial volume, we previously determined that the intraobserver correlation and estimate of reliability was 0.95 and 3.0 ml and the interobserver correlation and estimate of reliability was 0.89 and 7.2 ml.[23]

To determine left ventricular stroke volume, 2- and 4-chamber views were obtained so that left ventricular volumes could be calculated. The plane of each of these views was chosen to maximize left ventricular size. Attempts were made to optimize visualization of the endocardium by careful transducer and gain manipulations, by changes in the angle of the subject's trunk, and by alterations in the phase of the subject's respiration. Ventricular volumes were computed in a similar manner to that described for left atrial volumes with the use of a modified Simpson's rule formula.[27] In tracing the left ventricular endocardium, minor irregularities were ignored and the papillary muscles were excluded (Fig. 2). Left ventricular stroke volume was computed from the difference between left ventricular end-diastolic and end-systolic volumes. Intraobserver variability in ventricular volume measurement in our laboratory was determined as ±4%, and correlation coefficients for measurements obtained by 2 different observers (interobserver variability) were 0.82 for end-diastolic volume, 0.95 for end-systolic volume, and 0.95 for ejection fraction.[23]

The heart rate of each subject at the time of echocardiographic study was noted. To assess whether left atrial function was influenced by heart rate, standard methods were used to compute correlation coefficients between heart rate and each of the following variables: change in left atrial volume, ratio of the change in left atrial volume to left ventricular stroke volume, fractional left atrial emptying, and conduit volume. A p value $<0.05$ was considered significant. All results are expressed as the mean value ± standard deviation.

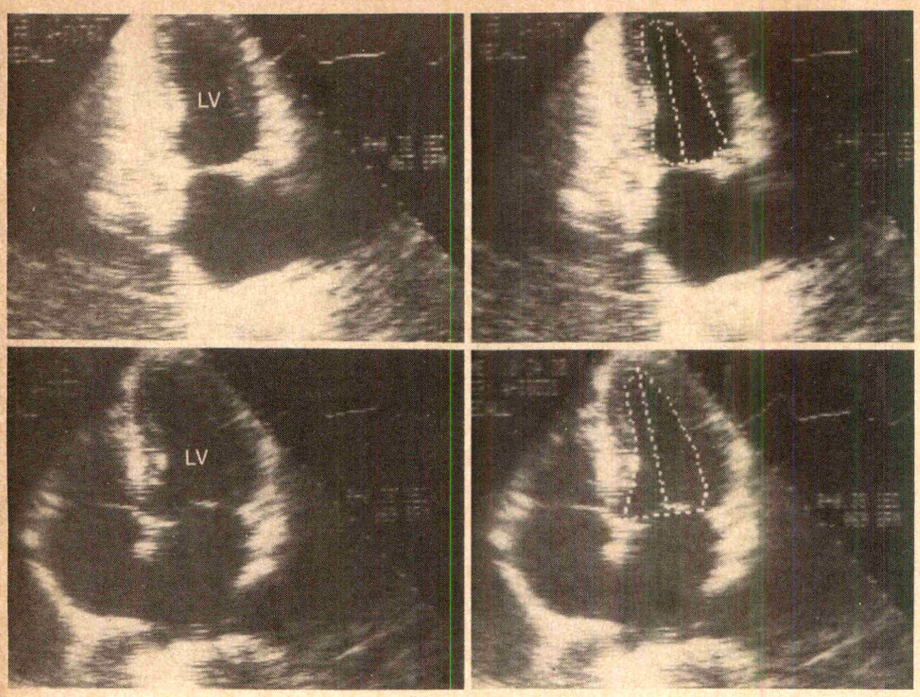

**FIGURE 2.** Determination of left ventricular volumes in a normal subject from apical 2-chamber views (**above**) and 4-chamber views (**below**) at end-systole. The outlines of the left ventricular endocardium, traced with a light pen, are **on the right.** LV = left ventricle.

## Results

The mean maximal left atrial volume (end-systolic volume) was 37 ± 11.7 ml or 21 ± 6.6 ml/m$^2$. Mean change in left atrial volume was 24 ± 7.6 ml or 13.5 ± 4.3 ml/m$^2$ and the mean fractional emptying was 65 ± 8.9% (Table I). It was determined from statistical analysis that correction for body surface area was not necessary when left atrial volume was measured in a normal population. To be complete, both values are presented here.

Mean left ventricular end-diastolic, end-systolic, and stroke volumes were 97 ± 17.8 ml or 54.5 ± 10 ml/m$^2$, 32 ± 10.7 ml or 18 ± 6 ml/m$^2$, and 65 ± 14.3 ml or 36.5 ± 8 ml/m$^2$. Thus, the change in left atrial volume was 37 ± 12.9% of left ventricular stroke volume. Mean left atrial conduit volume, calculated by subtracting the change in left atrial volume from left ventricular stroke volume, was 41 ± 14.0 ml or 23 ± 7.9 ml/m$^2$ and represented 63% of the left ventricular stroke volume.

Mean heart rate was 67 ± 11.3 beats/min (range 45 to 100). The correlation coefficient between heart rate and change in left atrial volume was 0.03, between heart rate and the ratio of the change in left atrial volume to left ventricular stroke volume 0.11, between heart rate and fractional emptying 0.21, and between heart rate and conduit volume 0.21. None of these correlations was significant.

**TABLE I Normal Values for Left Atrial Volume and Function in 52 Volunteers**

| Variable | Mean | SD | Range |
|---|---|---|---|
| LA volume at end-systole | | | |
| ml | 37 | 11.7 | 15–66 |
| ml/m$^2$ | 21 | 6.6 | |
| LA volume at end-diastole | | | |

## Discussion

**Normal values for left atrial function:** Our study provides the normal values for left atrial function in a sample population by means of 2-dimensional echocardiography (Table I). The results we obtained with echocardiography agree with those previously obtained with contrast angiography. The only exception is that our mean maximal left atrial volume (37 ml or 21 ml/m$^2$) underestimates the means derived from angiographic studies, which range from 55 to 66 ml.[7,8,13,16] However, previously reported echocardiographic determinations of left atrial and left ventricular volumes also underestimate the values obtained by angiography.[22,23] Whether the underestimation is due primarily to the angiographic or echocardiographic method is not known. The change we found in left atrial volume (24 ml or 13.5 ml/m$^2$) is similar to that documented in previous studies using contrast angiography (20 to 33 ml).[8,12,13] In addition, the mean fractional emptying value of 65% that we obtained is similar to the means

obtained from contrast angiography, which range from 37 to 75%.[7,8,13–16] In contrast, the value for fractional left atrial emptying obtained from radionuclide angiography, 39%,[21] is in the lower end of the range of these contrast angiographic studies. For the ratio between the change in left atrial volume and left ventricular stroke volume, our mean echocardiographic value (37%) was similar to the mean contrast angiographic values which ranged from 21 to 52%,[8,12–16] whereas the radionuclide measurement of 53%[21] was at the upper end of the range of these reported means.

The mean value for maximal left atrial volume that we obtained is almost identical to that calculated with a single plane formula from 2-dimensional echocardiograms.[29] This similarity occurred despite the echocardiograms being analyzed retrospectively and the transducer not being angled to maximize the left atrial dimension. However, the combination of only a 1 ml smaller maximal left atrial volume and a 3 ml larger change in left atrial volume resulted in a 10% higher value for fractional emptying than in our study. The reason for this is not apparent, but perhaps the transducer angle had a greater effect on reducing left atrial minimal volume and thus resulted in spuriously greater changes in left atrial volume.

Values for the change in left atrial volume, the ratio of the change in left atrial volume to left ventricular stroke volume, fractional emptying, and left atrial conduit volume did not correlate significantly with heart rate in our sample population. However, it may be expected that at very high heart rates, the relative contribution of left atrial conduit volume to left ventricular stroke volume would decrease, and the ratio of the change in left atrial volume to left ventricular stroke volume would approach unity.

**Limitations of the method:** Two-dimensional echocardiography may be limited by an inability to obtain adequate echocardiograms for volumetric analysis of the left ventricle and left atrium. Obtaining adequate echocardiograms relies not only on the skill and experience of the technician, but also on the physical habitus of the patient, especially the anatomic relations of the heart, lung, and chest wall. In certain subjects it may be impossible to visualize portions of the left ventricular endocardium, particularly the anterior left ventricular wall in the 2-chamber view in diastole. To overcome this limitation, we found that when the subject takes a small breath and then stops respiration, the anterior wall is more easily visualized than it is during full expiration. Although the left atrium is usually easier to outline than the endocardium of the left ventricle, dropout of the anterior atrial wall echoes in the 2-chamber view may cause errors in atrial volume measurement.

Even when adequate echocardiograms are recorded, other potential limitations are introduced because our method for determining both left atrial and ventricular volumes is time consuming and is based on certain geometric assumptions. Nevertheless, even in the presence of segmental left ventricular contraction abnormalities or left atrial enlargement, volumes calculated with Simpson's rule correlate well with left ventricular and atrial volumes from contrast angiography and radionuclide techniques.[22–24]

In contrast to left atrial and ventricular volumes, which are calculated directly, left atrial conduit volume can only be calculated indirectly from the difference between left ventricular stroke volume and the change in left atrial volume. This limitation, common to other techniques that estimate left atrial conduit volume, is due to the assumption that the left ventricular stroke volume is derived entirely from the left atrium. Obviously, the left atrial conduit volume would be overestimated in subjects with aortic regurgitation or a ventricular septal defect with a right to left shunt.

Because volumetric calculations of 2-dimensional echocardiograms require expertise and take considerable time, it may be impractical for some laboratories to obtain quantitative data for routine clinical use. To overcome these limitations, computerized technology[30,31] may decrease the time commitment that is necessary at present and may permit routine clinical use of 2-dimensional echocardiography to assess left atrial function.

**Clinical applications:** The relative importance and contribution of left atrial function vary in different disease states. These variations may become useful in distinguishing pericardial constriction from pericardial effusion, chronic from acute mitral regurgitation, predominantly mitral from predominantly aortic regurgitation, and predominantly mitral stenosis from predominantly mitral regurgitation. For example, in patients with pericardial constriction, fractional emptying of the left atrium is less than that in patients with pericardial effusions and in normal subjects.[7] Patients with chronic mitral regurgitation not only have an enlarged left atrium but also have large changes in left atrial volume[8,9] which correlate with the severity of chronic regurgitation.[10] Furthermore, patients with chronic mitral regurgitation have a larger left atrial volume and a greater change in left atrial volume than do patients with acute mitral regurgitation.[8] In contrast to patients with mitral regurgitation, patients with aortic regurgitation have low values for the change in left atrial volume relative to left ventricular stroke volume.[8] Also, patients with mitral stenosis have a lower change in left atrial volume than do patients with mitral regurgitation.[10] Calculation of left atrial function may not only be important in assessing pericardial and mitral and aortic valvular disease, but may also be clinically useful in patients with left ventricular abnormalities, such as left ventricular hypertrophy, in which altered ventricular compliance may affect left atrial emptying.

# Myocardial Function in Rocky Mountain Spotted Fever: Echocardiographic Assessment

JOSÉ MARIN-GARCIA, MD and FRED F. BARRETT, MD

**Nine patients with Rocky Mountain spotted fever underwent M-mode echocardiographic examination. Increased left ventricular dimension was found in 2 patients and decreased left ventricular shortening fraction in 7. Diminished mean velocity of circumferential fiber shortening, increased left ventricular systolic time intervals ratio, and increased mitral valve E point to ventricular septal separation were found in 6 patients. One patient died and at necropsy diffuse myocarditis was present. Repeat echocardiographic examination was available in the remaining 8 patients at follow-up (mean 10 months). Abnormal E mitral point to ventricular septal separation remained in 3 patients and decreased left ventricular shortening fraction in 2; in 1 there was also increased left ventricular end-diastolic dimension. Thus abnormal left ventricular function and chamber enlargement are frequently present in patients with Rocky Mountain spotted fever.**

Rocky Mountain spotted fever is a serious infectious disease that continues to occur in various areas of the United States. Over 1,000 cases were reported to the Center for Disease Control in 1980,[1] and a high case-fatality ratio (7 to 11%) persists despite the availability of adequate chemotherapeutic agents (tetracycline and chloramphenicol). Although data are available regarding the clinical and anatomic cardiac manifestations of Rocky Mountain spotted fever,[2,3] the effect of the disease on myocardial function has not been reported. Thus, a prospective analysis of the echocardiographic findings in patients with Rocky Mountain spotted fever was undertaken.

## Methods

From 1980 to 1982, 9 consecutive, unselected children—5 girls and 4 boys with an average age of 8.25 years (range 4 to 14)—were admitted to a children's hospital with clinical evidence of Rocky Mountain spotted fever. The criteria for diagnosis were similar to those previously reported[3] and are presented in Table I.

From the Department of Pediatrics, University of Tennessee Center for the Health Sciences and Le Bonheur Children's Medical Center, Memphis, Tennessee. Manuscript received May 17, 1982; revised manuscript received August 19, 1982; accepted August 20, 1982.

Address for reprints: José Marin-Garcia, MD, Section of Pediatric Cardiology, Department of Pediatrics, Le Bonheur Children's Medical Center, 1 Children's Plaza, Memphis, Tennessee 38103.

One patient died and necropsy examination was performed. Clinical, electrocardiographic, and radiologic data were available for study in each patient. M-mode echocardiograms were obtained at the time of admission in each patient and at late follow-up (mean 10 months) in 8 survivors. Normal control subjects were 15 boys and 10 girls with body surface areas similar to that of the study subjects. Echocardiograms were recorded with a Hoffrel 101 ultrasonoscope with use of either a 3.5 or 5 MHz nonfocused transducer. Left ventricular end-diastolic dimension (LVEDD), left ventricular end-systolic dimension (LVESD), left ventricular shortening fraction (LVSF), mean velocity of circumferential fiber shortening (VCF), and left ventricular preejection period to left ventricular ejection time ratio (LPEP/LVET) were measured using standard techniques.[4,5] E mitral point to ventricular septal separation (EPSS) was measured as previously reported by Massie et al.[6] Statistical analysis of data for EPSS and LVSF in the studied subjects and control group was done by contigency table analysis. Results are expressed as mean ± standard deviation.

## Results

*Clinical cardiac data:* Inappropriate sinus tachycardia for the degree of fever was present in all but 1 patient (Case 2) and gallop rhythm in 2 (Cases 2 and 6). A precordial murmur (grade 2/6 holosystolic) was heard in 3 patients (Cases 2, 6, and 8). Cardiac enlargement by radiogram was present in 2 patients (Cases 7 and 9). First degree atrioventricular block was present in 3 patients (Cases 1, 5, and 7), and left ventricular hyper-

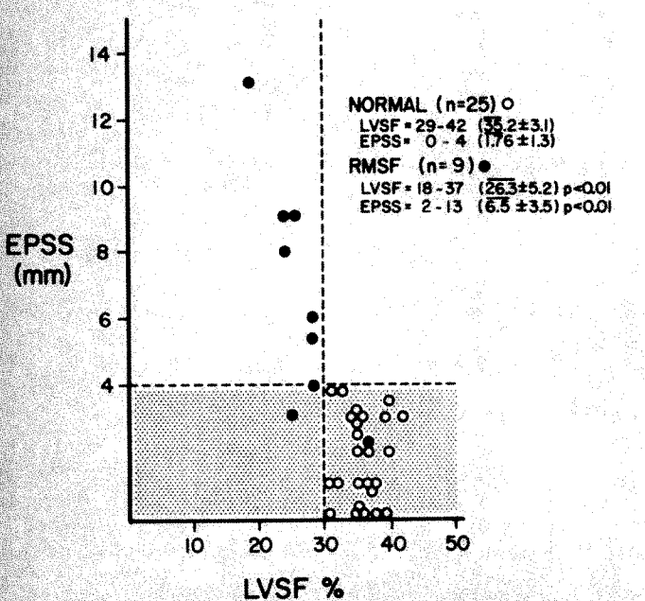

**FIGURE 1.** Comparison of mitral valve E point to ventricular septal separation (EPSS) and left ventricular shortening fraction (LVSF) in patients with Rocky Mountain spotted fever (RMSF) (**closed circles**) and normal subjects (**open circles**).

trophy in 1 (Case 2). Echocardiographic findings are presented in Table II. Data on left ventricular dimension was subdivided into 2 sections according to the body surface area. Comparison of EPSS and LVSF shows a significant difference between study and control subjects (Fig. 1).

In 2 cases (Patients 4 and 5) abnormal echocardiographic findings were the presenting manifestation before any clinical sign of cardiac involvement was detected. In the fatal case, myocarditis in combination with diffuse vasculitis and left ventricular enlargement was found at autopsy.

Follow-up echocardiograms (Table II) revealed decreased LVSF and LVEF in Patients 2 and 4; the latter also showed residual left ventricular enlargement and increased LPEP/LVET ratio. Although EPSS decreased in most patients, it was still abnormal at follow-up in 3 patients (Cases 2, 4, and 5).

## Discussion

Rocky Mountain spotted fever is an acute, potentially lethal illness caused by Rickettsia rickettsii and transmitted by ticks. The disease is characterized by generalized vasculitis involving many organs and systems.

Myocarditis and multifocal myocardial necrosis are frequently present, and this may play a significant role in the final outcome of some cases. Although a definitive diagnosis of myocardial disease can be made only after histologic examination of the myocardium, echocardiography offers a reliable way to evaluate chamber dimensions as well as myocardial performance in this disease. Inappropriate sinus tachycardia for the degree of fever was a common finding in our cases; nevertheless, variables such as LVSF, LPEP/LVET, and EPSS are not influenced by a wide variation in heart rate. On admission, left ventricular enlargement was found in 2 patients and abnormal left ventricular dimension remained in 1. LVSF was reduced at initial evaluation in 7 cases and remained abnormally low at late follow-up in 2. EPSS, a qualitative index of left ventricular ejection fraction, was abnormally elevated on admission in 6 cases and remained abnormal in 3. Although there has been some controversy as to whether EPSS is independent of left ventricular size, in our experience as well in others[7] increased left ventricular dimension does not affect EPSS unless depressed left ventricular function was also present. This variable appears to be an adequate index of depressed left ventricular ejection independent of the size of the chamber, in the absence of mitral valve stenosis or aortic valve regurgitation.

Although quantification of left ventricular dysfunction may not influence management in Rocky Mountain spotted fever it appears useful in identifying the patient with severe illness. The degree of left ventricular impairment correlated with the severity of the illness in all but Patients 2 and 5. These patients had substantial left ventricular dysfunction but only mild illness with normal or mildly decreased serum sodium and platelet levels. On the other hand, and except in patient 5, the severity of left ventricular dysfunction on admission correlated with the presence of residual abnormalities at follow-up. Patients 3, 6, and 9 had mild reduction of left ventricular function and no abnormalities were present at follow-up; Patients 2 and 4 presented with significant left ventricular dysfunction and residual abnormalities persisted.

The clinical recognition of myocardial involvement in Rocky Mountain spotted fever may be delayed if a high index of suspicion is not maintained. The initial echocardiogram in Patients 4 and 5 showed abnormal left ventricular performance before any clinical sign of cardiac involvement was detected. These findings suggest that myocardial dysfunction may be present early in the disease and it may require a variable length of time to manifest itself clinically. Thus, besides clinical examination and electrocardiography, echocardiography might be necessary if early identification of myocardial involvement is to be achieved. Although most patients recovered and the initial clinical manifestations disappeared, residual echocardiographic abnormalities suggests chronic disturbance in left ventricular function in some cases. The long-term prognosis for this group is unknown. In patients with Rocky Mountain spotted fever, close monitoring and aggressive therapeutic approach are essential if the high case fatality ratio is to be reduced. Treatment with tetracycline or chloramphenicol must be initiated before serologic confirmation.

# Mechanisms for Decreased Exercise Capacity After Bed Rest in Normal Middle-Aged Men

JOSEPH HUNG, MB, BS, FRACP, DANIELLE GOLDWATER, MD, VICTOR A. CONVERTINO, PhD, JAMES H. McKILLOP, MB, BS, PhD, MICHAEL L. GORIS, MD, PhD, and ROBERT F. DeBUSK, MD

**The mechanisms responsible for the decrease in exercise capacity after bed rest were assessed in 12 apparently healthy men aged 50 ± 4 years who underwent equilibrium gated blood pool scintigraphy during supine and upright multistage bicycle ergometry before and after 10 days of bed rest. After bed rest, echocardiographically measured supine resting left ventricular end-diastolic volume decreased by 16% ($p < 0.05$). Peak oxygen uptake during *supine* effort after bed rest was diminished by 6% (p = not significant [NS]), whereas peak oxygen uptake during *upright* effort declined by 15% ($p < 0.05$). After bed rest, increases in heart rate were also greater during exercise in the upright than in the supine position ($p < 0.05$). Values of left ventricular ejection fraction increased normally during both supine and upright effort after bed rest and were higher than corresponding values before bed rest ($p < 0.05$). After bed rest, increased left ventricular ejection fraction and heart rate largely compensated for the reduced cardiac volume during supine effort, but these mechanisms were insufficient to maintain oxygen transport capacity at levels during upright effort before bed rest. These results indicate that orthostatically induced cardiac underfilling, not physical deconditioning or left ventricular dysfunction, is the major cause of reduced effort tolerance after 10 days of bed rest in normal middle-aged men.**

Bed rest contributes to reduced physical working capacity of patients after myocardial infarction.[1–3] To develop effective strategies against bed rest deconditioning it is important to characterize those factors that contribute to a reduced functional capacity after prolonged bed rest. We previously found in normal middle-aged men that peak oxygen transport capacity ($VO_2$ max) declined more significantly during upright than supine exercise after 10 days of bed rest.[4] This finding indicated that orthostatic factors played an important role in the decline in exercise capacity of these subjects after bed rest. Previous investigations of the effects of bed rest,[5–9] including the classic work of Saltin et al in 1968,[10] have been limited to young persons aged 19 to 25 years whose responses to bed rest may differ significantly from those of older persons who are at risk for myocardial infarction. Saltin et al found a decrease in exercise stroke volume during supine as well as upright effort after bed rest.[10] Because this finding could not be accounted for by orthostatic factors, these investigators suggested that prolonged bed rest adversely affects ventricular function. To evaluate this problem, we measured left ventricular function with radionuclide angiography in the same normal middle-aged men as in our previous report and compared their cardiovascular and left ventricular functional responses with upright and supine effort before and after 10 days of bed rest.

## Methods

The 12 apparently healthy male subjects of the present report, aged 45 to 55 years, were previously described.[4] Significant abnormalities were excluded by a screening evaluation consisting of a detailed history, physical examination, complete blood count, urinary analysis, chest X-ray, resting electrocardiogram, maximal bicycle exercise test, and a chemistry panel consisting of measurements of fasting glucose, serum electrolytes, uric acid, cholesterol, calcium, phosphate,

and renal and liver function tests. Screening exercise testing was performed with the patient in the upright position on a Monark bicycle ergometer, the initial work load of 30 W increasing in 30-W increments every 3 minutes until voluntary physical exhaustion. Resting 12-lead electrocardiograms were normal in all 12 subjects and no chest discomfort, ischemic S-T segment depression, or significant ventricular arrhythmias were noted during or after the screening exercise test. The 12 subjects aged 50 ± 4 years gave written informed consent to participate as paid volunteers for the 15-day study. No subject was taking medication at the time of the study. Subjects were not allowed to smoke during the study or within 2 weeks before the start of the study.

The study group of 12 subjects was admitted to the Clinical Research Center of the Stanford University Hospital. During a 4-day ambulatory control period, subjects underwent M-mode echocardiographic imaging of the heart during supine rest. On the morning of the second day before bed rest, subjects performed 1 supine and 1 upright maximal exercise test on a bicycle ergometer. The 2 tests were separated by a 60-minute rest period. Six subjects were randomly assigned to perform supine exercise initially and 6 performed upright exercise initially. The same sequence was retained during testing after bed rest.

Supine and upright exercise testing consisted of 4 uninterrupted stages (I, II, III, and IV [maximum]) of exercise approximating 20, 45, 70, and 100% of the work loads utilized during the prehospital screening evaluation. Absolute work loads for these 4 stages were 250 ± 73, 525 ± 121, 835 ± 135, and 1,156 ± 194 kg/min, respectively. The same work loads, which were performed before and after bed rest, were designed to produce exhaustion during the 12 minutes available for radionuclide imaging of left ventricular function during exercise.

Upright testing was performed on a Schwinn electrically braked bicycle ergometer and supine exercise testing on a padded table with a Collins electrically braked bicycle ergometer. The physiologic comparability of work loads provided by these 2 ergometers were checked by $VO_2$ measurement before bed rest in these same 12 subjects. Oxygen uptake and heart rate were measured during the last 30 seconds of each work load. Heart rate was counted from an electrocardiographic record. Subjects used a Daniels respiratory valve and the volume of expired gas was measured with a Parkinson-Cowan high velocity low resistance meter. The composition of the expired air was determined by a Beckman E2 oxygen analyzer and a Godard capnograph carbon dioxide oxygen analyzer.

Equilibrium-gated cardiac blood pool scintigraphy was also performed during supine and upright exercise testing in 10 of the 12 subjects. Problems with computer acquisition prevented radionuclide data collection in the other 2 subjects. In vivo red cell labeling was achieved using the method of Pavel et al[11]; 15 mg of cold stannous pyrophosphate was injected intravenously, followed 30 minutes later by an intravenous injection of 20 to 25 mCi of technetium-99m pertechnetate. A gamma camera (Ohio Nuclear Series 120), fitted with a parallel hole, high resolution collimator, was positioned against the left chest wall for ideal separation of right and left ventricles in the left anterior oblique projection. For count data acquisition, the gamma camera was interfaced with an Informatek Simis IV computer. Radionuclide data were collected with the patient lying on the exercise table or sitting upright at rest on the bicycle for 4 minutes and during ≤12 minutes of graded bicycle ergometry.

All studies were subsequently analyzed automatically, that is, without operator intervention, using a previously reported series of algorithms.[12,13] The first step in processing was to combine the data from individual minutes at rest or at the same exercise level. All subjects completed 3 minutes of stage III exercise, during which values of heart rate averaged 88% of peak heart rate. Radionuclide data were omitted for stage IV (max) effort because an insufficient percentage of subjects (58%) was able to sustain exercise for up to 3 minutes of this peak work level both before and after bed rest. Subtraction of noncardiac background activity was achieved by a threshold technique.[12] Motion and phase analysis and edge detection algorithms were then used for automatic identification of the left ventricular end-diastolic region of interest.[13] The left ventricular time-activity curve was then obtained from this region and left ventricular ejection fraction was calculated from the standard formula: Ejection fraction = (end-diastolic counts − end-systolic counts)/end-diastolic counts.

Observer variability in the determination of ejection fraction was essentially removed because the studies were analyzed without operator intervention. Left ventricular stroke counts (end-diastolic − end-systolic counts), being the count correlates of stroke volume, were used to measure *relative* changes in left ventricular stroke volumes from rest to exercise during each study. Regional left ventricular function was assessed by analysis of wall motion: from static display of superimposed end-diastolic and end-systolic variables and regional ejection fraction images.

During the 10 days of bed rest, the subjects remained in the horizontal position continuously. M-mode echocardiographic imaging of the heart was repeated in the supine position 1 day before the end of bed rest. On the morning of the 10th day of bed rest, subjects repeated the same sequence of upright and supine exercise testing that they had undergone before bed rest. Before performing upright exercise, subjects sat on the exercise table with their legs dangling while blood pressure and heart rate stabilized. The interval between assumption of the sitting posture and the beginning of upright exercise averaged 17 ± 10 minutes. Initial orthostatic hypotension was often observed but no subject experienced syncope before upright exercise. No significant complications were noted during or after exercise testing.

**Statistical analysis:** The effects of test order, supine or upright position, and bed rest were tested using analysis of variance. If significance was found, paired $t$ testing was utilized for paired comparisons. Differences were considered significant for p values $<0.05$.

## Results

Test order did not have a statistically significant effect on values of oxygen uptake, heart rate, systolic blood pressure, or heart rate-systolic pressure product before and after bed rest.

**Effects of bed rest on cardiac volume:** Left ventricular end-diastolic volume measured echocardiographically in the supine position decreased 16%, from a baseline mean value of 121 ± 7 ml to 100 ± 9 ml after bed rest ($p < 0.05$).

**Effects of bed rest on oxygen uptake and exercise hemodynamics:** Values of oxygen uptake during all levels of submaximal and peak upright effort were significantly lower after bed rest and the decrease in oxygen uptake was significantly greater than during supine effort ($p < 0.05$, Fig. 1). Values of oxygen uptake during peak *upright* effort decreased by 15.1% from values before bed rest (21.9 ± 4.3 versus 25.8 ± 5.2 ml/kg/min, $p < 0.05$), whereas oxygen uptake during peak *supine* exercise after bed rest decreased only 6.1% (23.1 ± 4.7 versus 24.6 ± 5.1 ml/kg/min, respectively, NS). During

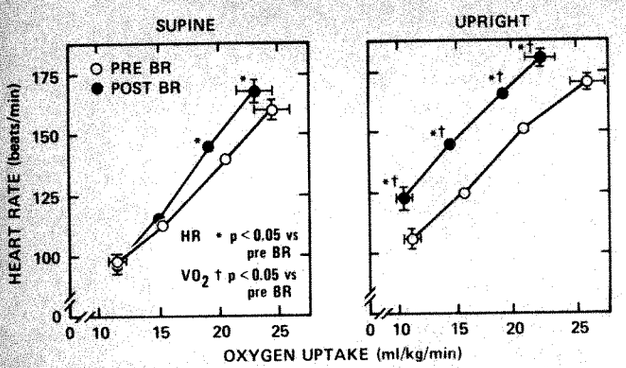

**FIGURE 1.** Changes in heart rate and oxygen uptake induced by bed rest. Values expressed are mean ± standard error of the mean. HR = heart rate; POST BR = after bed rest; PRE BR = before bed rest; $VO_2$ = oxygen uptake.

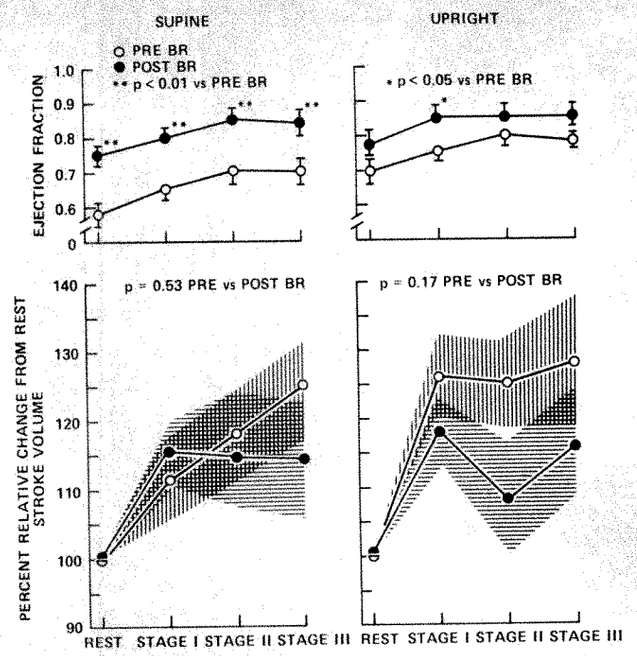

**FIGURE 2.** Changes induced by bed rest in left ventricular ejection fraction and stroke volume during rest and stages I to III of exercise. Values expressed are mean ± standard error of the mean. POST BR = after bed rest; PRE BR = before bed rest.

submaximal and peak upright effort after bed rest, heart rates were 10 to 21 beats/min higher than before bed rest ($p < 0.05$) (Fig. 1). In contrast, during supine effort after bed rest, heart rates were significantly augmented only during the last submaximal and peak work levels, by 5 and 8 beats/min, respectively ($p < 0.05$). Systolic blood pressures measured in either position were not significantly different after bed rest. Because of the augmentation of heart rate, the rate-pressure products during all levels of submaximal upright effort and during stage III of supine effort were increased after bed rest ($p < 0.05$). After bed rest, the rate-pressure products at all levels of submaximal upright effort were significantly higher than during submaximal supine effort ($p < 0.05$).

**Effect of bed rest on left ventricular function:** Before and after bed rest values of left ventricular ejection fraction at supine rest and during supine exercise were higher when the supine test was performed second than when it was performed first ($p < 0.01$). The test order did not significantly influence values of ejection fraction measured at upright rest or during upright effort.

Before bed rest the mean left ventricular ejection fraction at rest was lower in the supine than in the upright position (0.58, range 0.42 to 0.72 versus 0.69, range 0.53 to 0.84, respectively [$p < 0.01$]). In 3 subjects, values of left ventricular ejection fraction were <0.50 at supine rest. All subjects had values of ejection fraction >0.50 at upright rest and none demonstrated regional contraction abnormalities in either position. Left ventricular ejection fraction increased significantly between rest and stage III exercise: from 0.58 ± 0.11 to 0.70 ± 0.13 ($p < 0.001$) in the supine position and from 0.69 ± 0.10 to 0.78 ± 0.05 ($p < 0.001$) in the upright position. Only 1 subject failed to show a ≥0.05 increase in ejection fraction during stage III exercise: from 0.62 to 0.63 during supine effort and from 0.70 to 0.74 during upright exercise.

Values of rest and exercise left ventricular ejection fraction increased after bed rest: to 0.75 ± 0.08 and 0.77 ± 0.13 during supine and upright rest, respectively, and 0.84 ± 0.12 and 0.85 ± 0.11 during stage III supine and upright effort, respectively (Fig. 2, top). The higher values of ejection fraction after bed rest were significant at rest and during all levels of submaximal supine effort ($p < 0.01$). Values of left ventricular ejection fraction in the upright position increased after bed rest but these changes were statistically significant only at the stage I exercise level ($p < 0.05$). However, values of rest and exercise left ventricular ejection fractions were already significantly higher in the upright than supine position before bed rest ($p < 0.01$). Regional contraction abnormalities were not observed during supine or upright effort before or after bed rest.

Left ventricular end-systolic volume decreased normally ($p < 0.05$) during supine and upright exercise before and after bed rest. The augmentation of left ventricular stroke volume with exercise tended to be lower after bed rest than before—especially in the upright position (Fig. 2, bottom): The increase in left ventricular stroke volume at stage III effort was 125 ± 25% and 127 ± 26% of resting values during supine and upright effort, respectively, before bed rest versus 114 ± 29% and 116 ± 19%, respectively, during effort after bed rest (NS).

## Discussion

A decrease in physical working capacity in the supine position reflects central (cardiac) and peripheral (circulatory and musculoskeletal) deconditioning effects of bed rest, whereas a further decrease in physical working capacity in the upright position reflects the additional influence of orthostatic stress.

The exact mechanisms and the extent of their contribution to the decrease in exercise capacity after bed rest have not been fully defined in previous studies, because left ventricular function has not been measured, and the effects of bed rest on the cardiovascular responses to upright and supine exercise have not been directly compared in the same subjects as in the present study. For example, in the study by Saltin et al,[10] supine effort was performed on a bicycle ergometer and was submaximal whereas upright effort was performed on a treadmill and was maximal.

The extent of physical deconditioning in our normal middle-aged subjects was small, as evidenced by the small nonsignificant decrease in peak oxygen uptake during supine effort after bed rest. The 6% decrease in $VO_2$ max seen in our subjects was lower than the 9 to 13% decrease reported previously in young subjects during supine effort after 2 to 4 weeks of bed rest.[5–7] This may partially reflect the longer duration of bed rest in these studies as well as the fact that younger subjects are likely to be more athletically conditioned beforehand and thus subject to greater physical deconditioning. In other studies of young subjects, decreases in $VO_2$ max of 28% and 22% have been observed during upright effort after a similar duration of bed rest[9,10] and this decrease appears substantially larger than that measured during supine effort after bed rest. In the present study, we found that the decrease in peak oxygen uptake during upright effort was 2.5 times as large as that seen during supine effort after 10 days of bed rest. This finding suggests the importance of orthostatic factors.

Because Saltin et al noted a reduction in rest and exercise stroke volume even in the supine position, which could not be attributed to impairment of venous return as in the upright position, these authors postulated that bed rest might adversely affect myocardial function.[10] Blood volume decreases as much as 600 to 700 ml after 1 or more weeks of enforced immobilization.[6,10,14] In fact, in our subjects we found that echocardiographically measured left ventricular end-diastolic volume diminished 16% in the supine position and presumably more in the upright position, although this was not measured. Saltin and other investigators[10,14] have also found on chest radiography a substantial decrease in total heart volume during prolonged bed rest. Although venous return is facilitated in the supine position, a diminished volume may contribute to the decrease in stroke volume, peak cardiac output, and $VO_2$ max even during supine exercise. This decrease in cardiac volume is likely to be greater in young, athletically conditioned subjects. For example, in the study of Saltin et al the 2 subjects who were best conditioned before bed rest had the highest absolute values of heart volume and the greatest absolute decrease in heart volume after bed rest. In our middle-aged subjects we found no evidence for an adverse effect of bed rest on left ventricular function: Left ventricular ejection fraction was augmented during supine and upright exercise testing after bed rest. The augmentation of both left ventricular ejection fraction and exercise heart rate appeared to be compensatory mechanisms for a lower cardiac volume (preload) after bed rest. During supine effort after bed rest, these compensatory mechanisms appeared to be largely adequate because peak oxygen uptake did not decline significantly.

However, hypovolemia leads to even greater cardiac underfilling in the upright position because another 300 to 800 ml of blood is sequestered in the legs[15,16] and this orthostatic stress may be further accentuated after bed rest.[17] Even before bed rest, levels of heart rate and left ventricular ejection fraction in our subjects were higher at upright rest than at supine rest. We attribute this to a normal increase in sympathetic nervous activity in response to orthostatic stress.[17] After bed rest, values of ejection fraction at upright rest were even closer to their physiologic maximum, thus limiting the extent to which a further increase in left ventricular ejection fraction during upright effort could contribute to sustaining stroke volume. Thus, despite augmentation of their left ventricular ejection fraction and heart rate to levels equal to or exceeding those during supine exercise, our subjects were unable to compensate for cardiac underfilling and their $VO_2$ max decreased 15% after bed rest. The importance of orthostatic factors is underscored in the recent study by Convertino et al.[18] These investigators measured a 14% decrease in $VO_2$ max during upright bicycle effort in subjects after 14 days of bed rest but only a 5% decrease in subjects exposed to a reverse gradient garment simulating the effects of standing for 3 hours/day during this interval. Exposure to orthostatic effects also partially reversed the loss of plasma volume associated with bed rest.[18]

**Clinical implications:** Although our normal subjects manifested no deterioration in cardiac function, bed rest resulted in an augmented heart rate and rate-pressure product during submaximal effort. These factors are associated with increased myocardial oxygen demands[19,20] which are potentially hazardous to patients with coronary heart disease, especially those recovering from myocardial infarction. The findings of the present study indicate that these adverse effects of bed rest deconditioning can be largely obviated by early exposure to gravitational stress. This underscores the importance of sitting and of early ambulation in preventing or limiting unnecessary physical debility after myocardial infarction. Formal programs of in-hospital rehabilitation emphasizing exercise training may not be necessary for this purpose.

# Cardiac Performance in Thyrotoxicosis: Analysis of 10 Untreated Patients

ABDULMASSIH S. ISKANDRIAN, MD, LESLIE ROSE, MD, A-HAMID HAKKI, MD, BERNARD L. SEGAL, MD, and SALLY A. KANE, RN

**This study attempts to define cardiac performance at rest and during exercise in patients with untreated thyrotoxicosis. We studied 7 women and 3 men, aged 23 to 59 years (40 ± 10, mean ± standard deviation [SD]) and compared the results with those obtained in 12 normal subjects. In patients with thyrotoxicosis, the rhythm was sinus and the only untoward symptom was palpitations; the resting electrocardiographic results were normal in 8 patients and showed left ventricular hypertrophy in 2 patients; the left ventricular ejection fraction and volumes (measured by radionuclide ventriculography) were normal at rest. During exercise, 1 patient had dyspnea and 7 had leg fatigue; 2 were asymptomatic. Also, 7 patients had ≥5% increase in left ventricular ejection fraction, 2 had no change, and 1 had a decrease. In all 10 patients, the exercise ejection fraction was ≥60%. All normal subjects had a ≥5% increase in ejection fraction during exercise. There were no significant differences at rest between patients with thyrotoxicosis and normal subjects in blood pressure, ejection fraction, end-diastolic volume, stroke volume, end-systolic volume, or cardiac output, but the heart rate was significantly higher in patients with thyrotoxicosis (91 ± 10 versus 80 ± 12 beats/min, p <0.05). During exercise, there were no significant differences between patients with thyrotoxicosis and normal subjects in blood pressure, end-diastolic volume, stroke volume, end-systolic volume, or cardiac output. The exercise ejection fraction was significantly lower in patients with thyrotoxicosis than in normal subjects (68 ± 10% versus 75 ± 4%, p <0.05). *Cardiac performance is normal at rest in patients with thyrotoxicosis, but during exercise abnormal left ventricular reserve occurs in some patients.***

Thyroid hormones have profound effects on the metabolism of all tissues of the body, including the heart.[1,2] Thyrotoxicosis is more common in women than in men. Palpitations, dyspnea, tachycardia, and an increase in systolic pressure occur in approximately 30% of these patients. Also, many patients have an increase in the cardiac index, systolic ejection rate, coronary blood flow, and pulse pressure, but a decrease in systemic vascular resistance as well as in the systolic ejection and preejection periods.[3–10] The cardiac changes might be partly due to an increase in metabolic demand caused by the peripheral effects of thyroid hormones, but the cardiac output has been reported to be greater than the total body oxygen consumption, indicating some direct action on the heart as well. Atrial fibrillation might be seen in some patients.

The effects of thyroid hormones on the heart are either direct or indirect. The direct effects are complex and may include increased synthesis of myosin as well as alteration of the structure of myosin, such that the new myosin has better contractile properties.[11–14] Thyroid hormones are also known to enhance the enzymatic activity of the myocardium. The indirect effects are due either to increased activity of the sympathoadrenal system or enhanced cardiac response to normal sympathetic stimulation. Thus, tachycardia and the increase in cardiac output and contractility can be reduced by beta-adrenergic blocking agents.[15,16] The presence of low or normal levels of norepinephrine, epinephrine, and dopamine beta hydroxylase in the plasma and urine suggests that the function of the

sympathoadrenal system is probably not altered in these patients.[17]

To date, little has been reported concerning cardiac performance in patients with hyperthyroidism, especially during exercise.[18–20] This study evaluates cardiac peformance at rest and during upright exercise in 10 patients with untreated thyrotoxicosis.

## Methods

**Patient population:** The patient population consisted of 7 women and 3 men aged 23 to 59 years (mean ± SD 40 ± 10). The diagnosis of Graves disease with hyperthyroidism was confirmed by appropriate laboratory tests (Table I). The duration of symptoms was 3 to 6 months in all patients. No patient had noticeable weight loss. The rhythm was normal sinus in all patients. The only symptom in these patients was palpitations. Four patients (Patients 5, 6, 9, and 10) had been receiving small doses of propranolol (10 mg 4 times daily) for approximately 7 days; this was discontinued 1 day before the exercise studies. No patient had a known history of heart disease, specifically angina pectoris or dyspnea. The electrocardiographic results were normal in 8 patients but showed left ventricular hypertrophy in 2. The criteria for left ventricular hypertrophy were those of Romhilt and Estes[21] and were based upon a "point score" system. A minimal score of 6 points was needed to define left ventricular hypertrophy.

All patients underwent symptom-limited upright exercise testing on a bicycle ergometer (Quinton Instruments). The electrocardiograms (leads aVF and $V_5$) were continuously monitored, and blood pressure was measured every 2 minutes during exercise and recovery. The initial work load was 200 kpm/min and was increased by 100 kpm/min every 2 minutes until the endpoints of exercise, which in these patients were dyspnea (1 patient) and leg fatique (7 patients); the remaining 2 patients stopped the exercise because they achieved the target heart rate without symptoms.

Radionuclide ventriculograms at rest and during peak exercise were obtained with a computerized multicrystal gamma camera (Baird-Atomic System-77). The left ventricular ejection fraction, end-diastolic volume, end-systolic volume, stroke volume, and cardiac output were measured according to the method described previously.[22,23] Previous studies from this laboratory have shown excellent correlation between left ventricular ejection fraction, end-diastolic volume, and end-systolic volume measured with radionuclide ventriculography compared with similar measurements obtained by contrast angiography.[22]

The results in the study patients were compared with those obtained in 12 normal subjects who were evaluated for nonspecific chest pain and were found, upon cardiac catheterization, to have normal resting hemodynamics, normal left ventriculograms, and normal coronary angiograms. The age range in the normal subjects was 25 to 45 years (mean ± SD 38 ± 7).

**Statistical analysis:** The paired Student's $t$ test was used to compare differences in individual measurements at rest and during exercise in each group. Significance of differences between the groups was obtained using the unpaired $t$ test. A probability value of $<0.05$ was considered significant.

## Results

**Normal subjects:** The ejection fraction at rest was normal and increased during exercise by at least 5% in all subjects. During exercise, there was a significant increase in heart rate, systolic blood pressure, stroke volume, and cardiac output, but no significant change in diastolic blood pressure, end-diastolic volume, or end-systolic volume (Table II). The end-systolic volume in some normal subjects during exercise was greater than the end-systolic volume at rest. However, in these patients, the increase in end-diastolic volume was greater during exercise, resulting in a higher stroke volume and ejection fraction.

* Volumes at rest were not measured in this patient. BP = blood pressure (systolic and diastolic in mm Hg); BSA = body surface area ($m^2$); CO = cardiac output (liters/min); ECG = electrocardiogram; EDV = end-diastolic volume (ml); EF = left ventricular ejection fraction; ESV = end-systolic volume (ml); Ex = exercise; HR = heart rate (beat/min); LVH = left ventricular hypertrophy; NL = normal; P = propranolol; Pt = patient; R = rest; SV = stroke volume (ml); . . . = none.

**Patients with thyrotoxicosis:** Resting sinus tachycardia, as expected, was common. The systolic and diastolic blood pressure values were normal in all patients. The resting left ventricular ejection fraction and volumes were also normal. Four patients had high resting cardiac output levels (cardiac index ≥4.5 liters/min/$m^2$); in the remaining patients the cardiac output was normal (Table III).

During exercise, 7 patients had leg fatigue; 2 had no symptoms (Patients 8 and 10); Patient 9 had dyspnea. The exercise electrocardiographic results were normal in all patients.

The left ventricular ejection fraction during exercise was normal (≥60%) in all patients. Seven patients had a ≥5% increase in ejection fraction with exercise. In 2 patients, there was no change in ejection fraction with exercise (Patients 2 and 7); 1 patient (Case 8) had a decrease in ejection fraction with exercise. As a group, there were no significant changes in the end-diastolic and end-systolic volumes during exercise. Four patients had an increase in end-systolic volume with exercise (Patients 2, 4, 7, and 8). Three of the 4 patients also showed either no change or a decrease in ejection fraction with exercise; in the remaining patient, the ejection fraction increased with exercise (Table II).

**Correlation between normal subjects and patients with thyrotoxicosis:** At rest, there were no significant differences between the normal subjects and patients with thyrotoxicosis in systolic blood pressure, diastolic blood pressure, ejection fraction, end-diastolic volume, stroke volume, end-systolic volume, or cardiac output. The heart rate at rest was significantly higher in patients with thyrotoxicosis ($p < 0.05$) (Table II). During exercise, there were no significant differences in normal subjects and patients with thyrotoxicosis in heart rate, systolic blood pressure, diastolic blood pressure, end-diastolic volume, end-systolic volume, stroke volume, or exercise duration. The ejection fraction during exercise was significantly higher in normal subjects than in those with thyrotoxicosis ($p < 0.05$) (Table II).

## Discussion

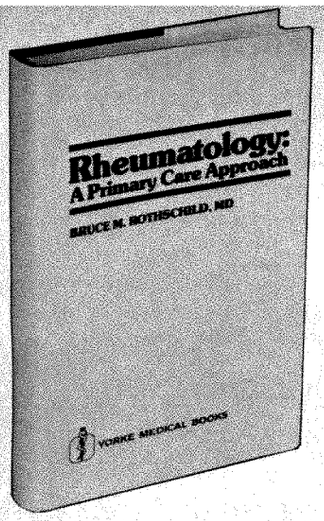
Our study is the first to describe changes in global left ventricular function and volume during exercise in patients with untreated thyrotoxicosis. Our results indicate that some patients have an abnormal ejection fraction response to exercise, as defined by failure to increase the ejection fraction from rest to exercise by at least 5% or by an actual decrease in ejection fraction during exercise. This incidence of abnormal left ventricular response to exercise is much lower than that reported by Shafer and Bianco.[20] These investigators found that the ejection fraction response to exercise was abnormal in 7 of the 8 patients with thyrotoxicosis. The reasons for the differences between our results and those of Shafer and Bianco are unclear, but several mechanisms can be postulated. First, all patients studied by Shafer and Bianco were men; this is unusual, since thyrotoxicosis is more common in women, and therefore underlying heart disease in these patients cannot be excluded with certainty.

Second, it is possible that the degree of thyrotoxicosis of our patients differs from those of the other investigators' patients; this possibility, however, is extremely unlikely, since the serum levels of $T_4$ were not significantly different in the 2 sets of patients. Furthermore, the mean resting heart rate was almost identical in both studies.

Third, myocardial oxygen consumption ($M\dot{V}O_2$) during exercise may have differed in the 2 studies; systolic blood pressure was higher in the study of Schafer

and Bianco than in our study. However, the exercise heart rate was higher in our study, and so the double product should not differ in the 2 studies.

Fourth, the method of study was different in the 2 studies. Schafer and Bianco used supine exercise for their patients and measured ejection fraction by the gated equilibrium technique; we used upright exercise for our patients and measured ejection fraction by the first-pass method with a computerized multicrystal gamma camera.



Finally, measurements of left-ventricular volumes were not reported by the other investigators; our results are shown in Tables II and III.

In our study, there was no significant change in end-diastolic and end-systolic volumes during exercise. Four of our 10 patients (including the 3 who had abnormal ejection fraction responses) had increases in the end-systolic volume with exercise. We previously showed that a slight increase in the end-systolic volume during exercise may occur even in normal subjects.[21] In these subjects, however, the end-diastolic volume increases to a greater extent during exercise, resulting in a higher stroke volume and ejection fraction. Our study also demonstrated no significant differences at rest in patients with thyrotoxicosis and normal subjects in systolic blood pressure, diastolic blood pressure, ejection fraction, end-diastolic volume, end-systolic volume, stroke volume, or cardiac output, whereas the resting heart rate, as expected, was higher in patients with thyrotoxicosis.

Similarly, during exercise, there were no significant differences between patients with thyrotoxicosis and normal subjects in heart rate, blood pressure, end-diastolic volume, end-systolic volume, stroke volume, and cardiac output, but the ejection fraction was lower in patients with thyrotoxicosis. The cardiac index was higher than 4.5 liters/m/m$^2$ in 5 of the 10 patients with thyrotoxicosis, but this finding was also seen in many of our normal subjects.

# The Diagnosis and Treatment Oriented Approach to Rheumatology with the Primary Care Physician in Mind

# Rheumatology

## A Primary Care Approach

Written by:

**Bruce M. Rothschild, MD**

Director, Division of Rheumatology, University Health Sciences, The Chicago Medical School Chief, Section of Rheumatology, V. A. Medical Center North Chicago, Illinois

**ISBN 0-914316-33-8 430 pp., illus., November 1982, $39.50**

## What is Rheumatology: A Primary Care Approach?

- a succinct (approx. 450 pp.) yet comprehensive presentation of the latest techniques in diagnosis and therapeutic interventions of most use to the primary care physician
- a practical "how-to" desk reference to a difficult but common disease affecting over 35 million patients in the U.S. alone
- a book meant to be used regularly, not read once and stored away on a library shelf
- the primary care physicians' answer to the huge, weighty tomes on Rheumatology which offer too little on diagnosis and treatment and too much on etiology and mechanisms of disease

## Rheumatology: A Primary Care Approach is Not

- a research monograph filled with esoteric information of little use to the practicing primary care physician
- a difficult to follow, badly organized reference tool requiring a thorough knowledge of the subject matter before it can be used effectively
- a massive and verbose dissertation more useful as a door stop than a clinical reference

We know of no other book on rheumatic disease which covers the subject as exhaustively in terms of diagnosis and treatment while avoiding wasting the busy practitioner's time by including information of little interest to the primary care physician. This book emphasizes that information necessary to recognize basic disease processes and their natural history. It provides the reader with the information necessary for making a diagnosis and initiating a plan of treatment. Information on differential diagnosis from the point of view of characteristics which would not fit with a given diagnosis is also provided. It is especially strong on the interpretation of rheumatologic radiology and in its approach to joint examination and assessment of lab results. Rheumatic disease cannot be cured but proper intervention can reduce and sometimes eliminate the attendant disability. This book provides you with the means to diagnose, assess and decide for yourself the necessary intervention.

## From the Preface:

*"More than 15 million individuals in the United States suffer from arthritis, and there are only 3,000 physicians practicing rheumatology. It is evident that the majority of patients receive continuing care from the nonrheumatologist, i.e., the internist, family practitioner, pediatrician and other disciplines in medicine. Therefore, we require concise and authoritative clinical guidelines for the primary care physician. With this as motivation Dr. Bruce Rothschild has skillfully structured a text geared to the particular and immediate needs of the practitioner. . . This text. . . is an important contribution to continuing medical education of the clinician. It will be of immediate interest and value to clinicians in a wide variety of specialties and should be of great assistance to the faculties and student bodies of our medical schools. We have long needed this type of approach to primary care of patients with musculoskeletal diseases and we are indebted to the author for his accomplishments."*

**Alfred Soffer, MD**
Chief Editor Archives of Internal Medicine

## Table of contents

**Section 1 - Investigative Techniques** • Chapter 1 - The Rheumatologic History and Physical Examination • Chapter 2 - Arthrocentesis and Joint Fluid Evaluation • Chapter 3 - Laboratory Studies • Chapter 4 - Radiology of Joint Disease • **Section 2 - Patterns of Disease** • Chapter 5 - Infectious Agent Arthritis • Chapter 6 - Arthritis of Mechanical Derivation • Chapter 7 - Crystalline Arthritis • Chapter 8 - Rheumatoid Arthritis • Chapter 9 - Juvenile Rheumatoid Arthritis • Chapter 10 - Ankylosing Spondylitis • Chapter 11 - Reiter's Syndrome and Psoriatic Arthritis • Chapter 12 - Arthritis Associated with Gastrointestinal Disease • Chapter 13 - Endocrine, Metabolic, and Deposition Disease • Chapter 14 - Arthritis Associated with Hematologic Disease • Chapter 15 - Miscellaneous Causes of Arthritis • Chapter 16 - Nonarticular Rheumatism • Chapter 17 - Systemic Lupus Erythematosus, Polymyositis, and Sjogren's Syndrome • Chapter 18 - Scleroderma • Chapter 19 - Vasculitis/Vasculopathy • **Section 3 - Management** • Chapter 20 - Approach to Diagnosis • Chapter 21 - Compliance and Quackery • Chapter 22 - Salicylate Pharmacodynamics • Chapter 23 -Medication Therapy • Chapter 24 - Rehabilitation Therapy • Chapter 25 - Surgical Intervention

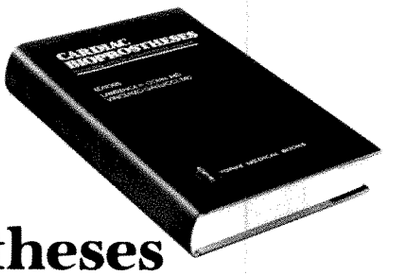
# Cheer up a low cholesterol diet with Saffola.



Saffola margarine is perfect for your patients following a low-cholesterol diet.

First of all, Saffola has no cholesterol. And it is higher in beneficial polyunsaturates than corn oil margarine, even Fleischmann's or Mazola.

But because Saffola margarine tastes great. It could mean the difference if your patient strays or stays on his diet.

**Absolutely no cholesterol and higher in beneficial polyunsaturates.**

**The most up-to-date presentation of the latest data on the entire range of clinical, bioengineering, pathology, and long-range follow-up issues on cardiac tissue valves.**

# Cardiac Bioprostheses

**Proceedings of the Second International Symposium**
**Rome, Italy, May 17-19, 1982**

**edited by Lawrence H. Cohn, MD, and Vincenzo Gallucci, MD**
**ISBN 0-914316-34-6, 609 pp., illus., Nov. 1982., $65.00**

An international program committee organized this symposium on a strictly competitive abstract basis. It was held less than six months ago. One-hundred-eighty abstracts were submitted and 45 in 8 categories were accepted. Virtually every major cardiovascular center in the world that has any meaningful experience with cardiac bioprosthetic valves was represented. Nowhere will you find between two covers as much *current* information on the field of cardiac valves.

Almost 20 years have gone by since the first reports of homograft valve replacement by Drs. Donald Ross and Brian Barratt-Boyes and almost 10 years since the first reports began to appear about commercially available, quality-controlled porcine bioprosthetic and bovine pericardial valves. This book brings you completely up-to-date on what has happened since and what is happening *today*.

If your interests include the clinical, pathological and bioengineering aspects of cardiac bioprostheses then this book is a *must buy!* It should not be missing from your own professional library.

## Who are the editors?

**Lawrence H. Cohn, MD,** is Professor of Surgery, Harvard Medical School, and Cardiothoracic Surgeon, Brigham and Womens' Hospital. He is the author of *Modern Techniques in Surgery* and co-author of the new annual, *Cardiology*, now available in its second issue, *Cardiology 1982*.

**Vincenzo Gallucci, MD,** is Professor of Cardiovascular Surgery, Departments of Cardiovascular Surgery and Cardiology, University of Padova Medical School, Padova, Italy.

**• Section 1 CLINICAL ANALYSIS • Section 2 HEMODYNAMICS • Section 3 THROMBOEMBOLISM • Section 4 PEDIATRIC VALVE REPLACEMENT • Section 5 EXPERIMENTAL PATHOLOGY • Section 6 EXPLANT PATHOLOGY • Section 7 BIOPROSTHETIC BIOENGINEERING • Section 8 LONG-TERM FOLLOW-UP • Section 9 SUMMING UP • AUTHOR INDEX • SUBJECT INDEX**

**NITROSTAT®**
(nitroglycerin tablets, USP)

**Before prescribing, please see full prescribing information.**
**A Brief Summary follows:**

INDICATIONS
Nitroglycerin is indicated for the prophylaxis, treatment and management of patients with angina pectoris.

CONTRAINDICATIONS
Sublingual nitroglycerin therapy is contraindicated in patients with early myocardial infarction, severe anemia, increased intracranial pressure, and those with a known hypersensitivity to nitroglycerin.

PRECAUTIONS
Only the smallest dose required for effective relief of the acute anginal attack should be used. Excessive use may lead to the development of tolerance. Nitrostat tablets are intended for sublingual or buccal administration and should not be swallowed. The drug should be discontinued if blurring of vision or drying of the mouth occurs. Excessive dosage of nitroglycerin may produce severe headaches.

ADVERSE REACTIONS
Transient headache may occur immediately after use. Vertigo, weakness, palpitation, and other manifestations of postural hypotension may develop occasionally, particularly in erect, immobile patients. Syncope due to nitrate vasodilation has been reported. Alcohol may accentuate the cerebral ischemia symptoms.

METHOD OF ADMINISTRATION
One tablet should be dissolved under the tongue or in the buccal pouch at the first sign of an acute anginal attack. The dose may be repeated approximately every five minutes until relief is obtained. Nitrostat may be used prophylactically five to ten minutes prior to engaging in activities which might precipitate an acute attack.

HOW SUPPLIED
Nitrostat is supplied in four strengths in bottles containing 100 tablets each, with color-coded labels, and in color-coded Patient Convenience Packages of four bottles of 25 tablets each.

0.15 mg (1/400 grain):
N 0071-0568-24—Bottle of 100 tablets
N 0071-0568-13—Convenience Package.

0.3 mg (1/200 grain):
N 0071-0569-24—Bottle of 100 tablets
N 0071-0569-13—Convenience Package.

0.4 mg (1/150 grain):
N 0071-0570-24—Bottle of 100 tablets
N 0071-0570-13—Convenience Package.

0.6 mg (1/100 grain):
N 0071-0571-24—Bottle of 100 tablets
N 0071-0571-13—Convenience Package.

**PARKE-DAVIS** 0568G060
Warner-Lambert Company
Morris Plains, NJ 07950

NITROSTAT® tablets are specially stabilized to resist the "slow leak" of nitroglycerin potency that often compromises ordinary sublingual nitroglycerin tablets—even in tightly stoppered bottles. Only NITROSTAT tablets are available in 4x25 packages—so that only one bottle of 25 tablets need be opened at a time: leaving the last 25 tablets just as fresh and potent as the first—or keeping emergency angina relief ready in up to four different locations.

NITROSTAT tablets have a full, well-documented 5-year expiration date*—testimony to its stability under the conditions of storage studied.

To your patients, that can mean consistently reliable angina relief. And that's an airtight case for NITROSTAT.

Please see preceding page for a brief summary of prescribing information.

*Five-year expiration date, data on file, Parke-Davis.

ANGINA
INDERAL® (PROPRANOLOL HCl) TODAY CAN TAKE THE CONCERN OUT OF TOMORROW.
Fewer angina attacks, less anginal pain, greater freedom from fear. That's what early use of INDERAL (propranolol HCl) can mean to today's angina patients. INDERAL works to reduce myocardial oxygen demand—by lowering the heart rate... reducing systolic blood pressure... decreasing contractility. Because it helps balance myocardial hemodynamics, INDERAL enables selected patients to do more—with less need for nitroglycerin, less fear of pain. When conventional measures are inadequate, prescribe INDERAL for angina early. INDERAL does more—so your patients may do more.
INDERAL®
(PROPRANOLOL HCl)
The sooner, the better.
Please see following page for Brief Summary of Prescribing Information.

# INDERAL®
## (PROPRANOLOL HCl)

# THE MOST WIDELY PRESCRIBED BETA BLOCKER IN THE WORLD.

The appearance of these tablets is a trademark of Ayerst Laboratories

*BRIEF SUMMARY (FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE CIRCULAR.)*
**Inderal®** (propranolol hydrochloride)

BEFORE USING INDERAL (PROPRANOLOL HYDROCHLORIDE), THE PHYSICIAN SHOULD BE THOROUGHLY FAMILIAR WITH THE BASIC CONCEPT OF ADRENERGIC RECEPTORS (ALPHA AND BETA), AND THE PHARMACOLOGY OF THIS DRUG.

### CONTRAINDICATIONS

1) bronchial asthma; 2) allergic rhinitis during the pollen season; 3) sinus bradycardia and greater than first degree block; 4) cardiogenic shock; 5) right ventricular failure secondary to pulmonary hypertension; 6) congestive heart failure (see WARNINGS) unless it is secondary to a tachyarrhythmia treatable with propranolol; 7) in patients on adrenergic-augmenting psychotropic drugs (including MAO inhibitors), and during the two week withdrawal period from such drugs.

### WARNINGS

CARDIAC FAILURE. In congestive heart failure, inhibition with beta-blockade carries the potential hazard of further depressing myocardial contractility and precipitating cardiac failure. In patients already receiving digitalis, propranolol may reduce the positive inotropic action of digitalis and may have an additive depressant effect on AV conduction.

IN PATIENTS WITHOUT A HISTORY OF CARDIAC FAILURE, in rare instances, cardiac failure has developed during propranolol therapy. At the first sign of impending cardiac failure, patients should be fully digitalized and/or given a diuretic, and observed closely. a) if cardiac failure continues, despite adequate digitalization and diuretic therapy, propranolol should be immediately withdrawn; b) if tachyarrhythmia is being controlled, patients should be maintained on combined therapy and closely followed until threat of cardiac failure is over.

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following *abrupt* discontinuation of INDERAL therapy. Therefore, when discontinuance of INDERAL is planned the dosage should be gradually reduced and the patient carefully monitored. In addition, when INDERAL is prescribed for angina pectoris, the patient should be cautioned against interruption or cessation of therapy without the physician's advice. If INDERAL therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute INDERAL therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease, who are given propranolol for other indications.

IN PATIENTS WITH THYROTOXICOSIS, possible deleterious effects from long term use have not been adequately appraised. Give special consideration to propranolol's potential for aggravating congestive heart failure. Propranolol may mask the clinical signs of developing or continuing hyperthyroidism or complications and give a false impression of improvement. Propranolol should be withdrawn slowly, since abrupt withdrawal may be followed by an exacerbation of symptoms of hyperthyroidism, including thyroid storm. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg propranolol.

IN PATIENTS UNDERGOING MAJOR SURGERY, beta-blockade impairs the ability of the heart to respond to reflex stimuli. Except in pheochromocytoma, propranolol should be withdrawn 48 hours prior to surgery. In case of emergency surgery, the effects of propranolol can be reversed by administration of beta-receptor agonists such as isoproterenol or levarterenol, but such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has been reported.

IN PATIENTS PRONE TO NONALLERGIC BRONCHOSPASM (e.g., CHRONIC BRONCHITIS, EMPHYSEMA), administer with caution, since propranolol may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta-receptors.

DIABETICS AND PATIENTS SUBJECT TO HYPOGLYCEMIA. Propranolol may prevent the appearance of premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia, especially in patients with labile diabetes. A precipitous elevation of blood pressure may accompany hypoglycemic attacks.

USE IN PREGNANCY. Safe use in human pregnancy not established. Embryotoxic effects have been seen in animals at doses about 10 times the maximum recommended human dose.

### PRECAUTIONS

Patients receiving catecholamine depleting drugs such as reserpine should be closely observed if propranolol is administered, since it may occasionally produce hypotension and/or marked bradycardia resulting in vertigo, syncopal attacks, or orthostatic hypotension.

Observe laboratory parameters at regular intervals. Use with caution in patients with impaired renal or hepatic function.

### ADVERSE REACTIONS

*Cardiovascular:* bradycardia; congestive heart failure; intensification of AV block; hypotension; paresthesia of hands; arterial insufficiency, usually of the Raynaud type; thrombocytopenic purpura. *Central Nervous System:* lightheadedness; mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics. *Gastrointestinal:* nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation, mesenteric arterial thrombosis, ischemic colitis. *Allergic:* pharyngitis and agranulocytosis; erythematous rash, fever combined with aching and sore throat; laryngospasm and respiratory distress. *Respiratory:* bronchospasm. *Hematologic:* agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura. *Miscellaneous:* reversible alopecia. Oculomucocutaneous reactions involving the skin, serous membranes and conjunctivae reported for a beta-blocker (practolol) have not been conclusively associated with propranolol. *Clinical Laboratory Test Findings:* Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

### HOW SUPPLIED

TABLETS

– Each hexagonal-shaped, orange, scored tablet is embossed with an "I" and imprinted with "INDERAL 10," contains 10 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0421-81) and 1,000 (NDC 0046-0421-91). Also in unit dose package of 100 (NDC 0046-0421-99).

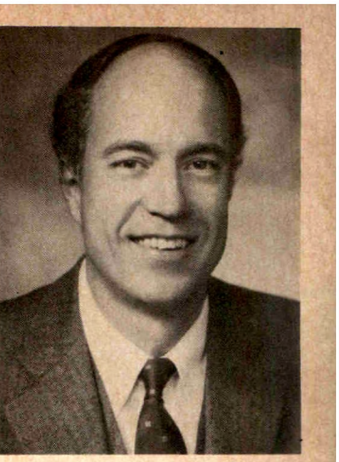
– Each hexagonal-shaped, blue, scored tablet is embossed with an "I" and imprinted with "INDERAL 20," contains 20 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0422-81) and 1,000 (NDC 0046-0422-91). Also in unit dose package of 100 (NDC 0046-0422-99).

– Each hexagonal-shaped, green, scored tablet is embossed with an "I" and imprinted with "INDERAL 40," contains 40 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0424-81) and 1,000 (NDC 0046-0424-91). Also in unit dose package of 100 (NDC 0046-0424-99).

– Each hexagonal-shaped, yellow, scored tablet is embossed with an "I" and imprinted with "INDERAL 80," contains 80 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0428-81) and 1,000 (NDC 0046-0428-91). Also in unit dose package of 100 (NDC 0046-0428-99).

The appearance of these tablets is a trademark of Ayerst Laboratories.

Store at room temperature (approximately 25° C).



INJECTABLE

– Each ml contains 1 mg of propranolol hydrochloride in Water for Injection. The pH is adjusted with citric acid. Supplied as 1 ml ampuls in boxes of 10 (NDC 0046-3265-10).

Store at room temperature (approximately 25° C).

# Paper Accepted/Abstract Rejected or Vice Versa: Differences In the Grading of Abstracts and the Reviewing of Manuscripts

Through the years I often have been amazed that an abstract I considered excellent was rejected, and yet when the subject of that abstract was submitted later in manuscript form, it was rapidly accepted. The grading of abstracts and the reviewing of manuscripts are 2 entirely different processes.

I have had the privilege of serving on program committees of both The American Heart Association and The American College of Cardiology, and this responsibility included grading abstracts for presentation at the annual scientific sessions. An abstract from either society is graded similarly—by a score of 0 to 10, with a 10 representing the highest quality. Each abstract is graded by about 7 to 10 reviewers, and the final grade given is the average of the multiple grades. The most common grade given is a 7; very few abstracts receive grades <5. The average grade of abstracts accepted for presentation—either from the podium or by poster—is about 7.7. If the grader happens to be an author of an abstract, he or she is instructed to use the letter *P* for "prejudiced," and if the grader is "unqualified"—that is, does not have sufficient knowledge of the subject of the abstract—the letter *X* is used. Although a single line is provided for it, no explanation or justification for the grade is required. On one program committee of which I was a member, 50% of the abstracts were graded 1 by one committee member, whereas another member on the same committee registered a 7 or 8 on all abstracts he graded. Few graders give many 10's, and some rarely give a 9. Of course, the most useful grader is the one who clearly differentiates the good abstracts from the bad ones. In the 1960s, only the members of the program committee graded the abstracts for 1 of the 2 national cardiology societies, and that meant that each member graded a large number—about 300. During recent years both organizations have used non-committee member experts as graders, so that no grader is asked to review more than about 100 abstracts; the period of time allowed, however, remains short—about 2 weeks.

In contrast, when a reviewer recommends to an editor that he or she accept or reject a manuscript, that recommendation must be substantiated by criticisms or the lack of them. Although one could argue that because abstracts have far more graders than manuscripts have reviewers, the selection process for abstracts is a just one. I have no constructive suggestions for how to improve the abstract grading process. My enthusiasm, however, for abstracts is far weaker than that for manuscripts; in fact, my enthusiasm is roughly proportional to the amount of space occupied by a published abstract compared with that occupied by an average published manuscript.

Several years ago 3 of my abstracts were rejected for presentation at the annual meeting of one of the 2 cardiology societies, and all 3 were accepted without change of a single word for the annual meeting of the other society. I have about reached the point where for me abstracts simply provide a specified date for submission of an investigation, whereas original manuscripts have no deadline for submission.

An abstract should be viewed as a preliminary report on an investigation. (Incidentally, the use of abstracts as references should be avoided, except in unusual circumstances.) Thus, give me the manuscript—this is the final forum.

# In Cardiac Edema*...

Each capsule contains 50 mg. of Dyrenium® (brand of triamterene) and 25 mg. of hydrochlorothiazide.

Dyazide® is a trademark of SK&F Co.

## When You Need to Conserve $K^+$

**SK&F CO.**
**a SmithKline company**
Carolina, P.R. 00630

## Serum $K^+$ and BUN should be checked periodically (see Warnings).

**Before prescribing, see complete prescribing information in SK&F CO. literature or *PDR*. The following is a brief summary.**

* **WARNING**

This drug is not indicated for initial therapy of edema or hypertension. Edema or hypertension requires therapy titrated to the individual. If this combination represents the dosage so determined, its use may be more convenient in patient management. Treatment of hypertension and edema is not static, but must be reevaluated as conditions in each patient warrant.

**Contraindications:** Concomitant use with other potassium-sparing agents such as spironolactone or amiloride. Further use in anuria, progressive renal or hepatic dysfunction, hyperkalemia. Pre-existing elevated serum potassium. Hypersensitivity to either component or other sulfonamide-derived drugs.

**Warnings: Do not use potassium supplements, dietary or otherwise, unless hypokalemia develops or dietary intake of potassium is markedly impaired.** If supplementary potassium is needed, potassium tablets should not be used. Hyperkalemia can occur, and has been associated with cardiac irregularities. It is more likely in the severely ill, with urine volume less than one liter/day, the elderly and diabetics with suspected or confirmed renal insufficiency. Periodically, serum $K^+$ levels should be determined. If hyperkalemia develops, substitute a thiazide alone, restrict $K^+$ intake. **Associated widened QRS complex or arrhythmia requires prompt additional therapy.** Thiazides cross the placental barrier and appear in cord blood. Use in pregnancy requires weighing anticipated benefits against possible hazards, including fetal or neonatal jaundice, thrombocytopenia, other adverse reactions seen in adults. Thiazides appear and triamterene may appear in breast milk. If their use is essential, the patient should stop nursing. Adequate information on use in children is not available. Sensitivity reactions may occur in patients with or without a history of allergy or bronchial asthma. Possible exacerbation or activation of systemic lupus erythematosus has been reported with thiazide diuretics.

**Precautions:** Do periodic serum electrolyte determinations (particularly important in patients vomiting excessively or receiving parenteral fluids, and during concurrent use with amphotericin B or corticosteroids or corticotropin [ACTH]). Periodic BUN and serum creatinine determinations should be made, especially in the elderly, diabetics or those with suspected or confirmed renal insufficiency. Cumulative effects of the drug may develop in patients with impaired renal function. Thiazides should be used with caution in patients with impaired hepatic function. They can precipitate coma in patients with severe liver disease. Observe regularly for possible blood dyscrasias, liver damage, other idiosyncratic reactions. Blood dyscrasias have been reported in patients receiving triamterene, and leukopenia, thrombocytopenia, agranulocytosis, and aplastic and hemolytic anemia have been reported with thiazides. Thiazides may cause manifestation of latent diabetes mellitus. The effects of oral anticoagulants may be decreased when used concurrently with hydrochlorothiazide; dosage adjustments may be necessary. Clinically insignificant reductions in arterial responsiveness to norepinephrine have been reported. Thiazides have also been shown to increase the paralyzing effect of nondepolarizing muscle relaxants such as tubocurarine. Triamterene is a weak folic acid antagonist. Do periodic blood studies in cirrhotics with splenomegaly. Antihypertensive effects may be enhanced in post-sympathectomy patients. Use cautiously in surgical patients. Triamterene has been found in renal stones in association with the other usual calculus components. Therefore, Dyazide should be used with caution in patients with histories of stone formation. A few occurrences of acute renal failure have been reported in patients on Dyazide when treated with indomethacin. Therefore, caution is advised in administering nonsteroidal anti-inflammatory agents with Dyazide. The following may occur: transient elevated BUN or creatinine or both, hyperglycemia and glycosuria (diabetic insulin requirements may be altered), hyperuricemia and gout, digitalis intoxication (in hypokalemia), decreasing alkali reserve with possible metabolic acidosis. Dyazide interferes with fluorescent measurement of quinidine. Hypokalemia is uncommon with Dyazide, but should it develop, corrective measures should be taken such as potassium supplementation or increased dietary intake of potassium-rich foods. Corrective measures should be instituted cautiously and serum potassium levels determined. Discontinue corrective measures and Dyazide should laboratory values reveal elevated serum potassium. Chloride deficit may occur as well as dilutional hyponatremia. Concurrent use with chlorpropamide may increase the risk of severe hyponatremia. Serum PBI levels may decrease without signs of thyroid disturbance. Calcium excretion is decreased by thiazides. Dyazide should be withdrawn before conducting tests for parathyroid function.

Thiazides may add to or potentiate the action of other antihypertensive drugs.

Diuretics reduce renal clearance of lithium and increase the risk of lithium toxicity.

**Adverse Reactions:** Muscle cramps, weakness, dizziness, headache, dry mouth, anaphylaxis, rash, urticaria, photosensitivity, purpura, other dermatological conditions, nausea and vomiting, diarrhea, constipation, other gastrointestinal disturbances, postural hypotension (may be aggravated by alcohol, barbiturates or narcotics). Necrotizing vasculitis, paresthesias, icterus, pancreatitis, xanthopsia and respiratory distress including pneumonitis and pulmonary edema, transient blurred vision, sialadenitis, and vertigo have occurred with thiazides alone. Triamterene has been found in renal stones in association with other usual calculus components. Rare incidents of acute interstitial nephritis have been reported. Impotence has been reported in a few patients on Dyazide, although a causal relationship has not been established.

**Supplied: Bottles of 1000 capsules; Single Unit Packages (unit-dose) of 100 (intended for institutional use only); in Patient-Pak™ unit-of-use bottles of 100.**

## State of the Heart A-V Sequential Pacing.

Introducing the most flexible A-V Sequential Pacemaker.

**Small.**

Physiologically sized and shaped for maximum patient comfort. Byrel-SX™ weighs just 52 grams.

**Smart.**

The most programmable A-V sequential pacemaker. Byrel-SX™ is a non-committed system, and features Ventricular Safety Pacing to provide:

- Programmable A-V Intervals
- Ventricular inhibition

**Friendly.**

Byrel™ brand pacemakers have long been known for their dependability, reliability, ease of programming, and ease of follow-up.

These are Medtronic differences physicians recognize and need.

The new Byrel-SX™, leading the way in A-V Sequential pacing. For further information call toll free 1-800-328-2518.

## Byrel-SX Model 5993-SX Programmable Parameters

| | DVI | VVI |
|---|---|---|
| Rate | 40-120 bpm | 40-130 bpm |
| A-V Internal | 25-250 ms | NA |
| Atrial Pulse Width | 0.05, 0.1, 0.2...1.5 ms | NA |
| Ventricular Pulse Width | 0.05, 0.1, 0.2...1.5 ms | 0.05, 0.1, 0.2...1.5 ms |
| Ventricular Sensitivity | 2.5, 5.0 mv Asynchronous | 2.5, 5.0 mv Asynchronous |

**Power Source Depletion Characteristics**

**Initial Stage**

| | |
|---|---|
| Mode | as programmed |
| Voltage | 2.2 V |
| Magnet rate | 75 bpm |

**Secondary Stage**

| | |
|---|---|
| Mode | VVI at 65 bpm |
| Voltage | 2.0 V |

**INTENDED USE**

The Model 5993-SX universal A-V pulse generator has a wide range of application in patients requiring permanent cardiac pacing or to protect against arrhythmias related to the sequence of cardiac impulse propagation.

In the A-V sequential (DVI) mode, the Model 5993-SX has application in the following:

Sick Sinus Syndrome (sinus brady-cardia, sinus arrest, S-A block, and the brady-tachy syndrome).

A-V nodal reentrant tachycardias. (Short A-V interval settings may be useful in controlling reentrant tachy-cardias.)

Atrial and ventricular ectopic arrhythmias.

At any time, the Model 5993-SX can be programmed to the VVI mode in which case the device functions as a ventricular inhibited pulse generator. This mode is intended primarily as a backup mode in situations where it is necessary to disable the atrial circuitry (e.g., atrial lead malfunction).

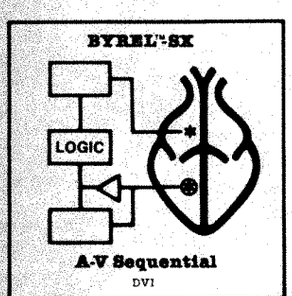
NOTE: The Medtronic* Model 5993-SX A-V pulse generator is under clinical investigation. The procedures for using this pulse generator, as well as its safety and efficacy, will be evaluated during this investigational study according to the Clinical Investigation Protocol. Therefore, the "Intended Use" section is based on Medtronic's experience with other physiologic pulse generators. No claims for safety and efficacy can be made for the Model 5993-SX pulse generator during its clinical investigation. Patients should be advised that the Model 5993-SX generator is under clinical investigation.

**CONTRAINDICATIONS**

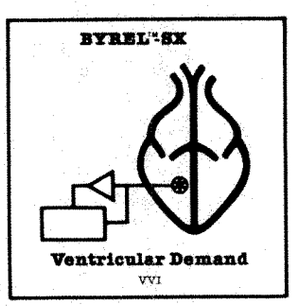
There are no known contraindications to the use of pacing as a therapeutic modality for control of heart rate. The patient's age and medical condition, however, may dictate the particular pacing system, mode of operation, and implantation procedure used by the physician. In the DVI mode, atrial pacing is ineffective in the presence of chronic atrial fibrillation of flutter.

**WARNINGS**

Diathermy should not be used on patients with pacemakers because of possible heating effects in the pulse generator and at the implant site. Electrosurgical units should never be used in the vicinity of unipolar pulse generators because of danger of introducing fibrillatory currents into the heart via the implanted pulse generator/lead. Pulse generators may be damaged by defibrillatory discharges if the paddles are placed over the implanted pulse generator.



Positioning a magnet or the programmer over the pulse generator makes it subject to programming. Do not use electrocautery, diathermy, or any other source of electromagnetic interference in the vicinity of the patient once a magnet or programmer has been positioned over the pulse generator.



**PRECAUTIONS**

The physician should be aware that all pulse generators will ultimately cease to function due to cell depletion, and may fail at any time due to random component or battery failures which cannot be predicted prior to failure. Also that the pacing system may cease to function at any time due to lead-related problems such as displacement, fracture, fibrotic tissue formation, elevated thresholds and medical complications, and that proper operation may be affected by electrical interference from certain electrical equipment.

**SIDE EFFECTS**

Body rejection phenomena, including local tissue reaction, muscle and nerve stimulation, infection, erosion of pulse generator/lead through skin, transvenous lead-related thrombosis, embolism and cardiac tamponade.

## CONTENTS IN BRIEF

FEBRUARY 1983 • VOLUME 51 • NUMBER 3

A note from the Editor-in-Chief, William C. Roberts, MD, appears on page A3 of this issue.

### CORONARY HEART DISEASE

353 **Effect of Coronary Artery Bypass Grafting on Subsequent Hospitalization.** William M. Hamilton, Karl E. Hammermeister, Timothy A. DeRouen, May S. Zia, and Harold T. Dodge

361 **Can Noninvasive Exercise Test Criteria Identify Patients With Left Main or 3-Vessel Coronary Disease After a First Myocardial Infarction?** Randolph E. Patterson, Steven F. Horowitz, Calvin Eng, Jose Meller, Stanley J. Goldsmith, Augusto D. Pichard, Doris A. Halgash, Michael V. Herman, and Richard Gorlin

373 **Papillary Muscle Rupture Complicating Acute Myocardial Infarction: Analysis of 17 Patients.** Rick A. Nishimura, Hartzell V. Schaff, Clarence Shub, Bernard J. Gersh, William D. Edwards, and Abdul J. Tajik

378 **Comparative Rates of Resolution of QRS Changes After Operative and Nonoperative Acute Myocardial Infarcts.** David E. Albert, Robert M. Califf, David A. LeCocq, Ray A. McKinnis, Raymond E. Ideker, and Galen S. Wagner

382 **Evaluation of a QRS Scoring System for Estimating Myocardial Infarct Size. III. Correlation With Quantitative Anatomic Findings for Inferior Infarcts.** Steven F. Roark, Raymond E. Ideker, Galen S. Wagner, Daniel R. Alonso, Sanford P. Bishop, Colin M. Bloor, Dean A. Bramlet, Jesse E. Edwards, John T. Fallon, Geoffrey J. Gottlieb, Donald B. Hackel, Harry R. Phillips, Keith A. Reimer, William J. Rogers, Wayne K. Ruth, Robert M. Savage, Richard D. White, and Ronald H. Selvester

390 **Segmental Right Ventricular Function After Acute Myocardial Infarction: Two-Dimensional Echocardiographic Study in 63 Patients.** Jose Lopez-Sendon, Miguel Angel Garcia-Fernandez, Isabel Coma-Canella, Mar Moreno Yangüela, and Fermin Bañuelos

397 **Variable Threshold Exertional Angina in Patients With Transient Vasospastic Myocardial Ischemia. Repeat Exercise Test Results and Therapeutic Implications.** Stefano de Servi, Giuseppe Specchia, Colomba Falcone, Antonello Gavazzi, Antonio Mussini, Luigi Angoli, Ezio Bramucci, Diego Ardissino, Laura Vaccari, Jorge Salerno, and Piero Bobba

403 **Cardiovascular Disease in the Very Elderly. Analysis of 40 Necropsy Patients Aged 90 Years or Over.** Bruce F. Waller and William C. Roberts

422 **Hemodynamic Effects of a New Antiarrhythmic Agent, Flecainide (R-818), in Coronary Heart Disease.** Victor Legrand, Michel Vandormael, Pierre Collignon, and Henri E. Kulbertus

427 **Pindolol and Propanolol in Patients With Angina Pectoris and Normal or Near-Normal Ventricular Function. Lack of Influence of Intrinsic Sympathomimetric Activity on Global and Segmental Left Ventricular Function Assessed by Radionuclide Ventriculography.** Dante E. Manyari, William J. Kostruk, S. George Carruthers, Donald J. Johnston, and Paul Purves

434 **Determination of the Angiographic Appearance of Coronary Vessels: The Importance of Supplying and Recipient Arteries.** Harvey L. Goldberg, Jonathan Goldstein, Jeffrey S. Borer, Michael B. Collins, Jeffrey W. Moses, and George Ellis, *With the technical assistance of* Richard Quiroz

440 **Identification of Septal Ischemia During Exercise by Q-Wave Analysis: Correlation With Coronary Angiography.** Michael A. Famularo, Yogesh Paliwal, Robert Redd, and Myrvin H. Ellestad

444 **Surgery for Coronary Heart Disease Due to Mucocutaneous Lymph Node Syndrome (Kawasaki Disease). Report of 6 Patients.** Soichiro Kitamura, Kanji Kawachi, Ryoichi Harima, Tetsuo Sakakibara, Hajime Hirose, and Yasunaru Kawashima

449 **The Changing "Natural History" of Symptomatic Coronary Artery Disease: Basis Versus Bias.** Lee Goldman, Gilbert H. Mudge, Jr., and E. Francis Cook

### CONGESTIVE HEART FAILURE

455 **Intermittent, Continuous Outpatient Dobutamine Infusion in the Management of Congestive Heart Failure.** Mark M. Applefeld, Kathryn A. Newman, William R. Grove, Frederick J. Sutton, David S. Roffman, William P. Reed, and Steven E. Linberg

### SYSTEMIC HYPERTENSION

459 **R-Wave Amplitude Change During Aerobic Exercise in Hypertensive Adolescents After Treatment.** Bonita Falkner, David T. Lowenthal, Melton B. Affrime, and Barbara Hamstra

464 **Increased Plasma Concentrations of Prostacyclin in Metabolite 6-Keto-PGF$_{1\alpha}$ in Essential Hypertension. Influence of Therapy With Labetalol.** Louis Roy, Jawahar Mehta, and Paulette Mehta, *With the technical assistance of* Nancy Ostrowski, Christine Horalek, and Georgia Kelley

468 **Analysis of Ventricular Emptying and Filling Indexes During Acute Increases in Arterial Pressure.** Robert A. Slutsky, G. B. John Mancini, Kenneth H. Gerber, Howard C. Dittrich, and Charles B. Higgins

### VALVULAR HEART DISEASE

476 **Serial Changes in Left Ventricular Function After Correction of Chronic Aortic Regurgitation. Dependence on Early Changes in Preload and Subsequent Regression of Hypertrophy.** John D. Carroll, William H. Gaasch, Michael Zile, and Herbert J. Levine

483 **Radionuclide Ventriculographic Study of Adaptations to Exercise in Aortic Regurgitation.** Richard M. Steingart, Corine Yee, Lawrence Weinstein, and James Scheuer

489 **Indexes of Intravascular Hemolysis, Quantification of Coagulation Factors, and Platelet Survival in Patients With Porcine Heterograft Valves.** Mark E. Thompson, Jessica H. Lewis, Frederick L. Porkolab, Ute Hasiba, and Joel A. Spero, *With the technical assistance of* John Wilson and Michael Snyder

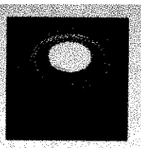
# Two added strengths for ease of titration.

## The new 5 cm² size.

Nitro-Dur™ (nitroglycerin) is the only transdermal nitroglycerin with four dosage strengths—5, 10, 15 and 20 cm² (approximately 2.5 mg, 5 mg, 7.5 mg and 10 mg released in 24 hours), permitting titration in increments of 5 cm². This gives Nitro-Dur greater dosage flexibility than any other form of transdermal nitroglycerin.

Nitro-Dur also has a sophisticated product design which includes a wide, microporous adhesive strip. The strip insures firm matrix-to-skin contact and helps keep the system sealed and in place.



Greater dosage flexibility and better adhesion. Two reasons why Nitro-Dur is the most widely prescribed transdermal nitroglycerin system.

**Nitro-Dur™**
(nitroglycerin)
Transdermal Infusion System

**The most widely prescribed transdermal nitroglycerin system.**

Please see next page for a summary of prescribing information.

# Nitro-Dur™
(nitroglycerin)
Transdermal Infusion System

## The most widely prescribed transdermal nitroglycerin system.

**DESCRIPTION:** The Nitro-Dur Transdermal Infusion System contains nitroglycerin in a gel-like matrix composed of glycerin, water (purified), lactose, polyvinyl alcohol, povidone and sodium citrate to provide a continuous source of the active ingredient. Nitro-Dur is available in dosage sizes 5cm², 10cm², 15cm² and 20cm², containing 26 mg, 51 mg, 77 mg and 104 mg of nitroglycerin, respectively, thereby providing precise dosing levels of nitroglycerin. Nitro-Dur has a rated release *in vivo* of approximately 0.5mg/cm²/24 hours. Each unit is sealed in a polyester-foil-polyethylene laminate. The bandage portion consists of a medical grade non-woven, heat sealable, microporous tape.

**CLINICAL PHARMACOLOGY:** When the Nitro-Dur system is applied to the skin, nitroglycerin is absorbed continuously through the skin into the systemic circulation. This results in active drug reaching the target organs (heart, extremities) before deactivation by the liver. Nitroglycerin is a smooth muscle relaxant with vascular effects manifested predominantly by venous dilation and pooling. The major beneficial effect of nitroglycerin in angina pectoris is a reduction in myocardial oxygen consumption secondary to vascular smooth muscle relaxation with resultant reduction in cardiac preload and afterload. In recent years there has been an increasing recognition of a direct vasodilator effect of nitroglycerin on the coronary vessels.

In bioavailability studies,[1] transdermal absorption of nitroglycerin from the gel-like matrix achieved steady state venous plasma levels comparable to that of sublingual nitroglycerin and maintained these levels for 24 hours. Therapeutic effect is achieved within 30 minutes after application of the unit, and persists about 30 minutes after removal of the unit.

**INDICATIONS AND USAGE:** Prevention and treatment of angina pectoris due to coronary artery disease.

**CONTRAINDICATIONS:** Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

**WARNINGS:** The Nitro-Dur system should be used under careful clinical and/or hemodynamic monitoring in patients with acute myocardial infarction or congestive heart failure.

In terminating treatment of angina patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks in order to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

**PRECAUTIONS:** Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension, may be due to overdosage. If during the course of treatment these symptoms occur, the dosage should be reduced.

Nitro-Dur is not intended for use in the treatment of acute anginal attacks. For this purpose, occasional use of sublingual nitroglycerin may be necessary.

**ADVERSE REACTIONS:** Transient headache is the most common side effect, especially when higher doses of the drug are administered. Headaches should be treated with mild analgesics while continuing Nitro-Dur therapy. If headache persists, the Nitro-Dur dosage should be reduced.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. Except for dermatitis, these symptoms are attributed to the pharmacologic effects of nitroglycerin. However, they may be symptoms of overdosage. When they persist, the Nitro-Dur dosage should be reduced or use of the product discontinued.

**HOW SUPPLIED:** Nitro-Dur Transdermal Infusion System, 5cm², 10cm², 15cm² and 20cm², is available in unit dose packages of 28.

**CAUTION:** Federal law prohibits dispensing without a prescription.

**PATIENT INSTRUCTIONS FOR APPLICATION:** Patient instructions are furnished with each unit dose package.

*For complete prescribing information, please see package insert.*

# Cardiac Bioprostheses

**Proceedings of the Second International Symposium**
**Rome, Italy, May 17-19, 1982**

**edited by Lawrence H. Cohn, MD, and Vincenzo Gallucci, MD**
**ISBN 0-914316-34-6, 609 pp., illus., Nov. 1982., $65.00**

An international program committee organized this symposium on a strictly competitive abstract basis. It was held less than six months ago. One-hundred-eighty abstracts were submitted and 45 in 8 categories were accepted. Virtually every major cardiovascular center in the world that has any meaningful experience with cardiac bioprosthetic valves was represented. Nowhere will you find between two covers as much *current* information on the field of cardiac valves.

Almost 20 years have gone by since the first reports of homograft valve replacement by Drs. Donald Ross and Brian Barratt-Boyes and almost 10 years since the first reports began to appear about commercially available, quality-controlled porcine bioprosthetic and bovine pericardial valves. This book brings you completely up-to-date on what has happened since and what is happening *today*.

If your interests include the clinical, pathological and bioengineering aspects of cardiac bioprostheses then this book is a *must buy!* It should not be missing from your own professional library.

## Who are the editors?

**Lawrence H. Cohn, MD,** is Professor of Surgery, Harvard Medical School, and Cardiothoracic Surgeon, Brigham and Womens' Hospital. He is the author of *Modern Techniques in Surgery* and co-author of the new annual, *Cardiology*, now available in its second issue, *Cardiology 1982*.

**Vincenzo Gallucci, MD,** is Professor of Cardiovascular Surgery, Departments of Cardiovascular Surgery and Cardiology, University of Padova Medical School, Padova, Italy.

## CONTENTS

### CORONARY HEART DISEASE

**353 Effect of Coronary Artery Bypass Grafting on Subsequent Hospitalization**

WILLIAM M. HAMILTON, KARL E. HAMMERMEISTER, TIMOTHY A. DeROUEN, MAY S. ZIA, and HAROLD T. DODGE

Rates of hospitalization during follow-up for a matched pair cohort of medically and surgically treated patients were compared. There was a 26% reduction in cardiovascular hospitalizations in the surgically compared with the medically treated patients, due to a significant reduction in hospitalization rates for myocardial infarction and other cardiovascular reasons. There was no significant difference between the 2 treatment groups in hospitalization rates for chest pain not due to myocardial infarction or for myocardial infarction including perioperative infarctions. Acute myocardial infarction accounted for only 8% of all cardiovascular hospitalizations and was not related to the number of stenotic vessels in medically treated patients.

**361 Can Noninvasive Exercise Test Criteria Identify Patients With Left Main or 3-Vessel Coronary Disease After a First Myocardial Infarction?**

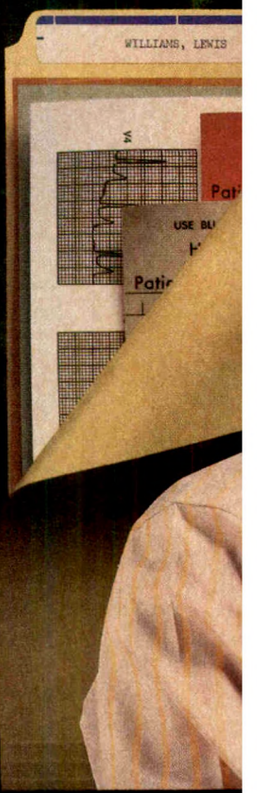
RANDOLPH E. PATTERSON, STEVEN F. HOROWITZ, CALVIN ENG, JOSE MELLER, STANLEY J. GOLDSMITH, AUGUSTO D. PICHARD, DORIS A. HALGASH, MICHAEL V. HERMAN, and RICHARD GORLIN

This study attempts to determine whether exercise treadmill testing with clinical, electrocardiographic, and thallium-201 myocardial perfusion imaging data can identify which patients have left main or 3-vessel (anatomically high risk) coronary disease after their first myocardial infarction. A thallium defect outside the vascular distribution of the infarct was the most reliable criterion for distinguishing anatomically high risk coronary disease. Failure to achieve 85% of predicted exercise heart rate was a useful criterion in patients not taking propranolol. Exercise electrocardiography could not distinguish anatomically high risk coronary disease after infarction. Cardiac catheterization is not required to exclude 3-vessel or left main coronary disease after infarction in patients with (1) absence of thallium-201 defects outside the vascular distribution of the infarction, and (2) 85% of the predicted peak exercise heart rate.

**373 Papillary Muscle Rupture Complicating Acute Myocardial Infarction: Analysis of 17 Patients**

RICK A. NISHIMURA, HARTZELL V. SCHAFF, CLARENCE SHUB, BERNARD J. GERSH, WILLIAM D. EDWARDS, and ABDUL J. TAJIK

Papillary muscle rupture is a rare but life-threatening complication of acute myocardial infarction. The records of 17 patients with this diagnosis were reviewed; 9 patients had the diagnosis confirmed at autopsy, and 8 underwent operation after papillary muscle rupture had been diagnosed. The site of myocardial infarction was inferolateral in 15 and anterior in 2; a mean of 6 days elapsed after myocardial infarction before rupture occurred. Five of 11 patients with pulmonary congestion alone died suddenly after stabilization; 5 of 6 patients with pulmonary congestion and hypotension died. Single-vessel coronary artery disease was present in 7 of 14 patients; autopsy evaluation revealed a small subendocardial myocardial infarction in half of the patients. The unpredictable clinical deterioration and the limited extent of coronary atherosclerosis suggest that early surgical intervention should be undertaken for papillary muscle rupture after acute myocardial infarction.



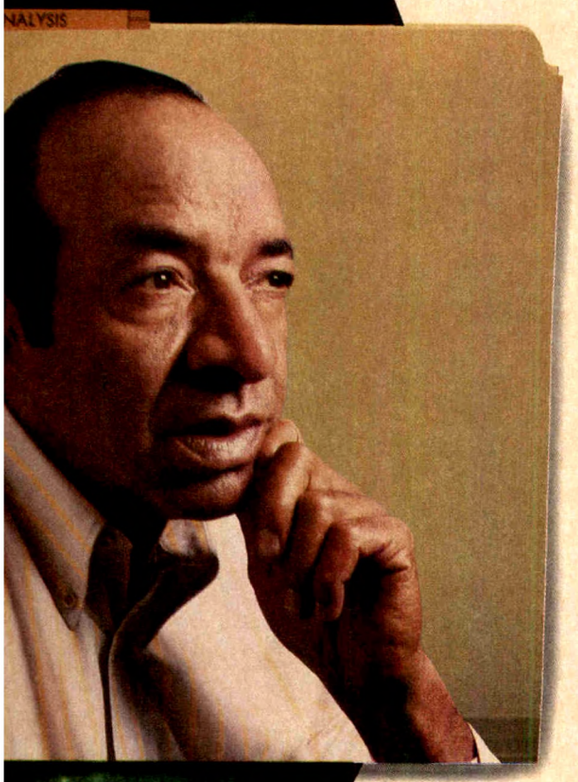
**378 Comparative Rates of Resolution of QRS Changes After Operative and Nonoperative Acute Myocardial Infarcts**

DAVID E. ALBERT, ROBERT M. CALIFF, DAVID A. LeCOCQ, RAY A. McKINNIS, RAYMOND E. IDEKER, and GALEN S. WAGNER

In this study a QRS scoring system which estimates myocardial infarct size was used to compare the evolution of the electrocardiogram in patients after operative and nonoperative myocardial infarction. Both groups showed similar peak QRS scores during the acute phase. However, QRS scores decreased more rapidly in the operative group than in the nonoperative group over the subsequent 2 months (43% versus 19%). After this period the

Continued on Page A17

# LOOKING BENEATH THE SURFACE...



## may reveal the cause of his hypertension...

In their study of the humoral mechanisms involved in hypertension, researchers are focusing not only on the kidneys and adrenal glands but on other glandular bodies as well.

Recently, a new aldosterone-stimulating factor (ASF) has been isolated from normal human urine.* Through immunofluorescence, ASF—a glycoprotein with a number of similarities to ACTH and angiotensin II—has been traced to the pituitary gland. By helping to raise plasma levels of aldosterone, which in turn leads to increased renal sodium retention, ASF presumably contributes to hypertension. The importance of its role must still be determined—and eventually will be, as researchers continue to look "beneath the surface."

## as well as the cause of his excessive anxiety

When the hypertensive patient also has anxiety which may cause him to resist, or even ignore, his medical regimen, discreet probing often provides sufficient information about possible underlying causes to help you deal with the situation. At times, however, neither counseling nor reassurance seems to work. The patient remains tense, apprehensive and—perhaps most damaging of all—noncompliant.

In such cases, adjunctive Valium (diazepam/Roche) can be distinctly helpful. Valium works promptly and dependably to relieve the excessive anxiety that patients may have because of their concern over their organic illnesses. Typically, initial calming occurs within hours—more sustained, decisive relief of anxiety symptoms in just a few days. With his intense anxiety under control, the hypertensive patient may be better able to cope with his problems and to tolerate the demands of his treatment program.

Another important advantage: Valium has been used with most primary cardiac medications, including cardiac glycosides, diuretics and vasodilators. Side effects more serious than drowsiness, fatigue and ataxia are rare and seldom severe. Patients should, of course, be cautioned against drinking alcoholic beverages or driving while taking Valium. Periodic reassessment of the need for psychotropic medication is also recommended.

# VALIUM® (IV)

## diazepam/Roche

2-mg, 5-mg, 10-mg scored tablets

## A primary choice for anxiety associated with hypertension

Please see summary of product information on the next page.

ROCHE®

# VALIUM®
## diazepam/Roche

**Before prescribing, please consult complete product information, a summary of which follows:**
**Indications:** Management of anxiety disorders, or short-term relief of symptoms of anxiety. Anxiety or tension associated with the stress of everyday life usually does not require treatment with an anxiolytic. Symptomatic relief of acute agitation, tremor, delirium tremens and hallucinosis due to acute alcohol withdrawal; adjunctively in skeletal muscle spasm due to reflex spasm to local pathology; spasticity caused by upper motor neuron disorders; athetosis; stiff-man syndrome; convulsive disorders (not for sole therapy).
The effectiveness of Valium in long-term use, that is, more than 4 months, has not been assessed by systematic clinical studies. The physician should periodically reassess the usefulness of the drug for the individual patient.
**Contraindicated:** Known hypersensitivity to the drug. Children under 6 months of age. Acute narrow angle glaucoma; may be used in patients with open angle glaucoma who are receiving appropriate therapy.
**Warnings:** Not of value in psychotic patients. Caution against hazardous occupations requiring complete mental alertness. When used adjunctively in convulsive disorders, possibility of increase in frequency and/or severity of grand mal seizures may require increased dosage of standard anticonvulsant medication; abrupt withdrawal may be associated with temporary increase in frequency and/or severity of seizures. Advise against simultaneous ingestion of alcohol and other CNS depressants. Withdrawal symptoms similar to those with barbiturates and alcohol have been observed with abrupt discontinuation, usually limited to extended use and excessive doses. Infrequently, milder withdrawal symptoms have been reported following abrupt discontinuation of benzodiazepines after continuous use, generally at higher therapeutic levels, for at least several months. After extended therapy, gradually taper dosage. Keep addiction-prone individuals under careful surveillance because of their predisposition to habituation and dependence.

***Usage in Pregnancy:* Use of minor tranquilizers during first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

**Precautions:** If combined with other psychotropics or anticonvulsants, consider carefully pharmacology of agents employed; drugs such as phenothiazines, narcotics, barbiturates, MAO inhibitors and other antidepressants may potentiate its action. Usual precautions indicated in patients severely depressed, or with latent depression, or with suicidal tendencies. Observe usual precautions in impaired renal or hepatic function. Limit dosage to smallest effective amount in elderly and debilitated to preclude ataxia or oversedation.
The clearance of Valium and certain other benzodiazepines can be delayed in association with Tagamet (cimetidine) administration. The clinical significance of this is unclear.
**Side Effects:** Drowsiness, confusion, diplopia, hypotension, changes in libido, nausea, fatigue, depression, dysarthria, jaundice, skin rash, ataxia, constipation, headache, incontinence, changes in salivation, slurred speech, tremor, vertigo, urinary retention, blurred vision. Paradoxical reactions such as acute hyperexcited states, anxiety, hallucinations, increased muscle spasticity, insomnia, rage, sleep disturbances, stimulation have been reported; should these occur, discontinue drug. Isolated reports of neutropenia, jaundice; periodic blood counts and liver function tests advisable during long-term therapy.
**Dosage:** Individualize for maximum beneficial effect. *Adults:* Anxiety disorders, symptoms of anxiety, 2 to 10 mg b.i.d. to q.i.d.; alcoholism, 10 mg t.i.d. or q.i.d. in first 24 hours, then 5 mg t.i.d. or q.i.d. as needed; adjunctively in skeletal muscle spasm, 2 to 10 mg t.i.d. or q.i.d.; adjunctively in convulsive disorders, 2 to 10 mg b.i.d. to q.i.d. *Geriatric or debilitated patients:* 2 to 2½ mg, 1 or 2 times daily initially, increasing as needed and tolerated. (See Precautions.) *Children:* 1 to 2½ mg t.i.d. or q.i.d. initially, increasing as needed and tolerated (not for use under 6 months).
**How Supplied:** For oral administration, Valium scored tablets — 2 mg, white; 5 mg, yellow; 10 mg, blue — bottles of 100* and 500;* Prescription Paks of 50, available in trays of 10;* Tel-E-Dose® packages of 100, available in trays of 4 reverse-numbered boxes of 25,† and in boxes containing 10 strips of 10.*

a company of The Dun & Bradstreet Corporation

rates of regression were similar in both groups. By 18 months the total decrease in the QRS score was 62% in the operative group and 37% in the nonoperative group. These results could mean that factors other than acute infarction are responsible for the perioperative QRS changes or that the infarct healing process may differ in the 2 clinical settings.

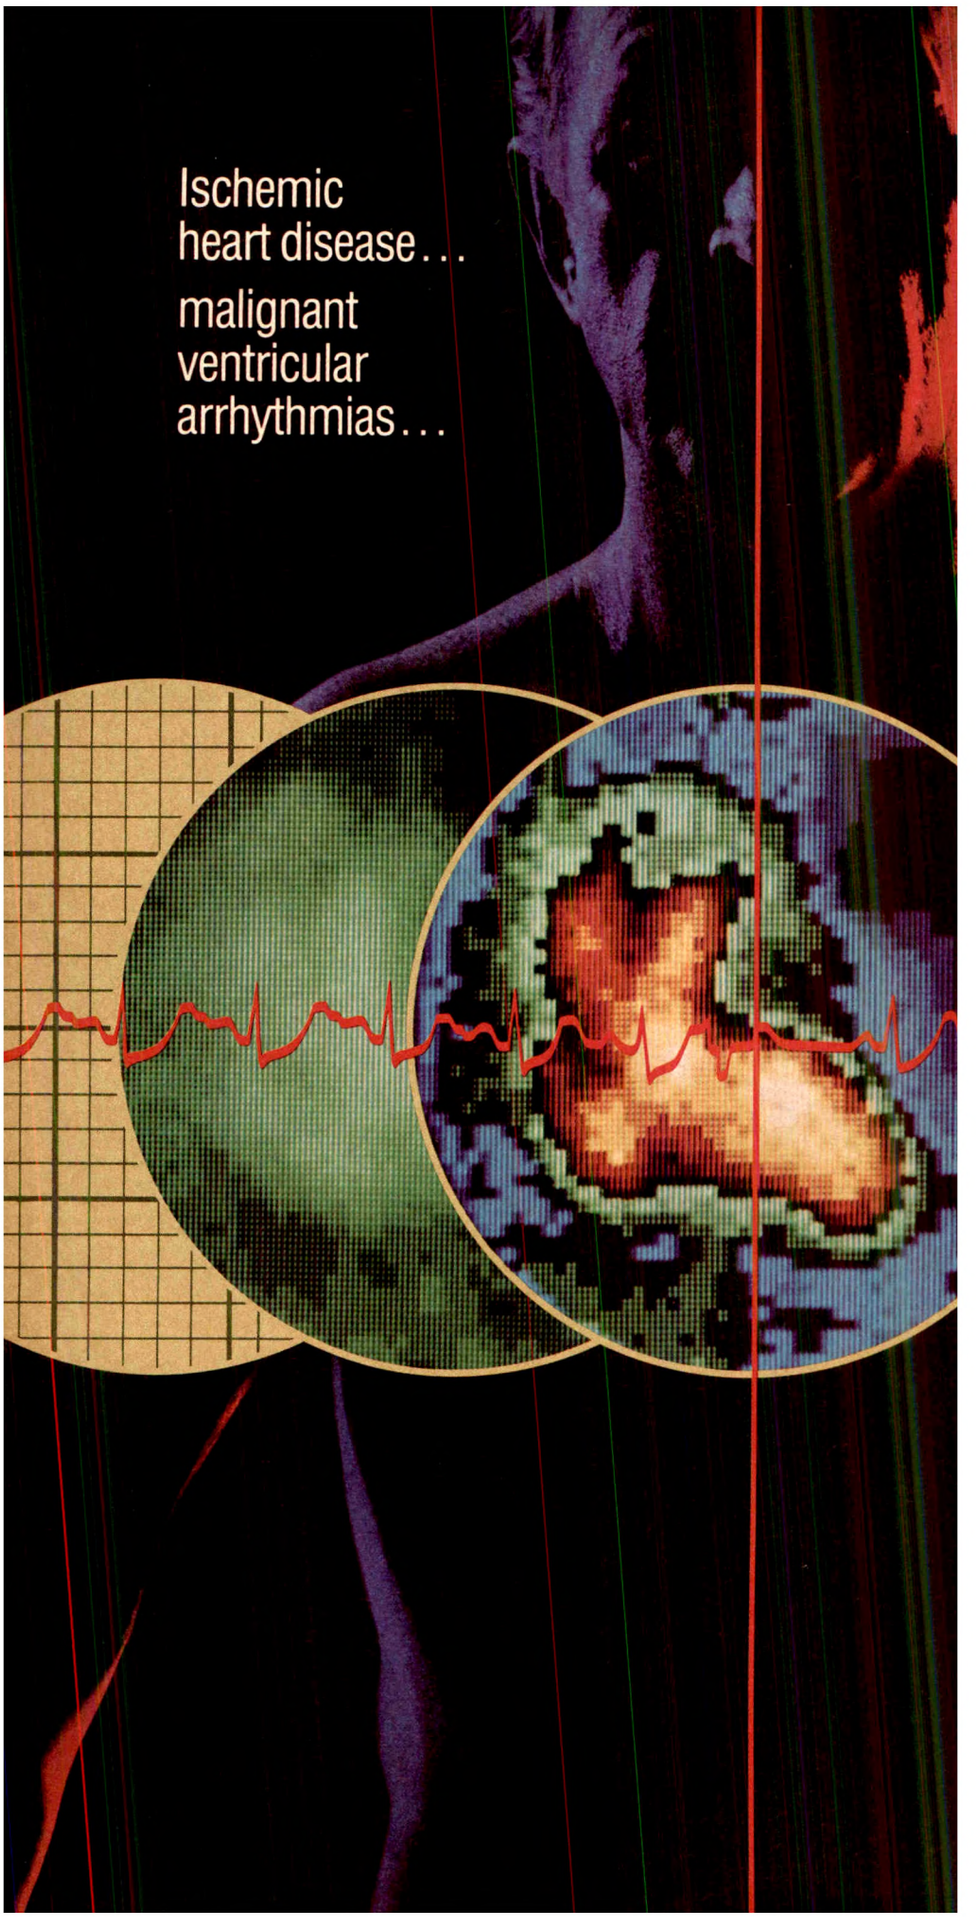
**382 Evaluation of a QRS Scoring System for Estimating Myocardial Infarct Size. III. Correlation With Quantitative Anatomic Findings for Inferior Infarcts**

STEVEN F. ROARK, RAYMOND E. IDEKER, GALEN S. WAGNER, DANIEL R. ALONSO, SANFORD P. BISHOP, COLIN M. BLOOR, DEAN A. BRAMLET, JESSE E. EDWARDS, JOHN T. FALLON, GEOFFREY J. GOTTLIEB, DONALD B. HACKEL, HARRY R. PHILLIPS, KEITH A. REIMER, WILLIAM J. ROGERS, WAYNE K. RUTH, ROBERT M. SAVAGE, RICHARD D. WHITE, and RONALD H. SELVESTER

A QRS scoring system for estimating the size of myocardial infarcts was evaluated by quantitative autopsy correlation in patients with single infarcts in the inferior third of the left ventricle. The study was limited to patients whose electrocardiogram did not indicate left or right ventricular hypertrophy, left or right bundle branch block, or left anterior or posterior fascicular block. Thirty-one patients from 6 medical centers met these criteria. In the electrocardiogram of 28 (90%) of the 31 patients, lead aVF exhibited a Q wave of at least 30 ms. The correlation coefficient between the total QRS score and the percent infarction of the left ventricle was 0.74. In patients without confounding factors in the electrocardiogram and with single infarcts, the electrocardiogram provides a marker for infarcts in the inferior third of the left ventricle and a quantitative QRS scoring system provides an estimate of infarct size.

**390 Segmental Right Ventricular Function After Acute Myocardial Infarction: Two-Dimensional Echocardiographic Study in 63 Patients**

JOSE LOPEZ-SENDON, MIGUEL ANGEL GARCIA-FERNANDEZ, ISABEL COMA-CANELLA, MAR MORENO YANGÜELA, and FERMIN BANUELOS



Right ventricular (RV) segmental contraction was studied in 63 patients with acute myocardial infarction (MI), using 2-dimensional (2-D) echocardiography. Group A included 32 patients with ischemic RV dysfunction: 19 had a disproportionate increase in right atrial pressure at the time of the examination (Group AI) and in 13 patients, right atrial pressure was normal when the echocardiogram was obtained (Group AII). Group B included 31 patients without ischemic RV dysfunction. Akinesia or dyskinesia of the RV wall was found in 30 patients: 19 from Group AI, 8 from Group AII, and 3 from Group B. Asynergy could be identified in all segments of the RV wall including the outflow tract, RV apex, and anterior wall, but was more frequently found in the posterior wall (29 patients), best seen in the transversal subcostal short-axis view. A significant difference was found either in the frequency of wall motion abnormalities or in the number of segments with asynergy among the 3 groups ($p < 0.001$). However, asynergy of the RV wall may be present in some patients with normal right heart hemodynamic function, suggesting that asynergy may be more sensitive than hemodynamic function in the diagnosis of acute RV infarction. Paradoxical septal motion was found in 8 patients, all in Group AI, and all had a right atrial pressure equal to or greater than pulmonary capillary pressure.

**397 Variable Threshold Exertional Angina in Patients With Transient Vasospastic Myocardial Ischemia. Repeat Exercise Test Results and Therapeutic Implications**

STEFANO DE SERVI, GIUSEPPE SPECCHIA, COLOMBA FALCONE, ANTONELLO GAVAZZI, ANTONIO MUSSINI, LUIGI ANGOLI, EZIO BRAMUCCI, DIEGO ARDISSINO, LAURA VACCARI, JORGE SALERNO, and PIERO BOBBA

Twelve patients with vasospastic angina at rest presented with a variable threshold of angina during exercise. In these patients 3 exercise tests, performed in the morning on different days, yielded different results because chest pain and ischemic electrocardiographic changes occurred at different work loads with a wide range of heart rate-systolic pressure product. Two patients, in whom great cardiac vein flow was measured during exercise before and after nifedipine, after the drug tolerated heavier work loads with a more marked increase in flow during exercise. Variable threshold exertional angina can be objectively demonstrated by repeated exercise tests in patients with vasospastic angina. Variability of the angina threshold may be due to a functional mechanism that causes myocardial ischemia in addition to increased myocardial metabolic requirements provoked by exercise.

# ZEROING IN ON THE CANDIDATE AT RISK

Frequent and complex forms of PVCs sharply increase the risk of sudden cardiac death (SCD) in patients with ischemic heart disease, especially in the presence of left ventricular dysfunction.[1,2]

To reduce the risk of potentially fatal arrhythmias in such patients

# QUINAGLUTE® 324 mg DURA-TABS®

## (quinidine gluconate)

- If initially tolerated, can usually be taken successfully over long periods.[3]
- Demonstrated by programmed ventricular stimulation to be effective in accepted "standard" doses.[4]
- BID or TID dosage helps improve compliance while providing 24-hour antiarrhythmic activity.
- "As a rule, GI toxicity associated with quinidine gluconate is less frequent and less severe than that associated with quinidine sulfate."[5]

**QUINAGLUTE® (quinidine gluconate) DURA-TABS®**

**INDICATIONS AND USAGE:** Quinaglute (quinidine gluconate) Dura-Tabs are indicated in the prevention and/or treatment of:

**1. Ventricular arrhythmias:** Premature ventricular contractions, ventricular tachycardia (when not associated with complete heartblock).

**2. Junctional (nodal) arrhythmias:** A-V junctional premature complexes, paroxysmal junctional tachycardia. **3. Supraventricular (atrial) arrhythmias:** Premature atrial contractions, paroxysmal atrial tachycardia, atrial flutter, atrial fibrillation (chronic and paroxysmal).

**CONTRAINDICATIONS:** 1. Idiosyncrasy or hypersensitivity to quinidine. 2. Complete A-V block. 3. Complete bundle branch block or other severe intraventricular conduction defects, especially those exhibiting a marked grade of QRS widening. 4. Digitalis intoxication manifested by A-V conduction disorders. 5. Myasthenia gravis. 6. Aberrant impulses and abnormal rhythms due to escape mechanisms.

**WARNINGS:** 1. In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by a progressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely rapid ventricular rate. This possible hazard may be reduced by digitalization prior to administration of quinidine.

2. Recent reports indicate that plasma concentrations of digoxin increase and may even double when quinidine is administered concurrently. Patients on concomitant therapy should be carefully monitored. Reduction of digoxin dosage may have to be considered.

3. Manifestations of quinidine cardiotoxicity such as excessive prolongation of the Q-T interval, widening of the QRS complex and ventricular tachyarrhythmias mandate immediate discontinuation of the drug and/or close clinical and electrocardiographic monitoring.

4. In susceptible individuals, such as those with marginally compensated cardiovascular disease, quinidine may produce clinically important depression of cardiac function such as hypotension, bradycardia, or heartblock. Quinidine therapy should be carefully monitored in such individuals.

5. Quinidine should be used with extreme caution in patients with incomplete A-V block since complete block and asystole may be produced. Quinidine may cause abnormalities of cardiac rhythm in digitalized patients and therefore should be used with caution in the presence of digitalis intoxication. 6. Quinidine should be used with caution in patients exhibiting renal, cardiac or hepatic insufficiency because of potential accumulation of quinidine in plasma leading to toxicity.

7. Patients taking quinidine occasionally have syncopal episodes which usually result from ventricular tachycardia or fibrillation. This syndrome has not been shown to be related to dose or plasma levels. Syncopal episodes frequently terminate spontaneously or in response to treatment, but sometimes are fatal.

8. A few cases of hepatotoxicity, including granulomatous hepatitis, due to quinidine hypersensitivity have been reported in patients taking quinidine. Unexplained fever and/or elevation of hepatic enzymes, particularly in the early stages of therapy, warrant consideration of possible hepatotoxicity. Monitoring liver function during the first 4-8 weeks should be considered. Cessation of quinidine in these cases usually results in the disappearance of toxicity.

**PRECAUTIONS: General:** The precautions to be observed include all those applicable to quinidine. A preliminary test dose of a single tablet of quinidine sulfate may be administered to determine if the patient has an idiosyncrasy to quinidine. Hypersensitivity to quinidine, although rare, should constantly be considered, especially during the first weeks of therapy. Hospitalization for close clinical observation, electrocardiographic monitoring, and possible determination of plasma quinidine levels is indicated when large doses are used, or with patients who present an increased risk.

**Drug Interactions:**

| *Drug* | *Effect* |
|---|---|
| Quinidine with anticholinergic drugs | Additive vagolytic effect |
| Quinidine with cholinergic drugs | Antagonism of cholinergic effects |
| Quinidine with carbonic anhydrase inhibitors, sodium bicarbonate, thiazide diuretics | Alkalinization of urine resulting in decreased excretion of quinidine |
| Quinidine with coumarin anticoagulants | Reduction of clotting factor concentrations |
| Quinidine with tubocurare, succinylcholine and decamethonium | Potentiation of neuromuscular blockade |
| Quinidine with phenothiazines and reserpine | Additive cardiac depressive effects |
| Quinidine with hepatic enzyme-inducing drugs (phenobarbital, phenytoin, rifampin) | Decreased plasma half-life of quinidine |
| Quinidine with digoxin | Increased plasma concentrations of digoxin (see WARNINGS) |

**Carcinogenesis, Mutagenesis and Impairment of Fertility:** Long-term studies in animals have not been performed to evaluate the carcinogenic potential of quinidine. There is currently no evidence of quinidine-induced mutagenesis or impairment of fertility.

**Pregnancy:** *Teratogenic Effects:* Pregnancy Category C. Animal reproduction studies have not been conducted with quinidine. There are no adequate and well-controlled studies in pregnant women. Quinaglute (quinidine gluconate) Dura-Tabs should be given to a pregnant woman only if clearly needed. *Nonteratogenic Effects:* Like quinine, quinidine has been reported to have oxytocic properties. The significance of this property in the clinical setting has not been established.

**Nursing Mothers:** Caution should be exercised when Quinaglute (quinidine gluconate) Dura-Tabs are administered to a nursing woman due to passage of the drug into breast milk.

**Pediatric Use:** There are no adequate and well-controlled studies establishing the safety and effectiveness of Quinaglute (quinidine gluconate) Dura-Tabs in children.

**ADVERSE REACTIONS:** Symptoms of cinchonism, ringing in ears, headache, nausea, and/or disturbed vision may appear in sensitive patients after a single dose of the drug. The most frequently encountered side effects to quinidine are gastrointestinal in nature. These gastrointestinal effects include nausea, vomiting, abdominal pain and diarrhea.

Less frequently encountered adverse reactions:

**Cardiovascular:** Widening of QRS complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms including ventricular tachycardia and fibrillation, paradoxical tachycardia, arterial embolism and hypotension.

**Hematologic:** Acute hemolytic anemia, hypoprothrombinemia, thrombocytopenia (purpura), agranulocytosis.

**Central Nervous System:** Headache, fever, vertigo, apprehension, excitement, confusion, delirium and syncope, disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasis, blurred vision, disturbed color perception, reduced vision field, photophobia, diplopia, night blindness, scotomata), optic neuritis.

**Dermatologic:** Rash, cutaneous flushing with intense pruritus, urticaria. Photosensitivity has also been reported.

**Hypersensitivity Reactions:** Angioedema, acute asthmatic episode, vascular collapse, respiratory arrest, hepatic toxicity, including granulomatous hepatitis (see WARNINGS). Although extremely rare, there have also been reports of lupus erythematosus in patients taking quinidine. A positive association with quinidine therapy has not been established.

*See package insert for full information.*

## CARDIAC ANGIOGRAPHY 1983

The department of radiology of Harvard Medical School in cooperation with the Council on Cardiovascular Radiology of the American Heart Association will sponsor its annual cardiac angiography course, "Cardiac Angiography 1983: Diagnostic and Therapeutic Coronary Arteriography", May 23–26, 1983 at the Marriott-Long Wharf, Boston, Mass. The program will consist of formal lectures in the morning, followed by panel discussions and small group workshops in the afternoons. Workshops will focus on cine techniques, intracoronary streptokinase, cardioactive drugs, interpretation of coronary angiograms, digital cardiac imaging, coronary angioplasty as well as other topics. Harvard Medical School faculty include Drs. Abrams, Block, Cohn, Collins, DeSanctis, Levin, Paulin, Pohost, and others. Guest faculty include Drs. Bulkley, Higgins, Kennedy, and Myler. The fee is $390 for physicians, $285 for residents, fellows and RTs. The course is approved for 26 Category I credits.

For further information contact: Jo-Anne Latino, Coordinator of Continuing Education, Brigham and Women's Hospital, Department of Radiology, 75 Francis Street, Boston, Massachusetts 02115.

## CARDIOLOGIST—ELECTROPHYSIOLOGIST

CREIGHTON UNIVERSITY MEDICAL CENTER is offering a position for a cardiologist who has special interest and sufficient training in clinical electrophysiology to direct the Electrophysiology Laboratory. Present 11 man faculty group conducts a busy clinical, research and teaching program and desires to expand and improve the Electrophysiology Laboratory. This is a fulltime academic position with salary and academic rank commensurate with the level of training and experience.

Please Contact
SYED M. MOHIUDDIN, M.D., CHAIRMAN
SEARCH COMMITTEE FOR DIRECTOR OF
ELECTROPHYSIOLOGY LABORATORY
CREIGHTON UNIVERSITY CARDIAC CENTER
601 NORTH 30th STREET, OMAHA, NEBRASKA 68131

**CARDIOLOGIST WANTED** to associate with another sub-specialist with busy clinical practice. Midwestern town of 40,000 near large metropolitan area. Invasive and non-invasive skills necessary. Excellent salary, benefits and practice opportunity with eventual partnership. Reply with C.V., to Box 250, The American Journal of Cardiology, 875 Third Ave., New York, N. Y. 10022.

# CONTENTS

**403 Cardiovascular Disease in the Very Elderly. Analysis of 40 Necropsy Patients Aged 90 Years or Over**

BRUCE F. WALLER and WILLIAM C. ROBERTS

Clinical and necropsy observations are described in 40 patients (29 women) aged 90 years and older. At necropsy, 39 had 1 or more major cardiac abnormalities, the most common being calcific deposits in the major epicardial coronary arteries in 37 (92%). In 28 patients (70%), 1 or more of the 4 major coronary arteries was narrowed 76 to 100% in cross-sectional area (XSA) by atherosclerotic plaques, an average of 1.9/4.0 per patient. Of the 12 patients with clinical events compatible with myocardial ischemia (angina pectoris or myocardial infarction), the average was 2.2/4 and in the other 28 patients, 1.0/4.0. In 36 patients, a histologic section was examined from each 5-mm long segment from each of the 4 major coronary arteries. Of the 1,789 segments, 6 (>1%) were narrowed 96 to 100% in XSA by plaques; 147 (8%), 76 to 95%; 339 (19%), 51 to 75%; 930 (52%), 26 to 50%; and 367 (21%), 0 to 25%. The average amount of XSA narrowing for each of the 1,789 segments was about 42%. Of 10 patients with clinical evidence of myocardial ischemia, the average amount of narrowing per segment was about 55%, and in the 26 patients without clinical ischemia it was about 38%. Of the 40 patients, 18 (45%) had left ventricular transmural foci of fibrosis or necrosis, or both.

**422 Hemodynamic Effects of a New Antiarrhythmic Agent, Flecainide (R-818), in Coronary Heart Disease**

VICTOR LEGRAND, MICHEL VANDORMAEL, PIERRE COLLIGNON, and HENRI E. KULBERTUS

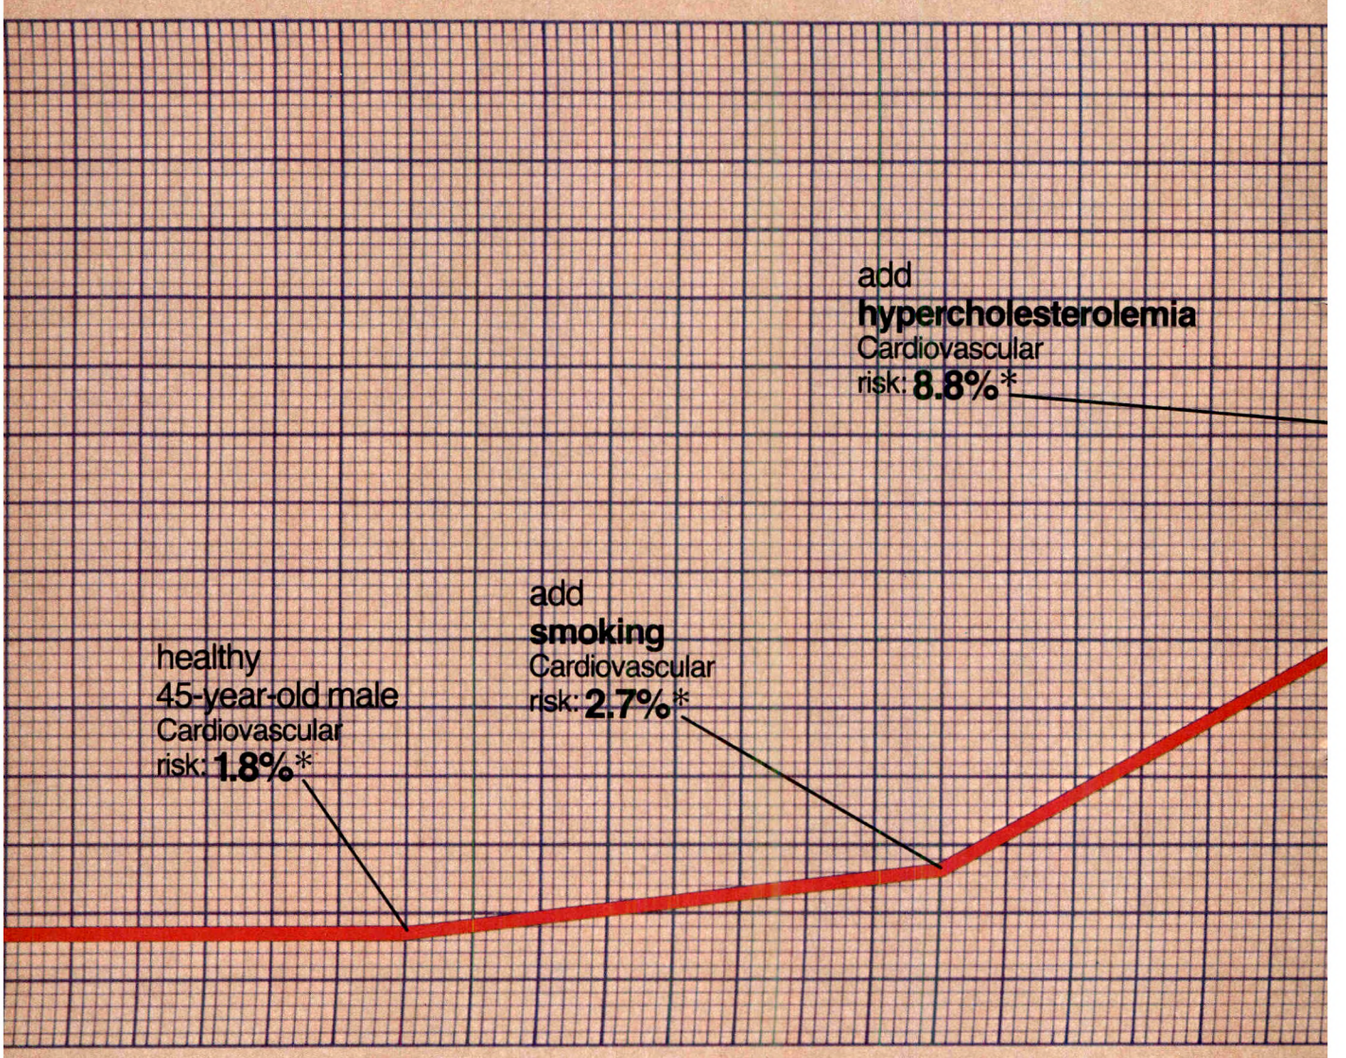
Flecainide acetate, a class I antiarrhythmic agent, was administered intravenously to 10 patients with coronary artery disease. It increased the P-R, QRS, and Q-T duration. Negative inotropic effects consisting of an increase of pulmonary wedge pressure and a decrease in stroke index, stroke work index, left ventricular ejection rate, and dP/dt were noted. No significant changes in mean aortic pressure or systemic or pulmonary vascular resistance were observed. Left ventriculography performed after drug administration revealed an increase in systolic volume as well as a decrease in ejection fraction and mean velocity of circumferential fiber shortening. The drug was well tolerated and the hemodynamic changes appeared moderate.

**427 Pindolol and Propranolol in Patients With Angina Pectoris and Normal or Near-Normal Ventricular Function. Lack of Influence of Intrinsic Sympathomimetic Activity on Global and Segmental Left Ventricular Function Assessed by Radionuclide Ventriculography**

DANTE E. MANYARI, WILLIAM J. KOSTRUK, S. GEORGE CARRUTHERS, DONALD J. JOHNSTON, and PAUL PURVES

The role of intrinsic sympathomimetic activity on left ventricular function during antianginal therapy with beta-blocking agents was evaluated in 23 patients with chronic exercise-induced angina pectoris. During 3 randomly allocated treatment periods (propranolol, a drug without intrinsic sympathomimetic activity; pindolol, a drug with intrinsic sympathomimetic activity; and control), left ventricular function was evaluated at rest and during supine exercise with radionuclide ventriculography. Both propranolol and pindolol exhibited similar effects on global and regional left ventricular function; neither decreased ejection fraction or wall motion at rest, while both prevented a decrease in ejection fraction and the development of wall motion abnormalities with exercise.

**434 Determination of the Angiographic Appearance of Coronary Vessels: The Importance of Supplying and Recipient Arteries**



HARVEY L. GOLDBERG, JONATHAN GOLDSTEIN, JEFFREY S. BORER, MICHAEL B. COLLINS, JEFFREY W. MOSES, and GEORGE ELLIS, *With the technical assistance of* RICHARD QUIROZ

To determine the relation between the angiographic appearance of the coronary arteries and coronary collateral vessels, 121 coronary angiograms were reviewed. The coronary arteries were graded on a 5 point scale (<75%, ≥75% to 89%, ≥90% to 99%, and total occlusion); collateral vessels were graded on a 3 point scale (absent, poor, or good). Stenosis of the recipient artery was an important determinant of collateral frequency and angiographic grade; as the grade of stenosis increased, the likelihood of demonstrability of collateral vessels and the probability that such vessels were "good" increased. Collateral grade also was influenced by the extent of stenosis of the artery supplying that collateral vessel; "good" collateral vessels were more likely to arise from arteries without important stenoses, and poor collateral vessels generally arose from more severely stenotic arteries. The probability that a totally occluded artery received collateral vessels was reduced to the extent that stenoses were present in all potential sources of collateral supply. Thus, the angiographic appearance of the recipient and supplying coronary arteries is a major determinant of the angiographic appearance of coronary collateral vessels.

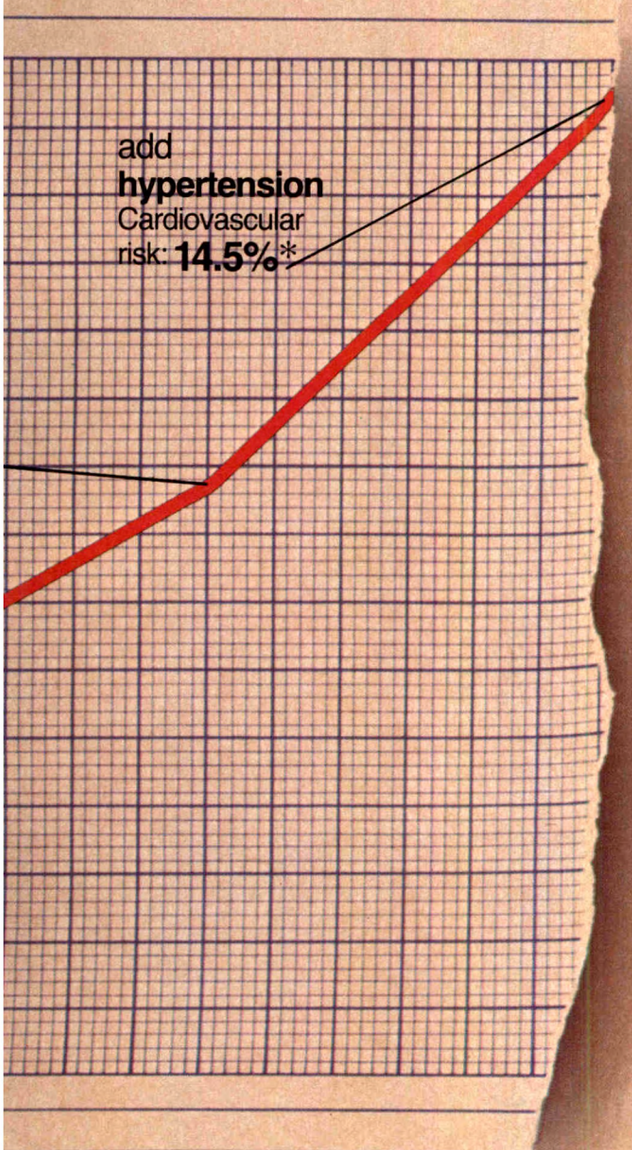
MEDICAL LIBRARY

# In hypertensive patients:



Other risk factors in CHD are diabetes, obesity, lack of exercise, stress, heredity, sex, age, race.

*Percent equals chances in 100 of developing coronary heart disease within 6 years.

Adapted from *Coronary Risk Handbook:* Estimating risk of coronary heart disease in daily practice. 1973, American Heart Assoc., Inc.

# Consider the Risks

- When selecting antihypertensive therapy, clinical consideration should be given to the effects of the specific drug on coronary risk factors. Blood pressure control should be achieved without adversely affecting blood lipids.

## Minipress Effectively Controls Hypertension Without Adverse Effect on Blood Lipids†

- Minipress effectively treats hypertension. Patients have benefited from the effectiveness of Minipress in over 5 years of clinical use in this country.[1-5]
- Minipress has been shown not to have an adverse effect on blood lipids, according to The Oslo Study and other reports.[6-9] Because Minipress lowers high blood pressure and does not produce lipid changes which are potentially atherogenic, it provides your patient with a net reduction in risk.

†Minipress is not indicated for the treatment of hyperlipidemia.

*Please see Minipress brief summary on following page.*

**Minipress®**
(prazosin HCl) Capsules 1 mg, 2 mg, 5 mg

© 1982, Pfizer Inc.

# Minipress® (prazosin HCl) Capsules 1mg, 2mg, 5mg

**B.I.D. Dosage Convenience**

**BRIEF SUMMARY**
**MINIPRESS® (prazosin hydrochloride) CAPSULES *For Oral Use***
**INDICATIONS:** MINIPRESS® (prazosin hydrochloride) is indicated in the treatment of hypertension. As an antihypertensive drug, it is mild to moderate in activity. It can be used as the initial agent or it may be employed in a general treatment program in conjunction with a diuretic and/or other antihypertensive drugs as needed for proper patient response.
**WARNINGS: MINIPRESS (prazosin hydrochloride) may cause syncope with sudden loss of consciousness. In most cases this is believed to be due to an excessive postural hypotensive effect, although occasionally the syncopal episode has been preceded by a bout of severe tachycardia with heart rates of 120-160 beats per minute. Syncopal episodes have usually occurred within 30 to 90 minutes of the initial dose of the drug; occasionally they have been reported in association with rapid dosage increases or the introduction of another antihypertensive drug into the regimen of a patient taking high doses of MINIPRESS (prazosin hydrochloride). The incidence of syncopal episodes is approximately 1% in patients given an initial dose of 2 mg or greater. Clinical trials conducted during the investigational phase of this drug suggest that syncopal episodes can be minimized by limiting the initial dose of the drug to 1 mg, by subsequently increasing the dosage slowly, and by introducing any additional antihypertensive drugs into the patient's regimen with caution (see DOSAGE AND ADMINISTRATION). Hypotension may develop in patients given MINIPRESS who are also receiving a beta-blocker such as propranolol.**
If syncope occurs, the patient should be placed in the recumbent position and treated supportively as necessary. This adverse effect is self-limiting and in most cases does not recur after the initial period of therapy or during subsequent dose titration.
Patients should always be started on the 1 mg capsules of MINIPRESS (prazosin hydrochloride). The 2 and 5 mg capsules are not indicated for initial therapy.
More common than loss of consciousness are the symptoms often associated with lowering of the blood pressure, namely, dizziness and lightheadedness. The patient should be cautioned about these possible adverse effects and advised what measures to take should they develop. The patient should also be cautioned to avoid situations where injury could result should syncope occur during the initiation of MINIPRESS (prazosin hydrochloride) therapy.
***Usage in Pregnancy:*** Although no teratogenic effects were seen in animal testing, the safety of MINIPRESS (prazosin hydrochloride) in pregnancy has not been established. MINIPRESS (prazosin hydrochloride) is not recommended in pregnant women unless the potential benefit outweighs potential risk to mother and fetus.
***Usage in Children:*** No clinical experience is available with the use of MINIPRESS (prazosin hydrochloride) in children.
**ADVERSE REACTIONS:** The most common reactions associated with MINIPRESS (prazosin hydrochloride) therapy are: dizziness 10.3%, headache 7.8%, drowsiness 7.6%, lack of energy 6.9%, weakness 6.5%, palpitations 5.3%, and nausea 4.9%. In most instances side effects have disappeared with continued therapy or have been tolerated with no decrease in dose of drug.
The following reactions have been associated with MINIPRESS (prazosin hydrochloride), some of them rarely. (In some instances exact causal relationships have not been established.)
Gastrointestinal: vomiting, diarrhea, constipation, abdominal discomfort and/or pain.
Cardiovascular: edema, dyspnea, syncope, tachycardia.
Central Nervous System: nervousness, vertigo, depression, paresthesia.
Dermatologic: rash, pruritus, alopecia, lichen planus.
Genitourinary: urinary frequency, incontinence, impotence, priapism.
EENT: blurred vision, reddened sclera, epistaxis, tinnitus, dry mouth, nasal congestion.
Other: diaphoresis.
Single reports of pigmentary mottling and serous retinopathy, and a few reports of cataract development or disappearance have been reported. In these instances, the exact causal relationship has not been established because the baseline observations were frequently inadequate.
In more specific slit-lamp and funduscopic studies, which included adequate baseline examinations, no drug-related abnormal ophthalmological findings have been reported.
**DOSAGE AND ADMINISTRATION:** The dose of MINIPRESS (prazosin hydrochloride) should be adjusted according to the patient's individual blood pressure response. The following is a guide to its administration:
***Initial Dose:*** 1 mg two or three times a day. (See Warnings.)
***Maintenance Dose:*** Dosage may be slowly increased to a total daily dose of 20 mg given in divided doses. The therapeutic dosages most commonly employed have ranged from 6 mg to 15 mg daily given in divided doses. Doses higher than 20 mg usually do not increase efficacy; however, a few patients may benefit from further increases up to a daily dose of 40 mg given in divided doses. After initial titration some patients can be maintained adequately on a twice daily dosage regimen.
***Use With Other Drugs:*** When adding a diuretic or other antihypertensive agent, the dose of MINIPRESS (prazosin hydrochloride) should be reduced to 1 mg or 2 mg three times a day and retitration then carried out.
**HOW SUPPLIED:** MINIPRESS (prazosin hydrochloride) is available in 1 mg (white #431), 2 mg (pink and white #437) capsules in bottles of 250, 1000, and unit dose institutional packages of 100 (10 x 10's); and 5 mg (blue and white #438) capsules in bottles of 250, 500 and unit dose institutional packages of 100 (10 x 10's).

PFIZER INC.

**ACADEMIC CARDIOLOGIST**

The Division of Cardiology of the University of Vermont, College of Medicine is seeking an academic cardiologist to supervise and expand our cardiac rehabilitation program. The development of research and teaching programs related to cardiac rehabilitation is an essential part of this position. Applicants should be Board eligible or certified in cardiology and have some additional training or experience in cardiac rehabilitation.

Send inquiries with curriculum vitae by March 1, 1983 to: Daniel S. Raabe, Jr., M.D., Division of Cardiology, Medical Center Hospital of Vermont, Burlington, Vermont 05401. The University of Vermont is an affirmative action employer. Women and minorities are encouraged to apply.

**CARDIOLOGY FELLOWSHIP**—3RD YEAR INVASIVE CARDIOLOGY FELLOWSHIP IN VERY ACTIVE CARDIAC AND CARDIAC SURGERY PROGRAM BEGINNING JULY 1, 1983. SALARY $27,940 PLUS FULL BENEFITS. CONTACT ST. JOHN HOSPITAL, DEPARTMENT OF HEALTH EDUCATION, 22101 MOROSS ROAD, DETROIT, MI 48236 (313) 343-3875.

**Northeastern Pennsylvania**—Dynamic practice opportunity in cardiology available. Modern JCAH approved, 160 bed general acute care hospital forty-five minutes northwest of Allentown, Pennsylvania, provides outstanding potential and opportunity in excellent geographic location for building specialty practice. Please send resume to Tod Mammuth, NEEMA Medical Services, Inc. 399 Market Street, Philadelphia, PA 19106 or call 800-523-0776 (outside PA) or 215-925-3511 (in PA).

**CARDIOLOGIST-ELECTROPHYSIOLOGIST.** The Marshfield Clinic is seeking a board certified/eligible cardiologist with extensive training and experience in electrophysiology and all aspects of arrhythmia evaluation and management. This individual will complement an existing eight member Department of Cardiology in a large multispecialty clinic. Send CV to W. Bruce Fye, M.D.; Chairman, Department of Cardiology; Marshfield Clinic; Marshfield, Wisconsin, 54449.

**440 Identification of Septal Ischemia During Exercise by Q-Wave Analysis: Correlation With Coronary Angiography**

MICHAEL A. FAMULARO, YOGESH PALIWAL, ROBERT REDD, and MYRVIN H. ELLESTAD

Changes in the precordial septal Q wave with exercise have been shown to correlate with ischemia. This study evaluates the concept that exercise-induced changes in the septal Q wave reflect the contractual state of the septum. An increase in Q-wave amplitude is associated with good contraction, whereas a decrease indicates ischemia and reduced function. Twenty-nine patients with single-vessel disease with >50% diameter reduction were compared with 12 whose coronary arteries were demonstrated normal on angiography. Of the 13 with left anterior descending disease, 8 had a decrease in Q-wave amplitude and 5 had no change. No patient with left anterior descending disease increased the magnitude of the septal Q amplitude, whereas 9 (75%) of the 12 patients with normal coronary arteries showed this change. No patient with normal coronary arteries with isolated right or circumflex disease had a loss of septal Q-wave amplitude. Thus, a decrease in septal Q-wave amplitude with exercise has a good sensitivity and a very high specificity for significant left anterior descending disease. An increase in the septal amplitude indicates normal septal contraction and usually good flow in the left anterior descending coronary artery.

**444 Surgery for Coronary Heart Disease Due to Mucocutaneous Lymph Node Syndrome (Kawasaki Disease). Report of 6 Patients**

SOICHIRO KITAMURA, KANJI KAWACHI, RYOICHI HARIMA, TETSUO SAKAKIBARA, HAJIME HIROSE, and YASUNARU KAWASHIMA

Early and late surgical results in 6 patients with coronary heart disease secondary to mucocutaneous lymph node syndrome (Kawasaki disease) are presented. They had severe coronary artery narrowings, obstructions, and aneurysms with or without mitral regurgitation. Previous myocardial infarction was documented in 5 patients. Aortocoronary bypass grafting utilizing the autologous saphenous vein was performed in 5 patients; in the remaining patient, mitral valve replacement was carried out. There were operative or late deaths. A long-term bypass graft patency was demonstrated in patients aged 26, 17, and 10 years with resulting clinical, angiographic, and/or scintigraphic improvements. However, the graft that had been patent in a 4-year-old boy was found completely obstructed 3 years after surgery without any symptomatic changes. The formation of rich collateral channels was found. The risk of saphenous vein graft closure may be high in young growing children. In older children or adolescents, however, coronary vein bypass grafting for this specific inflammatory coronary artery lesion has been effective with long-term graft patency. Severe mitral regurgitation is also an indication for surgery, but poor left ventricular function associated with mitral regurgitation, probably secondary to myocarditis, persists after surgery and may give rise to future problems.

**449 The Changing "Natural History" of Symptomatic Coronary Artery Disease: Basis Versus Bias**

LEE GOLDMAN, GILBERT H. MUDGE, Jr., and E. FRANCIS COOK

An uncritical reading of recent "natural history" studies would suggest far greater improvements in the survival of symptomatic coronary patients than has been demonstrated by national mortality statistics. However, attempts to compare patients from different studies and different eras may greatly overestimate the true improvement in natural history because of at least 3 biases in the selection of cases from the spectrum of diseased patients. Because of lead-time bias, patients who are diagnosed earlier live longer regardless of whether interventions are efficacious. Because of referral bias, current patients may have symptoms or anatomy that place them at a different stage of severity than patients who were chosen for earlier studies. Because of incidence-prevalence bias, prevalence studies will be over-represented with survivors of previous incidence cohorts who have slower-progressing disease. The authors suggest that all natural history studies be carefully scrutinized for such biases before they are compared with each other.

## CONGESTIVE HEART FAILURE

**455 Intermittent, Continuous Outpatient Dobutamine Infusion in the Management of Congestive Heart Failure**

MARK M. APPLEFELD, KATHRYN A. NEWMAN, WILLIAM R. GROVE, FREDERICK J. SUTTON, DAVID S. ROFFMAN, WILLIAM P. REED, and STEVEN E. LINBERG

Continuous dobutamine infusions were given twice weekly by a portable infusion pump-chronic venous access catheter system to 3 outpatients with heart failure. Left ventricular function and congestive failure improved with this therapy in each patient. The only complications during 58 cumulative weeks of treatment were 3 mild infections around the catheter exit site. This form of therapy shows promise for the management of refractory congestive heart failure.

## SYSTEMIC HYPERTENSION

**459 R-Wave Amplitude Change During Aerobic Exercise in Hypertensive Adolescents After Treatment**

BONITA FALKNER, DAVID T. LOWENTHAL, MELTON B. AFFRIME, and BARBARA HAMSTRA

The purpose of this study was to determine whether the blunted reduction in R-wave amplitude during progressive aerobic exercise observed in hypertensive adolescents could be altered by pharmacologic therapy to reduce blood pressure. Twenty-nine hypertensive adolescents were randomly assigned to either diuretic therapy (hydrocholorothiazide) or a centrally acting agent (clonidine). Exercise stress testing was performed before therapy and after 16 weeks of therapy. Therapy that lowered blood pressure also resulted in a change in R-wave response. In both treatment groups the change in R-wave amplitude during exercise corresponded to the R-wave response pattern observed in normotensive control subjects. These observations indicate that the altered R-wave response to exercise observed in young patients with hypertension is reversible. These findings suggest that the R-wave response before treatment may be related to a relatively higher vascular resistance.

**464 Increased Plasma Concentrations of Prostacyclin in Metabolite 6-Keto-$PGF_{1\alpha}$ in Essential Hypertension. Influence of Therapy With Labetalol**

LOUIS ROY, JAWAHAR MEHTA, and PAULETTE MEHTA, *With the technical assistance of* NANCY OSTROWSKI, CHRISTINE HORALEK, and GEORGIA KELLEY

The concentrations of 6-keto-$PGF_{1\alpha}$ and thromboxane $B_2$, stable metabolites of prostacyclin and thromboxane $A_2$, respectively, were measured in patients with essential hypertension. Plasma 6-keto-$PGF_{1\alpha}$ levels were markedly increased in the placebo phase, while thromboxane $B_2$ levels were normal. Intravenous labetalol lowered the blood pressure but did not reduce 6-keto-$PGF_{1\alpha}$ levels. Therapy with labetalol for 6 weeks decreased 6-keto-$PGF_{1\alpha}$ concentrations. Thromboxane $B_2$ levels were unaffected by intravenous or oral therapy. Increased plasma levels of 6-keto-$PGF_{1\alpha}$ in patients with untreated hypertension suggests that enhanced prostacyclin activity may be a protective mechanism to prevent organ damage. As blood pressure is controlled, prostacyclin activity declines as this increase is no longer needed.

**468 Analysis of Ventricular Emptying and Filling Indexes During Acute Increases in Arterial Pressure**

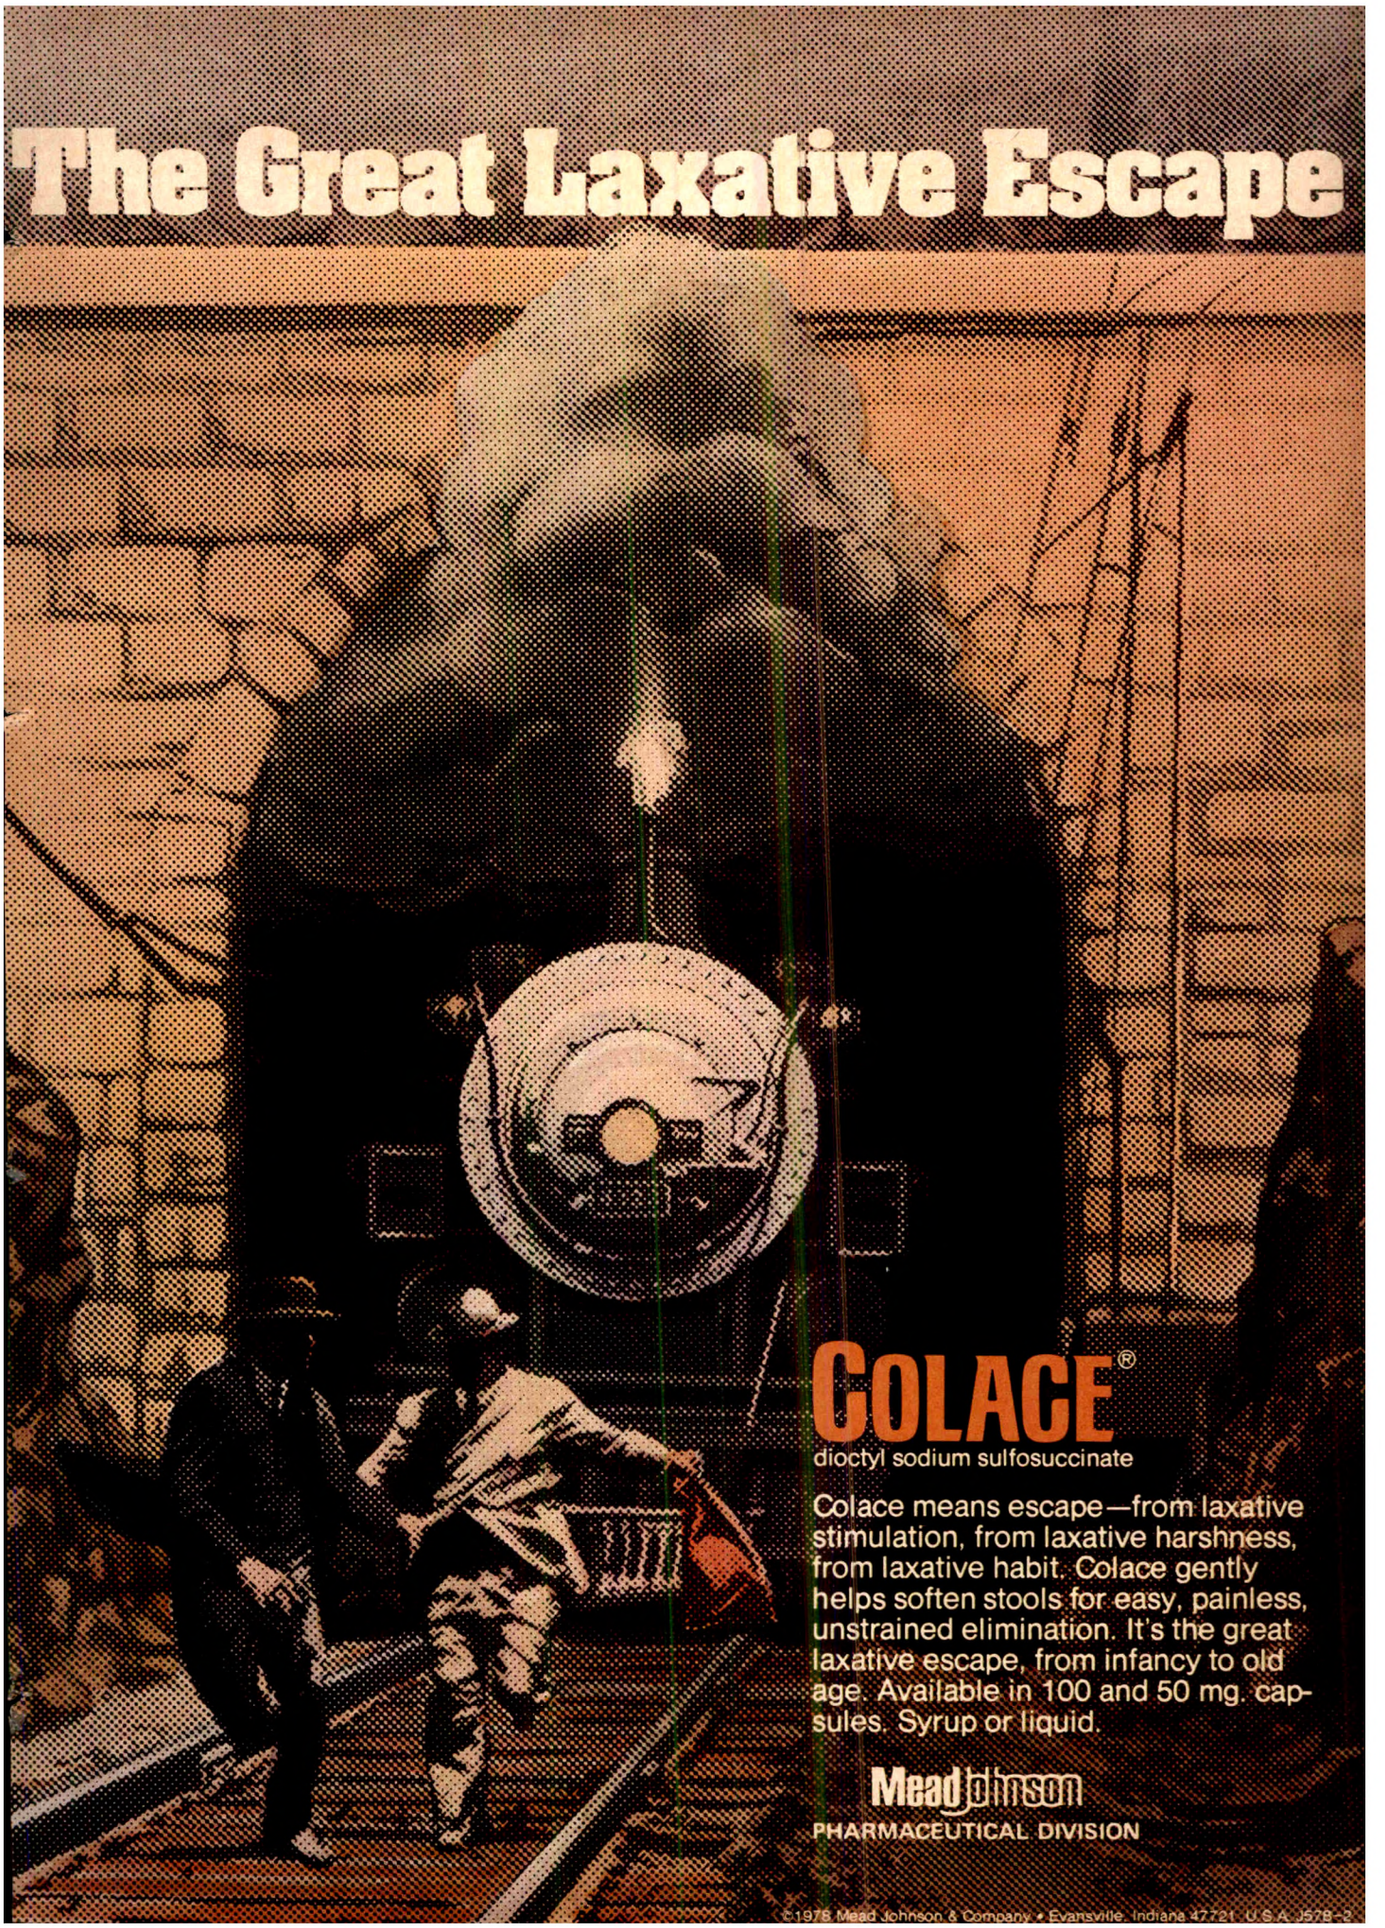
ROBERT A. SLUTSKY, G. B. JOHN MANCINI, KENNETH H. GERBER, HOWARD C. DITTRICH, and CHARLES B. HIGGINS

During periods of increased systemic arterial pressure, the ejection fraction, ejection rate, and filling rate behaved similarly in normal subjects and patients with previous myocardial infarction. Global indexes of mid-systole, holosystole, and diastole appeared of similar discriminatory value in differentiating normal subjects from patients with infarction.

## VALVULAR HEART DISEASE

**476 Serial Changes in Left Ventricular Function After Correction of Chronic Aortic Regurgitation. Dependence on Early Changes in Preload and Subsequent Regression of Hypertrophy**

JOHN D. CARROLL, WILLIAM H. GAASCH, MICHAEL ZILE, and HERBERT J. LEVINE



The early postoperative left ventricular dysfunction seen in many patients after correction of chronic aortic regurgitation is usually a temporary finding due to an acute reduction in left ventricular preload. The gradual improvement in ventricular function which occurs over the subsequent 6 to 9 months is partly related to the regression of hypertrophy. Persistent postoperative left ventricular enlargement and persistent hypertrophy are associated with persistent left ventricular dysfunction. In most patients left ventricular volume, mass, and function are not stable during the first postoperative year, and for this reason optimal assessment of ventricular function requires serial studies.

**483 Radionuclide Ventriculographic Study of Adaptations to Exercise in Aortic Regurgitation**

RICHARD M. STEINGART, CORINE YEE, LAWRENCE WEINSTEIN, and JAMES SCHEUER

Twenty patients with clinically isolated aortic regurgitation underwent supine rest and exercise-gated radionuclide ventriculography. The regurgitant index, a measure of the severity of regurgitation, was $3.46 \pm 1.25$ at rest and decreased to $2.6 \pm 0.8$ with exercise ($p < 0.001$). The greater the regurgitant index at rest, the greater the decrease with exercise. The wide variations in end-diastolic count and stroke count responses to exercise were explained in part by the decreasing regurgitant index. The data support the findings in previous catheterization studies and confirm that gated radionuclide ventriculography is a useful tool for monitoring adaptations to exercise in aortic regurgitation.

**489 Indexes of Intravascular Hemolysis, Quantification of Coagulation Factors, and Platelet Survival in Patients With Porcine Heterograft Valves**

MARK E. THOMPSON, JESSICA H. LEWIS, FREDERICK L. PORKOLAB, UTE HASIBA, and JOEL A. SPERO, *With the technical assistance of* JOHN WILSON and MICHAEL SNYDER

Ten patients with porcine heterograft valves who were not receiving anticoagulant agents were evaluated to determine effect of the valves on red blood cell survival, platelet activation and consumption, and chromium-51 platelet survival time. There was no evidence of significant intravascular hemolysis. The coagulation profile and the results of platelet function studies were normal. No statistically significant difference was observed between the platelet survival time calculated for the 10 unanticoagulated patients with porcine heterograft valves (half-life 3.2 ± 0.6 days) and the 11 normal control subjects (half-life 3.6 ± 0.6 days) ($p > 0.2$). The normal platelet survival time determined in patients with porcine heterograft valves is consistent with clinical experience indicating this device is associated with a low incidence of systemic embolization.

**492 Rheumatic Tricuspid Valve Disease: Two-Dimensional Echocardiographic, Hemodynamic, and Angiographic Correlations**

STEVEN J. DANIELS, GARY S. MINTZ, and MORRIS N. KOTLER

The authors studied 372 patients with rheumatic heart disease using 2-dimensional echocardiography; 23 (6%) had 2-dimensional echo evidence of tricuspid valve involvement. Nineteen patient with 2-dimensional echo tricuspid valve involvement underwent cardiac catheterization; only 4 patients had tricuspid stenosis. Twelve patients with 2-dimensional echo involvement had right ventriculography; 9 patients had predominant and significant tricuspid regurgitation. Thirty-one patients with no 2-dimensional echo involvement had right ventriculography; 11 had significant tricuspid regurgitation.

**497 Calcium Phosphorus Metabolism in Dialysis Patients With and Without Mitral Anular Calcium. Analysis of 30 Patients**

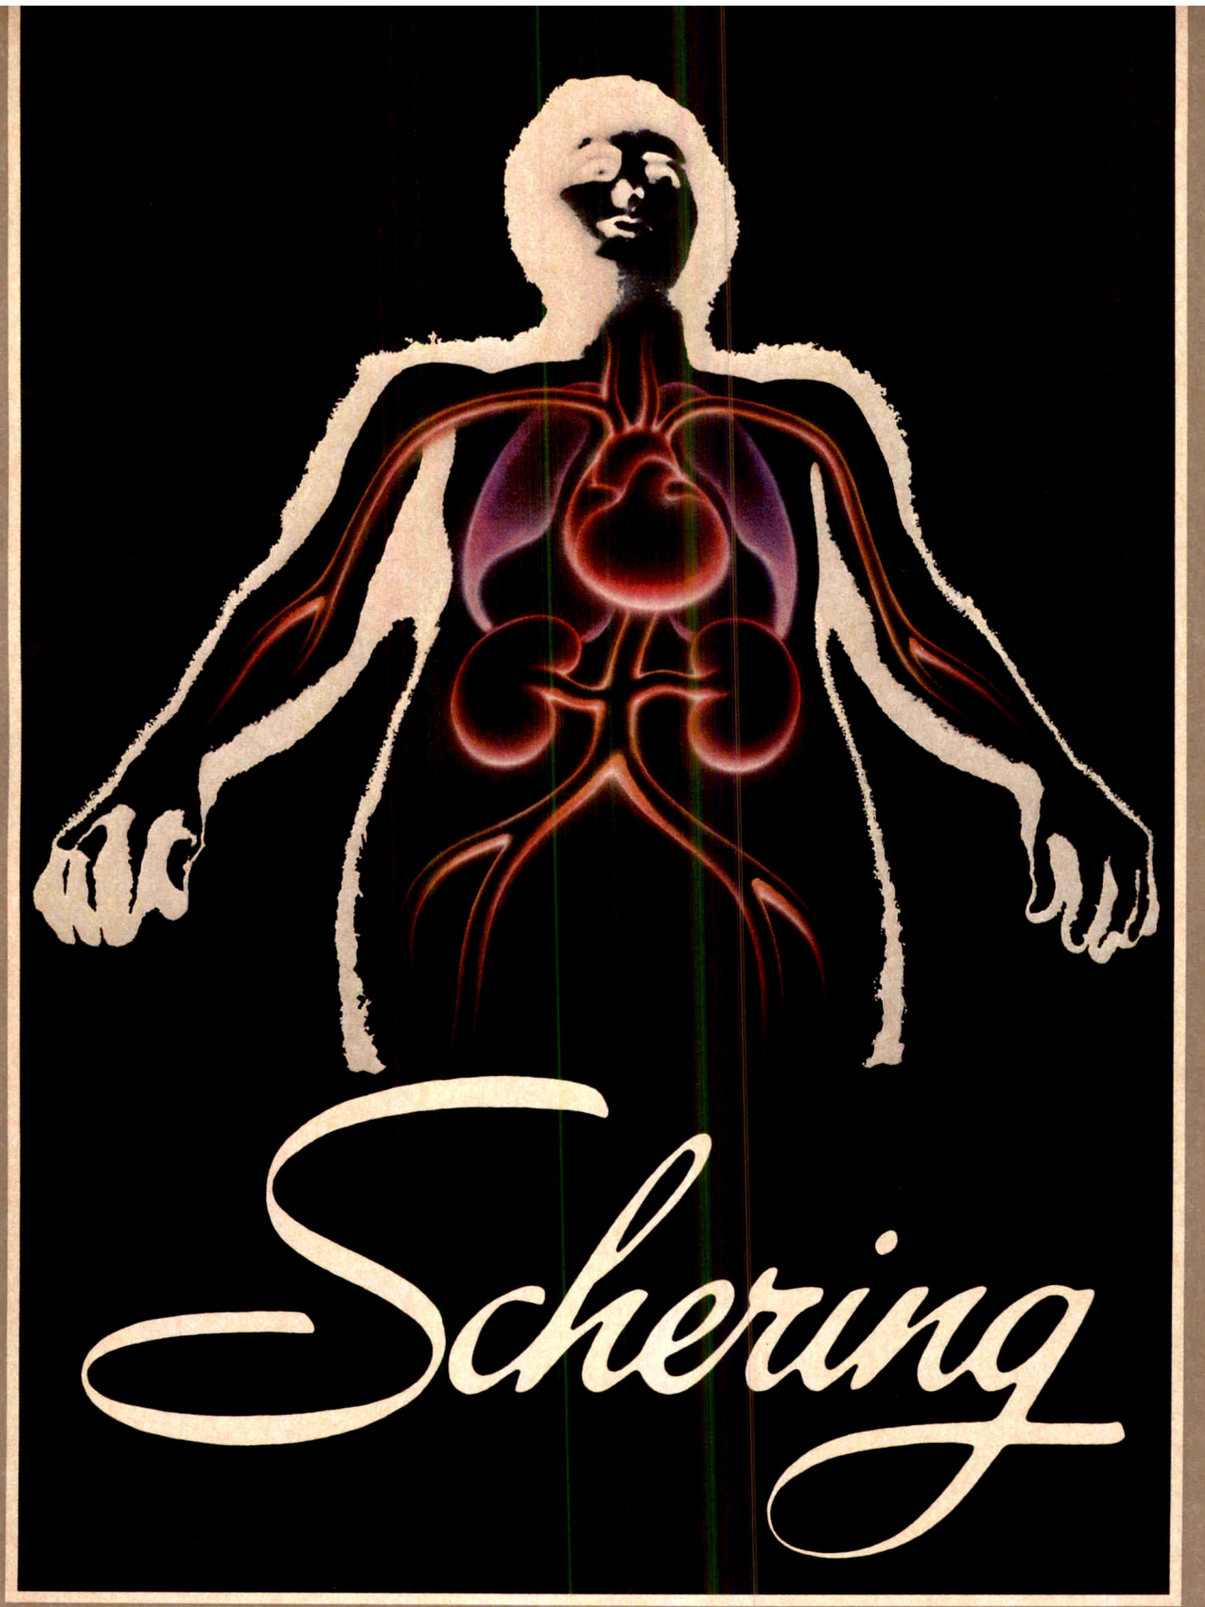
PASQUALE F. NESTICO, NICHOLAS L. DePACE, MORRIS N. KOTLER, LESLIE I. ROSE, JOSEPH H. BREZIN, CHARLES SWARTZ, GARY S. MINTZ, and ALLAN B. SCHWARTZ

In chronic dialysis patients mitral anular calcification (MAC) is frequently detected by M-mode echocardiography. In order to study calcium phosphorus metabolism in such patients, the biochemical findings in 10 dialysis patients with MAC were compared with those in 20 patients without MAC. Higher serum phosphorus levels 5.41 ± 0.82 mg/dl and calcium phosphorus products 49.7 ± 9.0 were found in MAC patients than in patients without MAC (phosphorus 4.09 ± 1.05 mg/dl, and calcium phosphorus product 34.46 ± 10.8). Both groups had increased parathyroid hormone levels, and there was no difference in the 2 groups with regard to age, supine predialysis systolic and diastolic blood pressure, and duration of dialysis. Thus, mitral anular calcification in dialysis patients is associated with disturbed calcium phosphorus metabolism and is independent of the level of parathyroid hormone.

## MYOCARDIAL HEART DISEASE

**501 Quantitative Morphologic Findings of the Myocardium in Idiopathic Dilated Cardiomyopathy**

FRANZ SCHWARZ, GERHARD MALL, HORST ZEBE, JOHANNES BLICKLE, HARALD DERKS, JOACHIM MANTHEY, and WOLFGANG KÜBLER



Left ventricular endomyocardial catheter biopsies were obtained from 73 patients. All patients had normal coronary arteriograms but abnormal electrocardiograms. Twenty-six patients had normal left ventricular function and 47 had contractile dysfunction. Myocardial fiber diameter, the volume fraction of interstitial fibrosis, and the intracellular volume fraction of myofibrils were determined from light microscopic morphometry, and these results were confirmed by electron microscopy. The coefficient of variation was 6% for determination of fiber diameter, 43% for interstitial fibrosis, and 3% for volume fraction of myofibrils. Fiber diameter and fibrosis showed a significant negative correlation and the volume fraction of myofibrils a significant positive correlation with the left ventricular ejection fraction. Thus, a reduction in the volume fraction of myofibrils and an increase in fibrosis are morphologic correlates of left ventricular dysfunction in patients with idiopathic dilated cardiomyopathy.

**507 Significance of Ventricular Tachycardia in Idiopathic Dilated Cardiomyopathy: Observations in 35 Patients**

SHOEI K. HUANG, JOSEPH V. MESSER, and PABLO DENES

Thirty-five patients with idiopathic dilated cardiomyopathy were studied in order to (1) evaluate the significance of ventricular tachycardia (VT), and (2) correlate the presence of ventricular arrhythmias with the hemodynamic findings. All patients had right and left heart catheterization and coronary angiography. Holter monitoring was done in all patients. Frequent ventricular premature beats were observed in 23 patients (83%). Twenty-one pa-

Continued on Page A30

1364-6029

**A familiar name in medicine becomes a new name in cardiovascular therapy.**

tients (60%) had nonsustained VT consisting of 3 to 46 beats (8 ± 4.7) with rates of 75 to 210 beats/min. No difference was found between patients with and without VT with regard to clinical or electrocardiographic findings or hemodynamic measurements. During follow-up study (mean 34.1 ± 16.6 months), 4 patients died. Two deaths were sudden (1 with and the other without previous VT); the other 2 patients died from intractable congestive heart failure and sepsis. It is concluded that (1) the incidence of ventricular arrhythmias in patients with idiopathic dilated cardiomyopathy is very high, (2) VT is common and usually occurs in the nonsustained form, and (3) there is no correlation between VT and the clinical and hemodynamic findings.

## ARRHYTHMIAS AND CONDUCTION DISTURBANCES

**513 Transesophageal Pacing for Prognostic Evaluation of Preexcitation Syndrome and Assessment of Protective Therapy**

GIUSEPPE CRITELLI, GINO GRASSI, FRANCESCO PERTICONE, FERNANDO COLTORTI, VITTORIO MONDA, and MARIO CONDORELLI

Decremental atrial pacing and elective induction of atrial fibrillation were performed using an esophageal lead in 5 patients with Wolff-Parkinson-White syndrome, before and after amiodarone therapy. In the control state, the mean cycle length with 1:1 conduction over accessory pathway was 232 ms. The average of the shortest R-R interval during atrial fibrillation was 198 ms and the mean ventricular rate was 196 beats/min. After amiodarone therapy, the shortest cycle length with 1:1 conduction increased in all patients, with a mean of 370 ms. During atrial fibrillation no preexcited beat was present in 2 patients, while the minimum preexcited R-R interval in the other 3 patients was 290, 240, and 370 ms, with the ventricular rate decreasing in all patients.

**519 Electrophysiologic Studies Before and After Myocardial Revascularization in Patients With Life-Threatening Ventricular Arrhythmias**

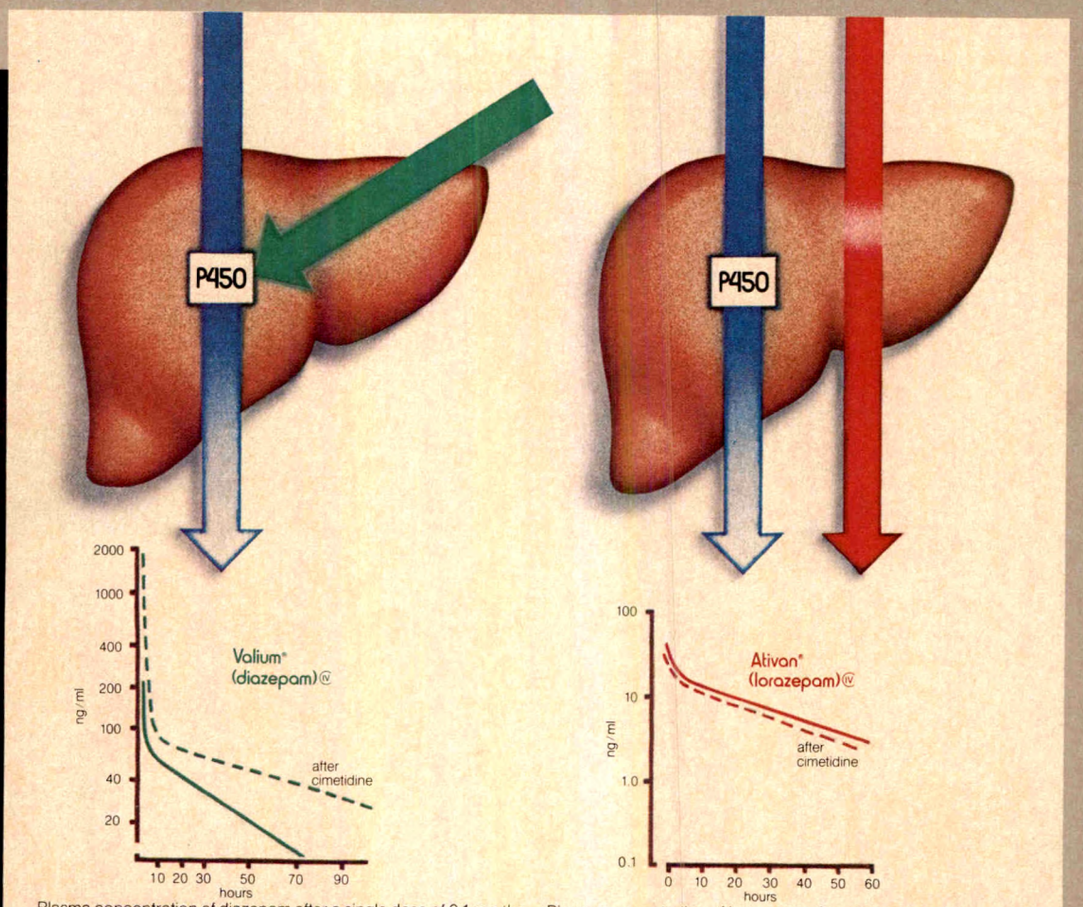
HASAN GARAN, JEREMY N. RUSKIN, JOHN P. DiMARCO, WAYNE M. DERKAC, CARY W. AKINS, WILLARD M. DAGGETT, W. GERALD AUSTEN, and MORTIMER J. BUCKLEY

Programmed cardiac stimulation was performed in 17 patients with severe proximal coronary artery disease and left ventricular ejection fractions >30% undergoing coronary artery bypass graft surgery after prehospital ventricular fibrillation (VF) or ventricular tachycardia (VT). Before surgery and off antiarrhythmic drugs, programmed cardiac stimulation induced VF in 4 patients and VT (≥5 beats) in 11 patients. When studied with programmed cardiac stimulation again an average of 19 days after coronary artery bypass graft surgery, 10 patients had no inducible VT or VF off all antiarrhythmic drugs, and 6 had induced VT. One patient had spontaneous VT. An effective antiarrhythmic regimen that suppressed inducible and spontaneous VT was defined by serial tests in 4 patients; 3 patients continued to manifest inducible VT with all drugs tested. All but 1 patient, in whom postoperative VT could not be suppressed, are free of arrhythmias after a mean follow-up period of 23 months (range 6 to 53).

**525 Electrophysiologic Mechanism of Exercise-Induced Sustained Ventricular Tachycardia**

RUEY J. SUNG, EDWARD N. SHEN, FRED MORADY, MELVIN M. SCHEINMAN, DAVID HESS, and ELIAS H. BOTVINICK

This report describes clinical and electrophysiologic findings in 12 patients in whom sustained ventricular tachycardia (VT) developed during treadmill exercise testing. Electrophysiologic studies provoked paroxysms of sustained VT identical to those observed during treadmill exercise testing in 10 patients. Seven patients had VT suggestive of a reentrant mechanism, as the VT could be initiated with programmed ventricular extrastimulation or terminated by overdrive ventricular pacing. The remaining 3 patients had VT suggestive of catecholamine-sensitive abnormal automaticity. In the latter 3 patients, VT could not be initiated with programmed electrical stimulation but could be provoked by intravenous isoproterenol infusion; furthermore, VT could not be terminated with overdrive ventricular pacing but could be abolished by discontinuing isoproterenol infusion. These observations suggest that the mechanism of exercise-induced VT varies among patients; it can be caused by either reentry or catecholamine-sensitive abnormal automaticity.



**531 Programmed Electrical Stimulation of the Heart in Coronary Artery Disease**

PETER R. KOWEY, EDWARD D. FOLLAND, ALFRED F. PARISI, and BERNARD LOWN

Patients who have had ventricular tachycardia or fibrillation frequently undergo electrophysiologic evaluation to permit the selection of appropriate therapy. However, these techniques have not been systematically applied to patients with coronary disease and no history of ventricular tachyarrhythmias. This study reports the results

# Ativan® Agent of Change
(lorazepam)

Plasma concentration of diazepam after a single dose of 0.1 mg/kg IV to a single subject administered before (—) and after (---) pretreatment with cimetidine—5 X 200 mg orally q6h. (Adapted from Klotz U, Reimann I: N Engl J Med *302*:1012-1014, 1980.)

Plasma concentration of lorazepam after single dose of 2 mg IV in 8 normal subjects before (—) and after (---) 7 days of treatment with cimetidine, 300 mg orally qid. (Adapted from Patwardhan RV, Yarborough GW, Desmond PV, et al: Gastroenterology *79*:912-916, 1980.)

## because it doesn't utilize the P450 system

All drugs inactivated by oxidative metabolism, including cimetidine and most benzodiazepines, utilize the cytochrome P450 oxidase enzyme system and, therefore, compete for it when given concomitantly. Patients on cimetidine, for example, are apt to experience excessive drowsiness when taking a benzodiazepine dependent on this system—because benzodiazepine clearance is delayed and plasma levels increase.

Ativan® (lorazepam) is inactivated by simple, one-step glucuronidation and is not subject to N-dealkylation or hydroxylation by the P450 system—unlike diazepam, chlordiazepoxide, clorazepate and prazepam, all CIV.

And, since Ativan does not compete for the P450 system, its elimination is not appreciably affected by concomitant use of cimetidine... one more reason why Ativan is becoming the anxiolytic of choice for an increasing number of physicians.

See important information on following page.

™

**Ativan®**
**for** (lorazepam)Ⓥ
**Anxiety**

**Brief Summary of Prescribing Information.**

**Indications and Usage:** Management of anxiety disorders or short-term relief of symptoms of anxiety or anxiety associated with depressive symptoms. Anxiety or tension associated with stress of everyday life usually does not require treatment with an anxiolytic.

Effectiveness in long-term use, i.e., more than 4 months, has not been assessed by systematic clinical studies. Reassess periodically usefulness of the drug for the individual patient.

**Contraindications:** Known sensitivity to benzodiazepines or acute narrow-angle glaucoma.

**Warnings:** Not recommended in primary depressive disorders or psychoses. As with all CNS-acting drugs, warn patients not to operate machinery or motor vehicles, and of diminished tolerance for alcohol and other CNS depressants.

Physical and Psychological Dependence: Withdrawal symptoms like those noted with barbiturates and alcohol have occurred following abrupt discontinuance of benzodiazepines (including convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Addiction-prone individuals, e.g. drug addicts and alcoholics, should be under careful surveillance when on benzodiazepines because of their predisposition to habituation and dependence. Withdrawal symptoms have also been reported following abrupt discontinuance of benzodiazepines taken continuously at therapeutic levels for several months.

**Precautions:** In depression accompanying anxiety, consider possibility for suicide.

For elderly or debilitated patients, initial daily dosage should not exceed 2mg to avoid oversedation. Terminate dosage gradually since abrupt withdrawal of any antianxiety agent may result in symptoms like those being treated: anxiety, agitation, irritability, tension, insomnia and occasional convulsions. Observe usual precautions with impaired renal or hepatic function. Where gastrointestinal or cardiovascular disorders coexist with anxiety, note that lorazepam has not been shown of significant benefit in treating gastrointestinal or cardiovascular component. Esophageal dilation occurred in rats treated with lorazepam for more than 1 year at 6mg/kg/day. No effect dose was 1.25mg/kg/day (about 6 times maximum human therapeutic dose of 10mg/day). Effect was reversible only when treatment was withdrawn within 2 months of first observation. Clinical significance is unknown; but use of lorazepam for prolonged periods and in geriatrics requires caution and frequent monitoring for symptoms of upper G.I. disease. Safety and effectiveness in children under 12 years have not been established.

ESSENTIAL LABORATORY TESTS: Some patients have developed leukopenia; some have had elevations of LDH. As with other benzodiazepines, periodic blood counts and liver function tests are recommended during long-term therapy.

CLINICALLY SIGNIFICANT DRUG INTERACTIONS: Benzodiazepines produce CNS depressant effects when administered with such medications as barbiturates or alcohol.

CARCINOGENESIS AND MUTAGENESIS: No evidence of carcinogenic potential emerged in rats during an 18-month study. No studies regarding mutagenesis have been performed.

PREGNANCY: Reproductive studies were performed in mice, rats, and 2 strains of rabbits. Occasional anomalies (reduction of tarsals, tibia, metatarsals, malrotated limbs, gastroschisis, malformed skull and microphthalmia) were seen in drug-treated rabbits without relationship to dosage. Although all these anomalies were not present in the concurrent control group, they have been reported to occur randomly in historical controls. At 40mg/kg and higher, there was evidence of fetal resorption and increased fetal loss in rabbits which was not seen at lower doses. Clinical significance of these findings is not known. However, increased risk of congenital malformations associated with use of minor tranquilizers (chlordiazepoxide, diazepam and meprobamate) during first trimester of pregnancy has been suggested in several studies. Because use of these drugs is rarely a matter of urgency, use of lorazepam during this period should almost always be avoided. Possibility that a woman of child-bearing potential may be pregnant at institution of therapy should be considered. Advise patients if they become pregnant to communicate with their physician about desirability of discontinuing the drug. In humans, blood levels from umbilical cord blood indicate placental transfer of lorazepam and its glucuronide.

NURSING MOTHERS: It is not known if oral lorazepam is excreted in human milk like other benzodiazepines. As a general rule, nursing should not be undertaken while on a drug since many drugs are excreted in milk.

**Adverse Reactions,** if they occur, are usually observed at beginning of therapy and generally disappear on continued medication or on decreasing dose. In a sample of about 3,500 anxious patients, most frequent adverse reaction is sedation (15.9%), followed by dizziness (6.9%), weakness (4.2%) and unsteadiness (3.4%). Less frequent are disorientation, depression, nausea, change in appetite, headache, sleep disturbance, agitation, dermatological symptoms, eye function disturbance, various gastrointestinal symptoms and autonomic manifestations. Incidence of sedation and unsteadiness increased with age. Small decreases in blood pressure have been noted but are not clinically significant, probably being related to relief of anxiety.

**Overdosage:** In management of overdosage with any drug, bear in mind multiple agents may have been taken. Manifestations of overdosage include somnolence, confusion and coma. Induce vomiting and/or undertake gastric lavage followed by general supportive care, monitoring vital signs and close observation. Hypotension, though unlikely, usually may be controlled with Levarterenol Bitartrate Injection U.S.P. Usefulness of dialysis has not been determined.

**Ativan®**
**for** (lorazepam)
**Anxiety**

***Dosage:*** **Individualize for maximum beneficial effects. Increase dose gradually when needed, giving higher evening dose before increasing daytime doses. Anxiety, usually 2-3mg/day given b.i.d. or t.i.d.; dosage may vary from 1 to 10mg/day in divided doses. For elderly or debilitated, initially 1-2mg/day; insomnia due to anxiety or transient situational stress, 2-4mg h.s.**

***How Supplied:*** **0.5, 1.0 and 2.0mg tablets.**

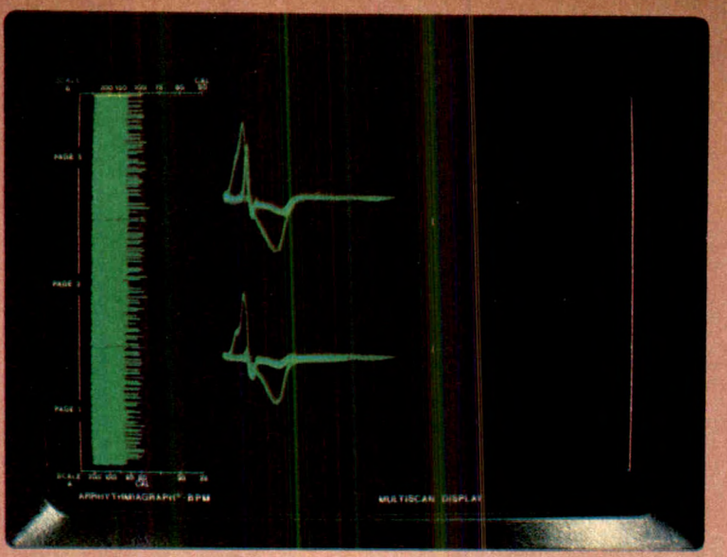
# CHAIRPERSON
## DEPARTMENT OF THORACIC-CARDIOVASCULAR SURGERY

Nassau Hospital, a 533-bed teaching hospital of SUNY at Stony Brook is seeking outstanding candidates to chair its cardio-thoracic department. Applicants should have demonstrated clinical, teaching and administrative skills as well as proven research productivity. Senior academic rank preferred (Professor or Associate Professor of Surgery). The department conducts a fully approved open heart program and a large volume of thoracic and vascular surgery is performed. There are hospital-supported fellowship positions and an opportunity for research activities. Send CV to John F. Aloia, M.D., Professor of Medicine, Chairman, Search Committee.

**NASSAU HOSPITAL**
259 FIRST STREET
MINEOLA, LONG ISLAND, NEW YORK 11501
*An Equal Opportunity Employer M/F*

## ASSOCIATE DIRECTOR CLINICAL RESEARCH



Our assignment for an outstanding pharmaceutical company requires a Board Eligible or Certified Cardiologist or a physician who has been specializing in Cardiology. Western sunbelt location. Excellent salary plus bonus and stock options.

Please mail cv to E. H. Sellmer, SELLMER & ASSOCIATES, P.O. Box 2883, Laguna Hills, CA 92653 or call (collect) (714) 768-5711.

**CARDIOLOGIST**

wanted to join three man cardiology-internal medicine group in Piedmont North Carolina. Please send curriculum vitae and references to Box 245, The American Journal of Cardiology, 875 Third Ave., New York, NY 10022.

**INVASIVE CARDIOLOGIST.** The Marshfield Clinic is seeking a Board certified/eligible cardiologist fully trained in all aspects of cardiac catheterization and angiography including PTCA. This individual would join eight cardiologists in an institution where over 1200 catheterizations and 450 open heart procedures are performed annually. Include CV with first letter. W. Bruce Fye, M.D.; Chairman, Department of Cardiology; Marshfield Clinic; Marshfield, Wisconsin. 54449.

# Critical Pattern Recognition.™
# The next wave in Holter data analysis.

## DEL MAR AVIONICS

No two patients have exactly the same ECG waveforms.

So to give you the most precise data analyzer for processing Holter tapes, we offer Critical Pattern Recognition.

Both the Trendsetter™ and Evaluator™ Data Analysis Systems are computer-controlled to recognize normal and variant ECG waveforms for each individual patient.

Waveforms are categorized, counted and compared to the patient's typical ECG, even though these normal patterns may vary throughout the monitoring period.

Moreover, analysis is halted automatically upon occurence of significant ectopic patterns, such as paired VEs/SVEs, R-on-T, V-Tach, SV-Tach, Ventricular Bigeminy, Bradycardia beats/runs and other critical events.

Dual 12-in CRT displays provide unsurpassed control of real-time data. And a wide selection of report formats (alphanumerics, graphics and analog trends) provide comprehensive permanent data for improved patient management.

Additionally, the Trendsetter can be updated to accommodate blood pressure, pacemaker analysis, dual floppy disks and other options. Choose only what you need now and add more capability later.

For more details on the first Holter data analysis systems to offer Critical Pattern Recognition, call or write: Del Mar Avionics, 1601 Alton Avenue, Irvine, California 92714, Telephone (714) 549-1500, or call toll free at (800) 854-0481, (in California 800/432-8446), Telex: 68-5621.

*Trendsetter and Evaluator are trademarks, Del Mar Avionics.*

of extrastimulation in 32 patients. Fourteen of the patients manifested ≥3 extraventricular responses to ≥3 right ventricular stimuli delivered during ventricular pacing. Twelve (86%) of these 14 had evidence of left ventricular dysfunction. The remaining 18 patients had ≤2 responses, and only 4 (22%) had ventricular dysfunction. Proximal 3-vessel coronary disease was more common in patients with ≥3 responses. Only 5 patients demonstrated complex arrhythmia during exercise testing or ambulatory monitoring. The induction of ventricular responses during extrastimulation may serve as an independent marker of electrical instability in the coronary population and is much more common in patients with ventricular dysfunction.

## CONGENITAL HEART DISEASE

**537 Juxtaductal Aortic Coarctation. Analysis of 84 Patients Studied Hemodynamically, Angiographically, and Morphologically After Age 1 Year**

D. LUKE GLANCY, ANDREW G. MORROW, ALLAN L. SIMON, and WILLIAM C. ROBERTS

Clinical, hemodynamic, angiographic, operative, and pathoanatomic features of juxtaductal aortic coarctation were correlated in 84 patients aged >1 year. Associated cardiovascular malformations occurred in 36 (43%). Aortic valve disease, patent ductus arteriosus, mitral valve disease, and ventricular septal defect, alone or in combination, occurred in 34. Systolic blood pressures were significantly elevated *for age* in 80% of all patients and in 90% of the 70 patients operated on. Of the latter, 3 (4%) died, and each had complex associated malformations. Blood pressure decreased after operation in most patients, but remained significantly increased for age late postoperatively in 25%. Detailed histologic studies of 72 coarctation specimens disclosed the luminal narrowing to be caused primarily by invagination of the elastic media of the posterior wall of aorta toward the ductus or ligamentum. Intimal jet lesions often caused further narrowing. The diameters of the aortic lumens correlated directly with the diameters measured angiographically and inversely with the prevalence of radiographically visible rib notching, the magnitude of collateral circulation seen angiographically, and, for luminal diameters ≥1.5 mm, the mean pressure gradient across the coarctation. The data suggest that with luminal diameters <1.5 mm, most blood reaches the descending aorta by collateral vessels.

**552 Hemodynamics and Intracardiac Conduction After Operative Repair of Tetralogy of Fallot**

DOLORES TAMER, GRACE S. WOLFF, PEDRO FERRER, ARTHUR S. PICKOFF, ALFONSO CASTA, ASHOK V. MEHTA, OTTO GARCIA, and ARTHUR GELBAND

Postoperative cardiac catheterization and electrophysiologic studies were done in 47 children 1 to 13 years after surgery for tetralogy of Fallot. Fifteen had arrhythmias, and 8 of these had ventricular extrasystoles. Abnormalities of intracardiac conduction were found in children with and without arrhythmia and were not related to residual hemodynamics. The prognostic significance of the arrhythmias and the conduction abnormalities will require further follow-up studies.

**557 Terminal Cardiac Electrical Activity in Pediatric Patients**

CHRISTINE KULL WALSH and EHUD KRONGRAD

To determine terminal cardiac electrical activity in children, 100 hospitalized pediatric patients were studied during the death process. The terminal cardiac electrical activity was bradycardic arrest throughout the death process in 88% of newborns, 67% of infants, and 64% of children. Although bradycardic arrest was still most common, the incidence of ventricular tachyarrhythmias increased in patients who were beyond the neonatal period, who weighed >2.23 kg, who had congenital heart disease, or who received cardiopulmonary resuscitation. No definite association could be established between arterial blood gases, electrolyte values, and type of terminal cardiac electrical activity. These clinical observations support electrophysiologic data suggesting that the development of ventricular fibrillation may be related to cardiac mass and the developing autonomic nervous system, and therefore that it may be less likely to occur in smaller hearts.

**562 Percutaneous Transluminal Angioplasty of Congenital Coarctation of the Aorta**

DONALD R. SPERLING, THOMAS J. DORSEY, MARSHALL ROWEN, and ALAN B. GAZZANIGA

Two cases in which congenital coarctation of the aorta was dilated using the Gruntzig technique are reported. The patients were aged 3 weeks and 11 months, and the gradients were reduced from 50 to 6 mm Hg and from 23 to 7 mm Hg. Surgery was postponed and symptoms abated in the 3-week-old infant. The older patient's pulses have remained palpable and blood pressures have remained equal for 8 months.

Continued on Page A39

# ISOPTIN® (verapamil HCl/Knoll) TABLETS OR NIFEDIPINE?

## Given these facts, which would you choose?

In angina of effort, Isoptin "...was more effective and better tolerated than nifedipine..."

B Subramanian, et al, *Am J Cardiol*, 1982[1]

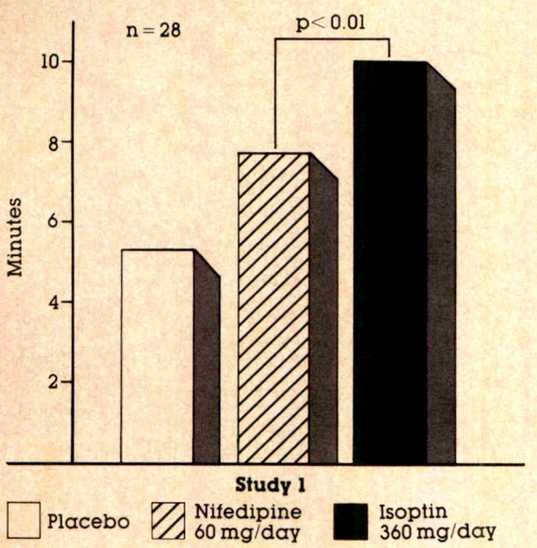
In angina of effort, Isoptin and nifedipine "...were equally effective...but side effects were more common with nifedipine."

JR Dawson, et al, *Br Heart J*, 1981[2]

In angina at rest, Isoptin and nifedipine "...are of similar efficacy...However, adverse effects occurred more frequently with nifedipine..."

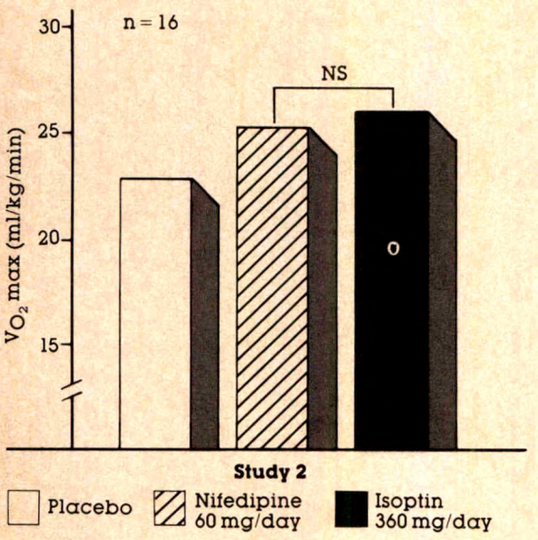
MD Winniford, et al, *Am J Cardiol*, 1982[3]

Please see last page of this advertisement for brief summary of prescribing information.



# ISOPTIN® (verapamil HCl/Knoll) TABLETS OR NIFEDIPINE?

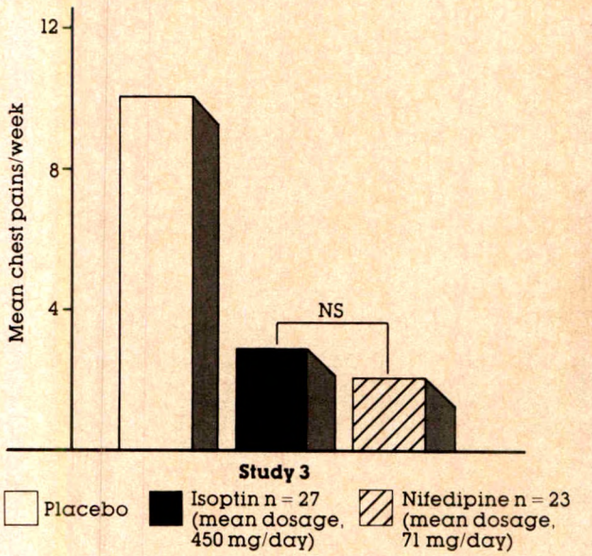
Over 20 years and 18 million patient years of experience make Isoptin the most thoroughly studied of the calcium channel blockers. Is it any wonder that Isoptin — not nifedipine or diltiazem — is indicated for first-line therapy of all forms of angina pectoris?



Before making your choice, consider the following clinical results. And consider the long history of safety and efficacy that makes Isoptin one of the most widely prescribed calcium channel blockers in the world.

# Isoptin was equal or superior in efficacy in angina of effort

Mean Maximal Exercise Time
**ISOPTIN MORE EFFECTIVE**[1]



Mean Maximal Work Capacity
**ISOPTIN AS EFFECTIVE**[2]

# Isoptin was equal in efficacy in angina at rest

Angina Frequency
**ISOPTIN AS EFFECTIVE**[3]

# In all forms of angina, Isoptin caused fewer side effects

**Study 1:** "Few adverse reactions were noted with verapamil (Isoptin); none were serious, and none required discontinuation ... In contrast, 7 of the 32 patients developed side effects during nifedipine therapy serious enough to require its withdrawal..."[1]

**Study 2:** "...side effects with nifedipine occur frequently...In contrast, verapamil (Isoptin) was relatively free from side effects apart from constipation..."[2]

**Study 3:** "...adverse reactions limited the amount of nifedipine that could be administered; in contrast, side effects during verapamil (Isoptin) administration were relatively minor and did not alter the dosage."[3]

Please see next page for brief summary of prescribing information.

2090

Isoptin is contraindicated in severe left ventricular dysfunction, hypotension (systolic pressure <90 mm Hg) or cardiogenic shock, sick sinus syndrome (if no pacemaker is present), and second- or third-degree AV block.

# ISOPTIN®

## (verapamil HCl/Knoll) 80 mg/120 mg Tablets

## The choice becomes easier, once you have the facts.

## ISOPTIN® TABLETS
(verapamil HCl/Knoll)

**Contraindications:** Severe left ventricular dysfunction (see *Warnings*), hypotension (systolic pressure <90 mm Hg) or cardiogenic shock, sick sinus syndrome (if no pacemaker is present), 2nd- or 3rd-degree AV block. **Warnings:** ISOPTIN should be avoided in patients with severe left ventricular dysfunction (e.g., ejection fraction <30%) or moderate to severe symptoms of cardiac failure. Control milder heart failure with optimum digitalization and/or diuretics before ISOPTIN is used. ISOPTIN may occasionally produce hypotension (usually asymptomatic, orthostatic, mild, and controlled by decrease in ISOPTIN dose). Occasional elevations of liver enzymes have been reported; patients receiving ISOPTIN should have liver enzymes monitored periodically. Patients with atrial flutter/fibrillation and an accessory AV pathway (e.g., W-P-W or L-G-L syndromes) may develop a very rapid ventricular response after receiving ISOPTIN (or digitalis). Treatment is usually D.C.-cardioversion. AV block may occur (3rd degree, 0.8%). Development of marked 1st-degree block or progression to 2nd- or 3rd-degree block requires reduction in dosage or, rarely, discontinuation and institution of appropriate therapy. Sinus bradycardia, 2nd-degree AV block, sinus arrest, pulmonary edema, and/or severe hypotension were seen in some critically ill patients with hypertrophic cardiomyopathy who were treated with ISOPTIN. **Precautions:** ISOPTIN should be given cautiously to patients with impaired hepatic function (in severe dysfunction use about 30% of the normal dose) or impaired renal function, and patients should be monitored for abnormal prolongation of the PR interval or other signs of overdosage. Studies in a small number of patients suggest that concomitant use of ISOPTIN and beta blockers may be beneficial in patients with chronic stable angina. Combined therapy can also have adverse effects on cardiac function. Therefore, until further studies are completed, ISOPTIN should be used alone, if possible. If combined therapy is used, patients should be monitored closely. Combined therapy with ISOPTIN and propranolol should usually be avoided in patients with AV conduction abnormalities and/or depressed left ventricular function or in patients who have also recently received methyldopa. Chronic ISOPTIN treatment increases serum digoxin levels by 50% to 70% during the first week of therapy, which can result in digitalis toxicity. The digoxin dose should be reduced when ISOPTIN is given, and the patient carefully monitored. ISOPTIN may have an additive hypotensive effect in patients receiving blood-pressure-lowering agents. Disopyramide should not be given within 48 hours before or 24 hours after ISOPTIN administration. Until further data are obtained, combined ISOPTIN and quinidine therapy in patients with hypertrophic cardiomyopathy should probably be avoided, since significant hypotension may result. Adequate animal carcinogenicity studies have not been performed. One study in rats did not suggest a tumorigenic potential, and verapamil was not mutagenic in the Ames test. *Pregnancy Category C*: There are no adequate and well-controlled studies in pregnant women. This drug should be used during pregnancy, labor, and delivery only if clearly needed. It is not known whether verapamil is excreted in breast milk; therefore, nursing should be discontinued during ISOPTIN use. **Adverse Reactions:** Hypotension (2.9%), peripheral edema (1.7%), AV block: 3rd degree (0.8%), bradycardia: HR<50/min (1.1%), CHF or pulmonary edema (0.9%), dizziness (3.6%), headache (1.8%), fatigue (1.1%), constipation (6.3%), nausea (1.6%). The following reactions, reported in less than 0.5%, occurred under circumstances where a causal relationship is not certain: confusion, paresthesia, insomnia, somnolence, equilibrium disorders, blurred vision, syncope, muscle cramps, shakiness, claudication, hair loss, maculae, and spotty menstruation. Overall continuation rate of 94.5% in 1,166 patients. **How Supplied:** ISOPTIN (verapamil HCl) is supplied in 80 mg and 120 mg sugar-coated tablets.
July 1982 2068

## MISCELLANEOUS TOPICS

**565 Subepicardial Adipose Tissue Producing Echocardiographic Appearance of Pericardial Effusion. Documentation by Computed Tomography and Necropsy**

JEFFREY M. ISNER, BARBARA L. CARTER, WILLIAM C. ROBERTS, and MARK S. BANKOFF

Computed tomographic imaging and necropsy examination were used to study the basis for an isolated anterior echo-free space in 3 patients and a combination anteroposterior echo-free space in 2 patients. In all 5 patients the echo-free spaces were determined to represent subepicardial adipose tissue. In 2 patients with cardiac neoplasms, the echo-free space caused by fat was interposed between the overlying neoplasm and the underlying myocardium. These findings confirm that subepicardial fat is the basis for the finding of an isolated anterior echo-free space as well as for echocardiograms previously reported as being falsely positive for pericardial effusion in patients with a cardiac neoplasm.

**570 Exercise-Induced Cardiac Dysfunction in Sickle Cell Anemia. A Radionuclide Study**

WESLEY COVITZ, CASIMIR EUBIG, IAN C. BALFOUR, RAJINDER JERATH, BRUCE S. ALPERT, WILLIAM B. STRONG, and ROBERT H. DuRANT, *With the technical assistance of* BONNIE G. HADDEN

The objective of this study was to characterize the abnormalities of cardiac function that result in poor exercise performance in adolescents with sickle cell anemia. Cardiac performance was studied by radionuclide angiography at rest and during exercise in 22 patients and 12 control subjects. At maximal exercise, the heart rate, ejection fraction, and percent increase in cardiac output were significantly lower than normal. Four subjects had an abnormal ejection fraction response in association with electrocardiographic signs of ischemia. The cardiac output response was related to the severity of anemia. A decrease in left ventricular end-diastolic volume at maximal exercise was noted in the sickle cell patients and was associated with a reduced cardiac output response. Exercise intolerance appears, therefore, to be due to the demands put on the circulation by the anemia itself; however, the ability of the heart to cope is reduced as abnormalities of systolic and diastolic function develop.

## METHODS

**576 Variability of Digitized Echocardiography: Size, Source, and Means of Reduction**

CHARLES POLLICK, PETER J. FITZGERALD, and RICHARD L. POPP

The technical and biologic variability of digitized M-mode echocardiographic measurements of the left ventricle was assessed. Technical variability was small, with correlation coefficients of 0.70 to 1.00 between and within observers. Biologic variability was large, with expected normal differences between 2 measurements (95% confidence limits) of 11 to 55%, and 37 to 106% for standard dimensions and rates of change, respectively. By averaging measurements of 5 beats from each of 2 days, the expected normal differences are reduced to 6 to 32%, and 23 to 63% for standard dimensions and rates of change. This study emphasizes the large biologic variability and rates of change of digitized left ventricular measurements. Normal variation between studies can be reduced and real physiologic or pathologic changes perceived best if many beats from more than 1 day are measured.

**583 Left Ventricular Isovolumic Pressure Decay and Diastolic Mechanics After Postextrasystolic Potentiation and During Exercise**

JOHN D. CARROLL, RENÉ WIDMER, OTTO M. HESS, HEINZ O. HIRZEL, and HANS P. KRAYENBUEHL

Left ventricular contraction, relaxation, and diastolic mechanics were examined in man after postextrasystolic potentiation and contrasted with dynamic exercise. Twelve patients had extrasystoles induced during left ventricular cineangiography (PES Group). Six patients with no or minimal cardiovascular disease underwent exercise (Exercise Group). From high-fidelity pressure curves the time constant of relaxation, a theoretical baseline for isovolumic pressure decay, and the lowest diastolic pressure were determined. Frame-by-frame analysis was used to quantitate filling and to construct diastolic pressure-volume relations. It is concluded that postextrasystolic potentiation, like dynamic exercise, enhances shortening and augments restoring forces by producing a smaller end-systolic chamber. Yet postextrasystolic potentiation prolongs relaxation. Diastolic mechanics are not subsequently altered, suggesting that enhanced restoring forces counterbalance the slower inactivation. With exercise diastolic filling is enhanced, with both more rapid pressure decay and increased restoring forces.

## EXPERIMENTAL STUDIES

591 **Comparison of the Antithrombotic Action of Calcium Antagonist Drugs With Dipyridamole in Dogs**

CHARLES W. PUMPHREY, VALENTIN FUSTER, MRINAL K. DEWANJEE, JAMES H. CHESEBRO, RONALD E. VLIETSTRA, and MICHAEL P. KAYE, *With the technical assistance of* JOHN RITTER and JAMES ROSEMARK

Because platelet activation involves a flux of calcium into the cytoplasm, calcium antagonist drugs such as verapamil and nifedipine may have value as platelet inhibitor drugs. Thus, the antithrombotic effects of these drugs in preventing indium-111–labeled platelet deposition and thrombus formation in bilateral polytetrafluoroethylene femorofemoral artery grafts in mongrel dogs were compared with those of dipyridamole, an established platelet inhibitor drug, and isotonic saline solution. Verapamil, nifedipine, and dipyridamole significantly reduced indium-111–labeled platelet deposition and the weight of thrombus in the grafts after 3 hours of blood flow compared with saline infusion. The calcium antagonist drugs are as effective as dipyridamole in preventing thrombus formation through inhibition of platelet deposition in this model but require further study in humans.

596 **Influence of Intracoronary Platelet Aggregation on Ventricular Electrical Properties During Partial Coronary Artery Stenosis**

PETER R. KOWEY, RICHARD L. VERRIER, BERNARD LOWN, and ROBERT I. HANDIN

Clinical studies have suggested that drugs which inhibit platelet function may protect against sudden death after myocardial infarction. That intracoronary platelet aggregation causes cardiac arrhythmia, however, has not been proven. Induction of coronary stenoses in dogs resulted in cyclical flow reductions, previously demonstrated to be associated with endothelial formation of platelet aggregates. These reductions were accompanied by a significant lowering of the vulnerable period threshold. Prostacyclin and indomethacin each caused a decrease in the frequency and intensity of the coronary flow reductions and returned the ventricular fibrillation threshold to control levels. The mechanism of flow reduction appears to be mechanical blockade of the vessel lumen by platelet thrombi. These results suggest that intracoronary platelet aggregation contributes to electrical instability and may predispose to ventricular tachyarrhythmias. A model is thus available for further work on the role of antiplatelet drugs in the prevention of sudden cardiac death.

# One system your cardiology

# that meets all imaging needs.

The cart-mounted mobile system can be taken anywhere it's needed. Compact and totally self-contained, it includes an integral strip chart recorder, a video tape recorder, and an alphanumeric keyboard.

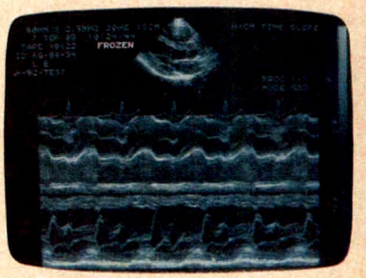
Hewlett-Packard's new Cardiac Imaging System (77020AC) is a full-featured ultrasound system specifically designed for echocardiography. Applying HP's own microprocessor-based, phased-array, imaging technology, it provides all the imaging, storage, and cardiac performance analysis needed for rapid, quality cardiology workups.

**Improved quantitative evaluations.**
HP's new imaging system allows the echocardiographer to make thorough quantitative cardiac evaluations either during the exam or afterwards on prerecorded tape. Cardiac dimensions at end-systole and end-diastole can easily be calculated right on the display screen. For greater accuracy, the same measurement can even be made from the same or differing images using the simultaneous sector scan and M-mode display. And the system computes the average value automatically.

In addition, valve areas, ejection fraction values, slopes, and ventricular volumes are all calculated on the display screen. And you can select from a menu of accepted methods for calculating chamber volumes.

**In-depth qualitative analysis.**
After examination, a hard-copy report of the findings can be made. This report lists both measurements and computations made during the exam, and can include clinical observations and patient identification information.

For complete image storage and recall, the integrated video tape system automatically searches for and stops at selected points on the tape.



**Simplified operation, superior image quality.**
All major controls are conveniently located in one central area. And because the system requires only a minimum of control adjustment, the operator can move rapidly from patient to patient. Our built-in self-test capability assures the operator that everything is functioning properly.

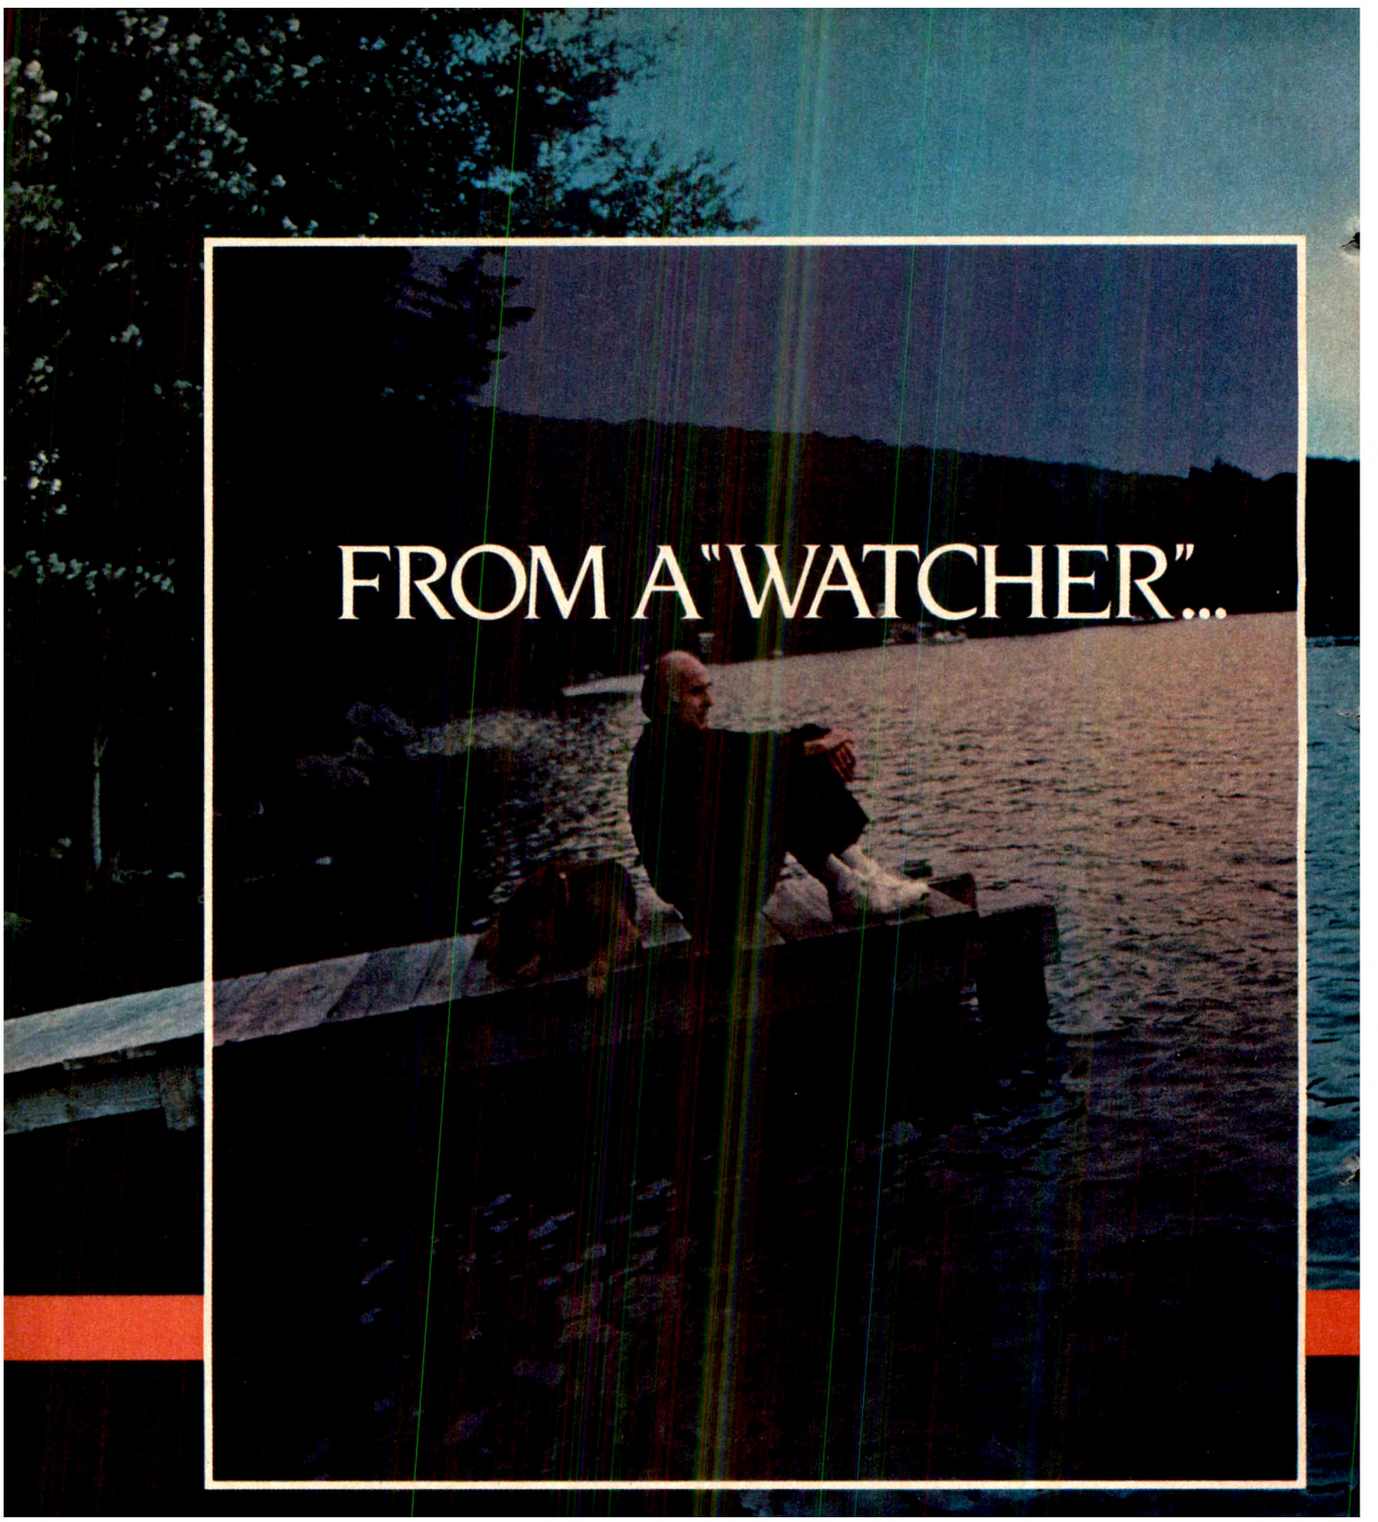
Quantitative analysis on both the 2-dimensional image and the M-mode is easily accomplished by using an electronic cursor and calipers.

Along with exceptional operating ease, the system offers extraordinarily high resolution images and a wide field of view. And since the entire field of view is in focus *at all times*, shallow as well as deep structures can be seen on the same picture.

**The computer-based advantages of the HP system.**
Unlike conventional echocardiographs, HP's new Cardiac Imaging System is built around three high-speed microcomputers. They provide software-controlled imaging and data processing and a wide range of

You can select 2-dimensional sector, M-mode, and independent dual ECG trigger presentations simultaneously on the same screen.

programs for imaging alternatives. The system can be updated by changing its electronic "chips." And digital electronics and microcomputer circuitry also ensure a new level of dependability and allow for future enhancements.



In the future, computerization will play an ever-increasing role in ultrasonography. Today, Hewlett-Packard already offers a computer-based ultrasound system.

For more complete information on the new Hewlett-Packard Model 77020AC, contact your local HP sales office, or write to the Inquiries Manager, Cardiac Imaging Systems, Hewlett-Packard, 100 Fifth Avenue, Waltham, MA 02254.

FROM A "WATCHER"...

Your angina patients* can become more active now...with PROCARDIA protection. They'll be pain-free more of the time[1] and find their need for nitroglycerin greatly reduced.[2] They'll be able to work harder, exercise more.[3] And be more active participants in their own lives once again.

*feeling better...doing more*

# PROCARDIA®
## (NIFEDIPINE) *Capsules 10 mg*

*Procardia is indicated for the management of:

- Confirmed vasospastic angina.
- Angina where the clinical presentation suggests a possible vasospastic component.
- Chronic stable angina without evidence of vasospasm in patients who remain symptomatic despite adequate doses of beta blockers and/or nitrates or who cannot tolerate these agents. In chronic stable angina (effort-associated angina) Procardia has been effective in controlled trials of up to eight weeks duration in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness and evaluation of long-term safety in these patients are incomplete.

*feeling better...doing more*

# PROCARDIA®
# (NIFEDIPINE) *Capsules 10 mg*

## *–Usual effective dosage is 30-60 mg/day*

For most patients, titrate over 7 to 14 days, using the patient's blood pressure response, attack frequency, sublingual nitroglycerin intake and activity level as a guide. Titration may be more rapid (e.g., 3 days) if symptoms warrant and the patient is observed closely.

Because Procardia decreases peripheral vascular resistance, careful monitoring of blood pressure during initial administration and titration is suggested. Close observation is especially recommended for patients taking medication known to lower blood pressure.

## *–Offers a favorable safety profile*

Most frequently reported side effects, usually mild, are dizziness or lightheadedness, peripheral edema, nausea, weakness, headache and flushing, each occurring in about 10% of patients, transient hypotension in about 5%, palpitation in about 2% and syncope in about 0.5%.

**BRIEF SUMMARY**
**PROCARDIA® CAPSULES** For Oral Use
(nifedipine)

**INDICATIONS AND USAGE: I. Vasospastic Angina: PROCARDIA** (nifedipine) is indicated for the management of vasospastic angina confirmed by any of the following criteria: 1) classical pattern of angina at rest accompanied by ST segment elevation, 2) angina or coronary artery spasm provoked by ergonovine, or 3) angiographically demonstrated coronary artery spasm. In those patients who have had angiography, the presence of significant fixed obstructive disease is not incompatible with the diagnosis of vasospastic angina, provided that the above criteria are satisfied. PROCARDIA may also be used where the clinical presentation suggests a possible vasospastic component but where vasospasm has not been confirmed, e.g., where pain has a variable threshold on exertion or in unstable angina where electrocardiographic findings are compatible with intermittent vasospasm, or when angina is refractory to nitrates and/or adequate doses of beta blockers.

**II. Chronic Stable Angina (Classical Effort-Associated Angina):** PROCARDIA is indicated for the management of chronic stable angina (effort-associated angina) without evidence of vasospasm in patients who remain symptomatic despite adequate doses of beta blockers and/or organic nitrates or who cannot tolerate those agents.

In chronic stable angina (effort-associated angina) PROCARDIA has been effective in controlled trials of up to eight weeks duration in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness and evaluation of long-term safety in those patients are incomplete.

Controlled studies in small numbers of patients suggest concomitant use of PROCARDIA and beta blocking agents may be beneficial in patients with chronic stable angina, but available information is not sufficient to predict with confidence the effects of concurrent treatment, especially in patients with compromised left ventricular function or cardiac conduction abnormalities. When introducing such concomitant therapy, care must be taken to monitor blood pressure closely since severe hypotension can occur from the combined effects of the drugs. (See Warnings.)

**CONTRAINDICATIONS:** Known hypersensitivity reaction to PROCARDIA.

**WARNINGS: Excessive Hypotension:** Although in most patients, the hypotensive effect of PROCARDIA is modest and well tolerated, occasional patients have had excessive and poorly tolerated hypotension. These responses have usually occurred during initial titration or at the time of subsequent upward dosage adjustment, and may be more likely in patients on concomitant beta blockers.

Severe hypotension and/or increased fluid volume requirements have been reported in patients receiving PROCARDIA together with a beta blocking agent who underwent coronary artery bypass surgery using high dose fentanyl anesthesia. The interaction with high dose fentanyl appears to be due to the combination of PROCARDIA and a beta blocker, but the possibility that it may occur with PROCARDIA alone, with low doses of fentanyl, in other surgical procedures, or with other narcotic analgesics cannot be ruled out.

**Increased Angina:** Occasional patients have developed well documented increased frequency, duration or severity of angina on starting PROCARDIA or at the time of dosage increases. The mechanism of this response is not established but could result from decreased coronary perfusion associated with decreased diastolic pressure with increased heart rate, or from increased demand resulting from increased heart rate alone.

**Beta Blocker Withdrawal:** Patients recently withdrawn from beta blockers may develop a withdrawal syndrome with increased angina, probably related to increased sensitivity to catecholamines. Initiation of PROCARDIA treatment will not prevent this occurrence and might be expected to exacerbate it by provoking reflex catecholamine release. There have been occasional reports of increased angina in a setting of beta blocker withdrawal and PROCARDIA initiation. It is important to taper beta blockers if possible, rather than stopping them abruptly before beginning PROCARDIA.

**Congestive Heart Failure:** Rarely, patients, usually receiving a beta blocker, have developed heart failure after beginning PROCARDIA. Patients with tight aortic stenosis may be at greater risk for such an event.

**PRECAUTIONS: General: Hypotension:** Because PROCARDIA decreases peripheral vascular resistance, careful monitoring of blood pressure during the initial administration and titration of PROCARDIA is suggested. Close observation is especially recommended for patients already taking medications that are known to lower blood pressure. (See Warnings.)

**Peripheral edema:** Mild to moderate peripheral edema, typically associated with arterial vasodilation and not due to left ventricular dysfunction, occurs in about one in ten patients treated with PROCARDIA. This edema occurs primarily in the lower extremities and usually responds to diuretic therapy. With patients whose angina is complicated by congestive heart failure, care should be taken to differentiate this peripheral edema from the effects of increasing left ventricular dysfunction.

**Drug interactions:** Beta-adrenergic blocking agents: (See Indications and Warnings.) Experience in over 1400 patients in a non-comparative clinical trial has shown that concomitant administration of PROCARDIA and beta-blocking agents is usually well tolerated, but there have been occasional literature reports suggesting that the combination may increase the likelihood of congestive heart failure, severe hypotension or exacerbation of angina.

Long-acting nitrates: PROCARDIA may be safely co-administered with nitrates, but there have been no controlled studies to evaluate the antianginal effectiveness of this combination.

Digitalis: Administration of PROCARDIA with digoxin increased digoxin levels in nine of twelve normal volunteers. The average increase was 45%. Another investigator found no increase in digoxin levels in thirteen patients with coronary artery disease. In an uncontrolled study of over two hundred patients with congestive heart failure during which digoxin blood levels were not measured, digitalis toxicity was not observed. Since there have been isolated reports of patients with elevated digoxin levels, it is recommended that digoxin levels be monitored when initiating, adjusting, and discontinuing PROCARDIA to avoid possible over- or under-digitalization.

Carcinogenesis, mutagenesis, impairment of fertility: When given to rats prior to mating, nifedipine caused reduced fertility at a dose approximately 30 times the maximum recommended human dose.

Pregnancy: Category C. Please see full prescribing information with reference to teratogenicity in rats, embryotoxicity in rats, mice and rabbits, and abnormalities in monkeys.

**ADVERSE REACTIONS:** The most common adverse events include dizziness or light-headedness, peripheral edema, nausea, weakness, headache and flushing each occurring in about 10% of patients, transient hypotension in about 5%, palpitation in about 2% and syncope in about 0.5%. Syncopal episodes did not recur with reduction in the dose of PROCARDIA or concomitant antianginal medication. Additionally, the following have been reported: muscle cramps, nervousness, dyspnea, nasal and chest congestion, diarrhea, constipation, inflammation, joint stiffness, shakiness, sleep disturbances, blurred vision, difficulties in balance, dermatitis, pruritus, urticaria, fever, sweating, chills, and sexual difficulties. Very rarely, introduction of PROCARDIA therapy was associated with an increase in anginal pain, possibly due to associated hypotension.

In addition, more serious adverse events were observed, not readily distinguishable from the natural history of the disease in these patients. It remains possible, however, that some or many of these events were drug related. Myocardial infarction occurred in about 4% of patients and congestive heart failure or pulmonary edema in about 2%. Ventricular arrhythmias or conduction disturbances each occurred in fewer than 0.5% of patients.

**Laboratory Tests:** Rare, mild to moderate, transient elevations of enzymes such as alkaline phosphatase, CPK, LDH, SGOT, and SGPT have been noted, and a single incident of significantly elevated transaminases and alkaline phosphatase was seen in a patient with a history of gall bladder disease after about eleven months of nifedipine therapy. The relationship to PROCARDIA therapy is uncertain. These laboratory abnormalities have rarely been associated with clinical symptoms. Cholestasis, possibly due to PROCARDIA therapy, has been reported twice in the extensive world literature.

**HOW SUPPLIED:** Each orange, soft gelatin PROCARDIA CAPSULE contains 10 mg of nifedipine. PROCARDIA CAPSULES are supplied in bottles of 100 (NDC 0069-2600-66), 300 (NDC 0069-2600-72), and unit dose (10x10) (NDC 0069-2600-41). The capsules should be protected from light and moisture and stored at controlled room temperature 59° to 77°F (15° to 25°C) in the manufacturer's original container.

# Millar Catheter-Tip Pressure Transducers are now more stable and durable than ever before !

## Our new MT-10™ Pressure Sensor makes it all possible

The totally new MIKRO-TIP® MT-10™ pressure sensor, manufactured with the latest semiconductor technology, is extremely durable, with several times the impact resistance of previous sensors. It is insensitive to ambient light and to changes in temperature and provides accurate, high fidelity pressure measurements with exceptional baseline stability.

In addition, transducers with the new MT-10™ pressure sensor have all the excellent features of our previous transducers, such as good linearity, negligible hysteresis, large output signal with good signal-to-noise ratio, and high frequency response for the detection of intracavitary sounds.

The new MT-10™ pressure sensor has been used selectively in transducers for many months and is now the standard pressure sensor in all MIKRO-TIP® Catheter Pressure Transducers, size 5F (1.7mm o.d.) and larger. These transducers are compatible with existing Millar accessories.

Millar offers a wide variety of catheter pressure transducers for applications in Cardiology, Urology and Gastroenterology. Models are available with one or more pressure sensors optionally with lumen(s) for simultaneous fluid sampling or high speed injection. Also available are models with a fluid-velocity sensor and one or more pressure sensors. Catheter sizes range from 3F (1mm o.d.) through 9F (3mm o.d.). You select the size and configuration that's right for your specific need.

***For complete information contact Millar, the world's largest manufacturer of high fidelity catheter-tip pressure transducers for clinical and research applications.***

CORONARY HEART DISEASE

# Effect of Coronary Artery Bypass Grafting on Subsequent Hospitalization

WILLIAM M. HAMILTON, PhD, KARL E. HAMMERMEISTER, MD, TIMOTHY A. DeROUEN, PhD, MAY S. ZIA, MS, and HAROLD T. DODGE, MD

**The rates of hospitalization during follow-up for a matched pair cohort of medically and surgically treated patients from the Angiography Registry of Seattle Heart Watch were compared. Medically and surgically treated patients were matched according to extent of disease, left ventricular ejection fraction, age, and 3 other survival rate-related characteristics. There was a 26% reduction in cardiovascular hospitalizations in the surgically treated patients (19%/year) compared with the medically treated patients (26%/year). This was due to a significant reduction in hospitalization rate for myocardial infarction (surgically treated patients 1.1%/year, medically treated patients 2.6%/year), and for other cardiovascular reasons (surgically treated patients 12.5%/year, medically treated patients 15.7%/year). No significant (p = 0.146) reduction occurred in hospitalization rate for chest pain not due to myocardial infarction (surgically treated patients 5.6%/year, medically treated patients 7.7%/year). When the perioperative infarctions are included for the surgical cohort, the overall myocardial infarction rate is not significantly different (p = 0.173) between the 2 treatment groups (surgically treated patients 1.9%/year, medically treated patients 2.6%/year). Acute myocardial infarction was an uncommon reason for hospitalization, accounting for only 8% (55 of 685) of all cardiovascular hospitalizations, and was not related to the number of stenotic vessels in medically treated patients.**

There is now reasonable evidence to document the efficacy of coronary artery bypass grafting in prolonging survival (left main disease[1] and 3-vessel disease[2]) and in relieving symptoms of severe angina.[3,4] However, the efficacy of coronary artery bypass surgery in reducing other measures of morbidity such as frequency of hospitalization has not been previously reported. The purpose of this report is to compare the rates of hospitalization during follow-up of a well-characterized, nonrandomized, matched pair cohort of medically and surgically treated patients with coronary artery disease from the Angiography Registry of Seattle Heart Watch.

From the Veterans Administration Medical Center, and the Division of Cardiology and Department of Biostatistics, University of Washington, Seattle, Washington. This research was supported by Veterans Administration Institutional funds, Washington, D.C., and Grant HL 18805 from the National Heart, Lung, and Blood Institute, the National Institutes of Health, Bethesda, Maryland. Manuscript received March 16, 1982; revised manuscript received September 2, 1982, accepted September 3, 1982.

Address for reprints: William M. Hamilton, PhD, Cardiology Section, Veterans Administration Medical Center, 4435 Beacon Avenue South, Seattle, Washington 98108.

## Methods

The Angiography Registry of Seattle Heart Watch was a cooperative; community-wide registry of patients undergoing coronary arteriography for suspected coronary disease. Treatment (medical or surgical) assignment was made on a nonrandom basis by the patient's physician(s). The surgical cohort consists of patients who were operated upon between 1968 and 1974 inclusively, and represents 94% (1,870 of 1,985) of all patients undergoing direct myocardial revascularization

during this period in Seattle. From the 1,870 surgically and 746 medically treated patients initially entered into Seattle Heart Watch, 287 pairs were selected by matching 1 surgical with 1 medical patient according to 7 variables determined previously by multivariate analyses to be predictive of survival.[5] These variables are ejection fraction, ventricular arrhythmia on electrocardiography, age, heart murmur, left main coronary artery stenosis ≥50%, number of vessels with stenosis(es) ≥70%, and diuretic use. Ninety-seven percent (279 of 287) of operated patients had angina; in 44% (126 of 287) this was thought to be unstable. Both the mean number of grafts and the mean number of stenotic vessels (≥70%) per patient were 1.7. Of the 99 operated patients undergoing repeat arteriography, an average of 6 months postoperatively, 56% (55 of 99) had all grafts patent; 34% (34 of 99) at least 1 patent graft, but 1 or more occluded grafts; and 10% (10 of 99) had total occlusion of all grafts. Myocardial protection techniques were those commonly used during this period (1968 to 1974). Systemic, topical hypothermia, or both, were used in 79% (226 of 287), but 21% (61 of 287) were operated at normothermia.

Follow-up for death and hospitalization was by mailed questionnaire at 6-month intervals. Mean follow-up was 6.1 years for medically treated patients and 6.2 years for surgically treated patients. Follow-up has been complete in 92% (263 of 287) of medically treated patients and in 97% (277 of 287) of surgically treated patients. Death occurred in 22% (62 of 287) of the medically treated patients, but only 11% (21 of 287) of the surgically treated patients. Reasons for hospitalization were classified as nonfatal myocardial infarction, chest pain not due to myocardial infarction (includes unstable angina), other cardiovascular causes, and noncardiovascular disease. Diagnoses included among other cardiovascular causes were atherosclerotic heart disease, rhythm disorders, congestive heart failure, embolization, defibrillation, pacemaker implantation, and repeat cardiac catheterization. Hospitalizations culminating in death are not included in this report, so as to not overlap with our other analyses on survival rates.[6-9]

If a patient reported he had been hospitalized for myocardial infarction, heart attack, or symptoms thereof, confirmation of myocardial infarction was obtained from the patient's physician. To ascertain the accuracy of classification of reason for hospitalization into myocardial infarction or chest pain (not myocardial infarction) categories, one of the investigators (KEH) reviewed the discharge summaries, serum enzyme data, and electrocardiograms on 29 randomly selected hospitalizations in these categories. A diagnosis of myocardial infarction was confirmed if any 2 of the following 3 were present: (1) history of prolonged ischemic pain, (2) typical serum enzyme increase and decrease, and (3) appearance of new Q waves on the electrocardiogram. This review agreed with the coded diagnosis in 83% (24 of 29). The electrocardiograms of all patients coded as having a perioperative infarction by their physician were reviewed by one of the investigators (KEH). A diagnosis of perioperative infarction was confirmed if, within 1 week after surgery, there were new Q waves ≥0.02 second in duration or if existing Q waves had widened by ≥0.02 second.

Rates of hospitalization were determined by dividing the number of events (hospitalizations) experienced by the total number of person-years of follow-up time for individual patients and for groups.

Determinations of differences between hospitalization rates for medically versus surgically treated patients used the Wilcoxon signed rank test[10] on paired differences in patient rates. Actuarial curves were constructed to compare time with first hospitalization. Zero time is taken as the date of coronary arteriography for medically treated patients and the date of surgery for surgically treated patients.

## Results

There were no significant differences between the 2 treatment groups in frequency of unstable angina, cardiomegaly, left ventricular hypertrophy on electrocardiography, resting S-T segment depression or elevation, mitral regurgitation, $S_3$ gallop, use of digitalis, or left ventricular end-diastolic pressure, as well as the 7 matching variables. However, some differences in baseline characteristics between medically and surgically treated patients were observed. More surgical

patients were in functional class III or IV (175 of 287, 61%) compared with medically treated patients (92 of 287, 32%; $p < 0.01$). This difference in functional class was consistent with the exercise results; mean functional aerobic impairment (percent decrement from age, sex, and activity status predicted maximal oxygen uptake) was 39 ± 24% for surgically treated patients and 33 ± 24% for medically treated patients ($p < 0.05$). On the other hand, the medically treated patients had a higher frequency of prior myocardial infarction (148 of 287, 52% compared with 113 of 287, 39%; $p < 0.01$). This probably accounted for the slightly larger end-diastolic volume in medically treated patients (75 ± 26 ml/m$^2$) compared with surgically treated patients (68 ± 22 ml/m$^2$; $p < 0.01$).

Table I compares the rates of hospitalization for myocardial infarction during follow-up of medically and surgically treated patients. The rate of hospitalization for myocardial infarction during follow-up in surgically treated patients (1.1%/year) is less than half that of medically treated patients (2.6%/year); the subgroup with the largest difference was comprised of patients

with 3-vessel coronary disease. Figure 1 is an actuarial display of time to first hospitalization for myocardial infarction showing that at 5 years approximately 14% of medically treated patients, but only 5% of surgically treated patients, will have been hospitalized at least once for myocardial infarction.

The preceding analysis did not include perioperative infarctions (12 of 287, 4.2%) in the surgically treated patients. The analysis shown in Table II includes the data in Table I with the addition of these 12 surgical perioperative infarctions. There is now no significant difference ($p = 0.173$) in total myocardial infarction rate between medically (2.6%/year) and surgically (1.9%/year) treated patients for the total cohort or any subgroup. Figure 2 shows the actuarial curves of time to first myocardial infarction (perioperative infarctions included), again indicating no difference between treatment groups.

The numbers and rates of hospitalization for chest pain not due to myocardial infarction for medically and surgically treated patients are shown in Table III. While the differences in the rates are not significant, there is a trend toward a lower rate of hospitalization for surgically treated patients both for the total cohort (5.6%/year versus 7.7%/year; $p = 0.146$) and for patients with 3-vessel disease (6.0%/year versus 1.7%/year; $p = 0.069$).

Table IV shows that the rate of hospitalization for other cardiovascular reasons is significantly lower ($p = 0.004$) in surgically treated patients (12.5%/year) compared with medically treated patients (15.7%/year). When patients are divided into subgroups according to number of stenotic vessels, patients with 2-vessel disease show a highly significant difference ($p = 0.001$). Table V shows the frequency of hospitalization by each specific diagnosis included under "other" cardiovascular reasons; fewer hospitalizations occurred in surgically treated patients even though they were hospitalized more frequently for cardiac catheterizations, some of which were undoubtedly investigational.

Table VI lists the rates of hospitalization for all cardiovascular reasons during follow-up (perioperative myocardial infarctions were excluded). There is a highly significant ($p < 0.001$) difference overall in favor of surgical therapy, due primarily to the differences in the 2-vessel disease subgroup. Linearized annual hospitalization rates are 25.9% for medically treated patients and 19.1% for surgically treated patients, which is 26% fewer total cardiovascular hospitalizations for surgically treated patients. Figure 3 is an actuarial display of time to first hospitalization for any cardiovascular reason

comparing medically and surgically treated patients. Half of the medically treated patients had 1 or more hospitalizations for cardiovascular disease within 3 years of angiography, while it took 5 years before 50% of surgically treated patients had been hospitalized at least once after surgery.

In Table VII, the numbers of patients with none, 1, or more than 1 cardiovascular disease hospitalization are shown. No cardiovascular hospitalizations were observed in 41% (118 of 287) of medically treated patients and 50% (143 of 287) of surgically treated patients, while multiple hospitalizations occurred in 34% (98 of 287) of medically treated patients and 24% (69 of 287) of surgically treated patients.

Table VIII and Figure 4 show no significant differences in rate of hospitalization for noncardiovascular reasons between medically and surgically treated patients or between patients with 1-, 2-, or 3-vessel disease. Hospitalization for noncardiovascular reasons accounts for 34% (357 of 1,042) of all hospitalizations.

## Discussion

A 26% reduction in cardiovascular hospitalization was observed in surgically treated compared with medically treated patients with coronary disease in our matched pair cohort. This was due to significant reductions in hospitalization among patients treated surgically for myocardial infarction and other cardiovascular reasons and a trend toward a reduced rate for chest pain.

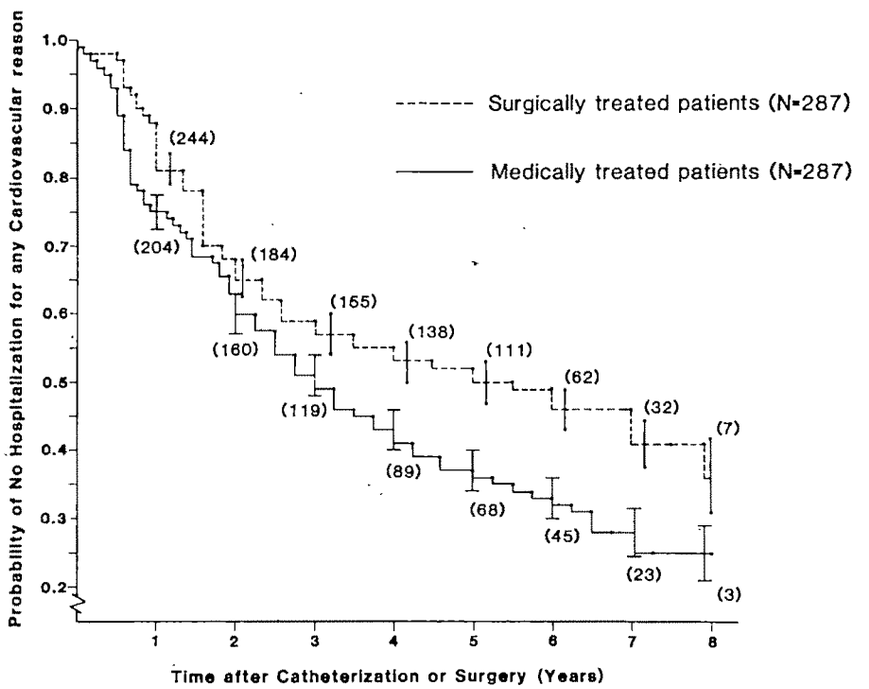

**FIGURE 3.** Actuarial display of time to first hospitalization for any cardiovascular reason.

However, when the perioperative myocardial infarctions are also counted, there is not a statistically significant difference in infarction rates between the 2 treatment groups.

The comparison of nonfatal coronary event rates between medically and surgically treated coronary disease patients is complicated by a number of problems. First is the detection of the event. Our data include only events associated with hospitalization. Thus, myocardial infarctions not resulting in hospitalization (for example, "silent infarction") are not included, because routine electrocardiograms were not obtained on our patients.

In the Framingham study 23% (73 of 319) of first myocardial infarctions between 1950 and 1970 were "unrecognized," that is, did not result in medical attention with a correct diagnosis, but were detected on a study electrocardiogram.[11] The proportion of undetected infarctions in Seattle Heart Watch is likely to be lower than that for Framingham study of 10 to 30 years earlier, given the widespread public education about coronary heart disease, the relative medical sophistication of the Seattle community, and the ready availability of a superb, rapid-response, emergency medical care system (Medic I). Regardless, we know of no reason to believe that undetected infarction would occur more frequently in 1 treatment group than the other. The rate of nonfatal myocardial infarction reported here for medically treated patients (2.6%/year) is identical to that reported by Harris et al[12] from the Duke data bank (2.6%/year). Both studies show that nonfatal infarction occurs about half as frequently as death. Total myocardial infarction rates are also underestimated by the limitation to nonfatal events. We chose to do this both because we did not want these analyses overlapping with our survival analyses,[5-9] and because of the difficulty of diagnosing myocardial infarction in patients who die soon after onset of acute symptoms; 49% (46 of 93) of the deaths in the matched pair cohort occurred within 24 hours of the onset of acute symptoms.

Second is the problem of accuracy of diagnosis. Follow-up of our patients was by a questionnaire mailed to the patient. If the patient reported a reason for hospitalization that was suggestive of acute infarction, confirmation was sought from the patient's physician, but primary data (electrocardiographic and enzyme changes) were not included in the data file. However, a careful review of detailed data (discharge summary, serial serum enzyme values, and serial electrocardiograms) on a random sample of 29 hospitalizations coded as chest pain (not infarction) or myocardial infarction indicated 83% (24 of 29) correct diagnoses.

Third is the problem presented by the unequal loss of patients from both treatment groups. Twice as many medically treated patients (62) died as surgically treated patients (31). Furthermore, 16% (47 of 287) of the initially medically treated patients crossed over to surgical therapy during follow-up because of unacceptable symptoms. While both of these events were treated as "patient lost-to-follow-up" in the data analyses, it is likely that these patients were at higher risk for hospitalization, myocardial infarction, or both, than the patients who remained in the medical cohort. This problem, for which there is no entirely satisfactory solution, is likely to bias the results against surgical therapy.

Fourth, we are comparing 2 forms of therapy that have clearly evolved and improved since the entry of these patients into Seattle Heart Watch. Both operative mortality and perioperative infarction rates have fallen by ≥50%—due in large part to improved myocardial protection.[13,14] Medical therapy has undoubtedly improved as well, but this change is less easily quantified. Yet, it is impossible to assess relatively infrequently occurring events such as death or hospitalization without long-term follow-up, which implies outmoded initial therapy (the "catch-22" of long-term coronary disease studies).

Finally, there is a problem peculiar to nonrandomized observational studies: the 2 treatment groups are not identical. We have documented this in our patients

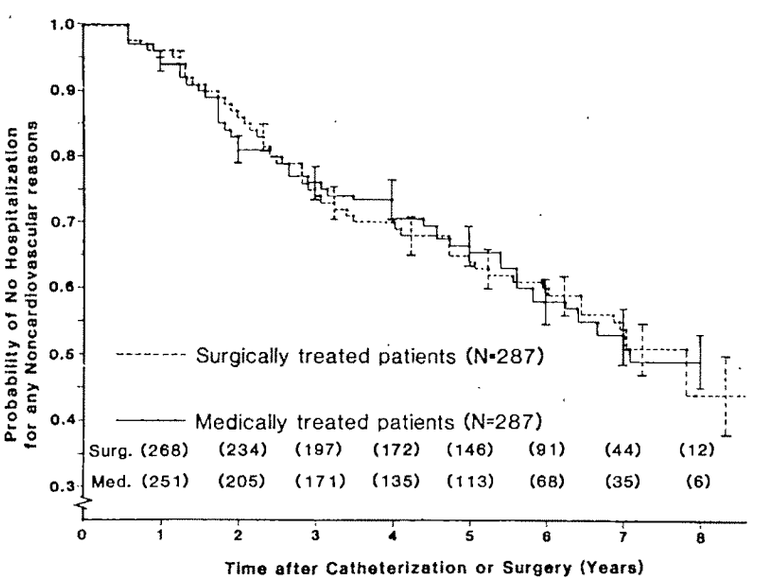

**FIGURE 4.** Actuarial display of time to first hospitalization for any noncardiovascular reason.

despite matching on 7 different baseline characteristics. However, it is not clear in which direction the observed differences in baseline characteristics would influence the outcome variables. It might well be that the greater symptomatic status of the surgically treated patients at entry has an effect opposite to the slightly poorer left ventricular function and greater frequency of prior myocardial infarction in the medically treated patients. The virtually identical rates of hospitalization for noncardiovascular reasons indicate that the general health status of the 2 treatment cohorts was similar.

We would predict the various biases discussed above to either act equally in both treatment groups (incomplete detection of myocardial infarction, <100% accurate diagnosis of myocardial infarction, unequal distribution of baseline characteristics) or to bias the results against surgical therapy (excessive loss of medically treated patients at risk and recent improvements in surgical techniques). Thus, we would attribute the reduction in hospitalization rate for all cardiovascular reasons as being most likely due to surgical therapy. The reduction is not dramatic (26%), but may be influenced by a higher frequency of postoperative catheterization (93 of 287, 32%) then than now.

Whether myocardial infarction can be prevented by coronary bypass surgery has been a question of great interest. The 2 large randomized trials on stable angina[2,15] have not reported data on this question, perhaps because of the methodologic problems discussed above. Two small single-institution randomized trials comparing medical with surgical therapy of stable angina pectoris have not shown any difference in myocardial infarction rates,[3,16] as was the case with an observational nonrandomized study of patients with disease confined to the proximal left anterior descending coronary artery.[17] The number of patients in these 3 studies probably was not large enough to be reasonably certain of detecting a treatment difference, if such difference did actually exist—for example, an acceptably low type II or beta error.[18] In patients presenting with unstable angina, neither the small single-institution randomized trial from Portland,[19] nor the much larger National Heart, Lung, and Blood Institute sponsored multicenter randomized trial[20] have shown a reduction in myocardial infarction rates with surgery. The perioperative infarction rate in the latter study, however, was high (24 of 141, 17%), possibly because the protocol was designed to test the effect of immediate surgery (with no medical "cooling off" period) against conventional medical therapy. Our data on hospitalization rates for myocardial infarction do not provide a convincing answer to the question. While the hospitalization rate for myocardial infarction during follow-up in the surgically treated patients (1.1%/year) was less than half that of the medically treated patients (2.6%/year, $p = 0.004$), the inclusion of the perioperative infarctions eliminates the statistically significant difference, even though there continues to be a trend favoring surgical therapy (1.9%/year compared with 2.6%/year). We look forward to data from the 3 large, randomized trials of medical versus surgical therapy (the European Coronary Surgery Study,[2] the Veterans Administration Cooperative Study,[15] and the National Heart, Lung, and Blood Institute-sponsored coronary artery surgery study[21]), which will hopefully shed light on this important question.

Our data provide 2 interesting insights into the occurrence of hospitalization for myocardial infarction in patients with documented coronary disease. First, it is an uncommon cause of hospitalization, accounting for only 8% (55 of 685) of all cardiovascular hospitalizations, with the percentage being fairly similar for medical (9.9%; 37 of 375) and surgical (5.8%; 18 of 310) cohorts. Hospitalization for chest pain (not myocardial infarction) was, by far, the most frequent cause of hospitalization, accounting for 29% (201 of 685) of all cardiovascular hospitalizations. Second, there does not appear to be an increased likelihood of being hospitalized for myocardial infarction with increasing extent of coronary disease. Among medically treated patients, there is only a slight increase in the hospitalization rate for infarction in patients with 3-vessel disease (3.0%/year) compared with patients with 1-vessel disease (2.5%/year). In fact, in the surgical cohort, a gradient in the opposite direction is seen (0%/year in 3-vessel disease patients; 1.4%/year in 1-vessel disease patients). This is in striking contrast to the relation between extent of disease and mortality, where there is about a 3-fold increase in mortality in patients with 3-vessel disease compared with 1-vessel disease.[5,22] There is, of course, no a priori reason why variables predictive of death should be the same as those predictive of nonfatal infarction. In another report from Duke, the probability of developing a nonfatal infarction over 5 years appears to be about equal between medically treated patients with 1-, 2-, or 3-vessel disease.[23]

Great emphasis should not be placed on the fact that there was a statistically significant reduction in hospitalization for other cardiovascular reasons, but not for chest pain (not infarction). The proportionate reduction

in hospitalization rate among surgically treated patients was similar for the 2 categories (21% reduction in hospitalization for other cardiovascular reasons, 27% reduction in hospitalization for chest pain). The likely reason for the lack of statistical significance ($p = 0.146$) in the chest pain category is the fewer number of end points (hospitalizations). There is still the question of why we did not observe a greater reduction in chest pain hospitalizations in the surgically treated patients, as most studies have shown elimination or marked reduction of angina in most operated patients. It is likely that hospitalization for nonischemic chest pain (postoperative pain, musculoskeletal pain, pericarditis) was more common in surgically treated than in medically treated patients. Our data base does not allow separation of these various entities.

Comparison of nonmorbid events between medically and surgically treated coronary disease patients is a complex task with many factors influencing the conclusions. Our data show a 26% reduction in hospitalization rate for all cardiovascular reasons in the surgical cohort, with a similar proportionate reduction in hospitalization for chest pain (not infarction) and other cardiac reasons. This reduction is likely due to surgical therapy and not confounding factors. While we observed a trend toward a reduction in myocardial infarction with surgical therapy, further studies are needed before the effect of myocardial revascularization on subsequent infarction is clear.

**Acknowledgment:** We express our appreciation for technical assistance to Barbara Buck, Rosario Fontanilla, Verona Hofer, and Gladys Pettet. We also thank Dr. John A. Murray, who participated in the organization and early years of this registry, and the cardiologists and cardiac surgeons in Seattle who contributed data on their patients.

# Can Noninvasive Exercise Test Criteria Identify Patients With Left Main or 3-Vessel Coronary Disease After a First Myocardial Infarction?

RANDOLPH E. PATTERSON, MD, STEVEN F. HOROWITZ, MD, CALVIN ENG, MD, JOSE MELLER, MD, STANLEY J. GOLDSMITH, MD, AUGUSTO D. PICHARD, MD, DORIS A. HALGASH, BS, RN, MICHAEL V. HERMAN, MD, and RICHARD GORLIN, MD

**This study attempts to determine whether exercise treadmill testing with clinical, electrocardiographic, and thallium-201 myocardial perfusion imaging data can identify which patients have left main or 3-vessel (anatomically high-risk) coronary artery disease (CAD) after their first transmural myocardial infarct (MI). Twelve exercise test criteria for high-risk disease were compared in 40 patients referred for cardiac catheterization; 34 had a history of chest pain and 17 had angiographically defined high-risk CAD. A thallium image defect outside the vascular distribution of the MI was the most reliable criterion to distinguish patients with high-risk CAD ($p = 0.00052$ for Fisher's exact test of discrimination). Thallium imaging was somewhat more sensitive (92 versus 65%, $p = 0.108$) when patients with negative thallium imaging criteria who failed to achieve 85% of the age-predicted maximal heart rate were excluded. Failure to achieve 85% of predicted heart rate was by itself a useful criterion for detecting high-risk CAD ($p = 0.017$), especially in patients not taking propranolol ($p = 0.004$). Development of positive S-T segment depression at <70% predicted heart rate also discriminated left main or 3-vessel disease from less extensive CAD ($p = 0.016$). Other criteria failed to discriminate significantly between high-risk and less extensive CAD in patients after their first MI ($p > 0.05$). S-T segment depression ($p = 0.199$) or chest pain ($p = 0.577$) during exercise testing were particularly unreliable. Further, none of the criteria for high-risk CAD were influenced by irreversible left ventricular dysfunction.**

**It is concluded that patients with thallium imaging defects outside the region of the infarct, decreasing blood pressure during exercise, failure to achieve 85% of predicted heart rate, or S-T depression at <70% of predicted heart rate have a high probability of having left main or 3-vessel disease. Patients without these criteria have a very low probability of having high-risk CAD and probably do not need coronary angiography for the purpose of excluding these high-risk coronary lesions after a first MI.**

The annual mortality rate after a first transmural MI averages 5%/year but varies widely for different groups of patients.[1-4] The prognosis after MI depends on the size of the MI and resulting left ventricular dysfunction[3,5,6] and on the extent of CAD jeopardizing the noninfarcted myocardium.[7,8] Most clinical indicators of a poor prognosis after a first MI primarily reflect the extent of irreversible myocardial damage.[9,10] Anginal chest pain after infarct suggests but does not prove the patient has multivessel CAD—chest pain is absent in many patients with extensive CAD.[1,2,11] Exercise electrocardiography has been reported as helping to identify subgroups of patients at greater risk of death after MI.[12-14] Although positive S-T segment responses to exercise identify patients with multivessel CAD moderately well,[15-19] it is not clear whether a positive exercise electrocardiogram identifies patients with a poor prognosis due to large infarcts (irreversible) or due to extensive CAD (potentially reversible by surgery). The usefulness of exercise electrocardiography in the presence of MI may be limited by the MI itself.[20,21] The many false-negative and false-positive results in anginal histories and exercise electrocardiograms after a first MI lend support to the proposal that coronary angiography should be recommended to every young and otherwise healthy patient after a first MI.[22] Adoption

of this policy for the 600,000 patients who have infarcts each year would greatly increase the number of patients undergoing cardiac catheterization, with its risks, inconvenience, and expense, which might be considered by many to be excessive.[23–25] Thus, it would be useful to have a reliable noninvasive test to detect multivessel disease. Thallium-201 myocardial imaging has proven useful in diagnosing the presence of CAD, but its value in distinguishing multivessel disease is controversial[26–30] and may be influenced by the presence of the infarct defect per se.[1,7]

This study examines whether exercise treadmill testing with clinical, electrocardiographic, and thallium imaging data can identify patients in whom left main or 3-vessel disease adversely influences the prognosis. The continuing controversy concerning the effects of coronary artery bypass graft surgery on prognosis suggests a need to identify specifically those patients with left main or 3-vessel disease who may benefit most from surgery.[1,2,31,32]

## Methods

**Patient selection:** We analyzed results in 150 consecutive patients who had been referred by their private physicians for cardiac catheterization, exercise treadmill testing with electrocardiography, and thallium imaging. From this group we identified the 40 patients who had had a transmural MI within the preceding 3 to 24 months. MI was confirmed by history, pathologic Q waves on resting electrocardiogram in all patients, and asynergic regional contraction patterns on contrast left ventricular angiography (36 of 40 patients). Chest pain syndromes were present in 34 patients after MI and were believed to be typical of angina pectoris in 29. Only 4 patients were women; the age range was 26 to 64 years (mean ± standard deviation 51.3 ± 7.5). Patients with 2 or more MIs were excluded.

**Cardiac catheterization:** Each patient had left ventricular and coronary angiography by the Sones[33] or Judkins[34] technique. Two angiographers analyzed all angiograms independently and without knowledge of the other data about the patient, as described previously.[35,36] Significant CAD was defined as ≥50% narrowing of luminal diameter seen in 2 or more views, or ≥70% narrowing in only 1 view. Nitroglycerin was administered before coronary angiography in all patients, and no patient had significant valvular or cardiomyopathic heart disease.

**Exercise treadmill test with electrocardiography:** All patients had an exercise test performed within 2 months of cardiac catheterization; there were no clinical episodes suggesting new MI or intermediate coronary syndrome between the time of exercise testing and catheterization. Exercise testing was performed within 3 to 24 months of the patient's first infarct, using the Bruce protocol.[37] Each patient continued exercise until the occurrence of limiting symptoms, a blood pressure decrease >5 mm Hg, or flat or downsloping S-T segment depression ≥2.0 mm below control values, 0.08 second after the J point. A 12-lead electrocardiogram was recorded before, during, and after exercise. If the S-T segment shifted more than 1.0 mm from the baseline or from a resting abnormality, then the electrocardiogram was also read as positive during exercise. The electrocardiogram was considered uninterpretable if S-T depression >1.0 mm occurred in a patient receiving digitalis or in the presence of an intraventricular conduction delay or left ventricular hypertrophy. Exercise electrocardiography was considered equivocal with S-T elevation or upsloping S-T segment depression >1.0 mm but <2 mm, 0.08 second after the J point. Arterial blood pressure was monitored by cuff sphygmomanometer every 2 to 3 minutes before, during, and after exercise.

**Thallium-201 myocardial perfusion imaging (Fig. 1 and 2):** As described previously,[34,35] 1.5 to 2.0 mCi of thallium-201 was injected intravenously during exercise when symptoms suggested that the patient was near the limits of his or her tolerance for exercise. Each patient exercised for an additional 30 to 120 seconds at the same or reduced work load to allow thallium tissue distribution during the period of maximal coronary blood flow. Each patient was imaged 5 to 10 minutes after exercise for the "exercise image" and 3 to 4 hours later for the "delayed rest image."[38] Images were recorded with the patient in a supine position in the 45° left anterior oblique, anterior, and left lateral views to a total of 500,000 counts/image.

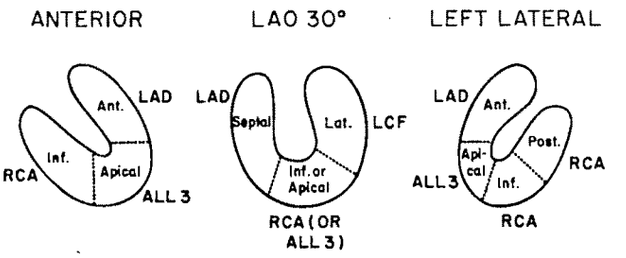

FIGURE 1. Nomenclature for segments of left ventricle seen on the thallium-201 perfusion image. These diagrams indicate the correspondence between particular coronary arteries and the myocardial image in each view. Note that the apical region did not correspond to the distribution of any 1 specific artery. Ant = anterior; Inf = inferior; LAD = left anterior descending coronary artery; LCF = left circumflex coronary artery; RCA = right coronary artery.

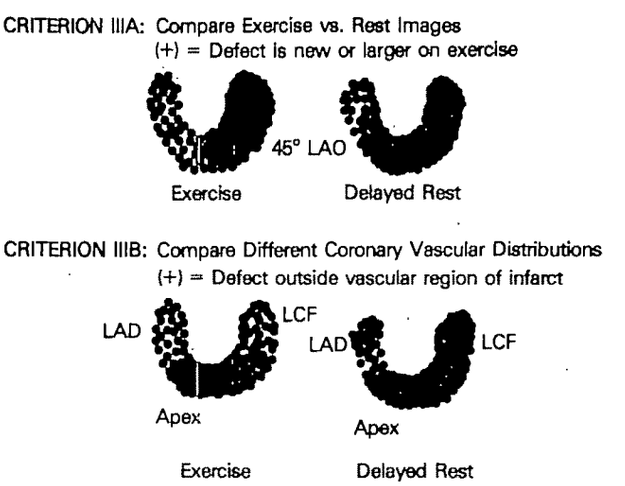

FIGURE 2. Two thallium-201-imaging criteria, A and B, for high-risk CAD involving the left main trunk or 3 vessels after myocardial infarction. Criterion IIIA compares exercise (**left**) and delayed rest (**right**) images and is considered positive (+) when an exercise defect disappears or decreases in size or severity on the delayed rest image (as shown for the septal defect here). Criterion IIIB compares different coronary vascular distributions using the scheme in Figure 1 and is considered positive when there is a defect in a vascular region outside the infarct region as shown for the septal, left anterior descending, and lateral wall-circumflex defects here. Ant = anterior; Inf = inferior; LAD = left anterior descending coronary artery; LCF = left circumflex coronary artery; RCA = right coronary artery.

We set a 20% window centered on the photopeak of thallium, using an Ohio Nuclear model 120 portable gamma camera with a high-sensitivity, parallel-hole collimator. Each image was recorded on Kodak SO-179 transparency film in both unprocessed and contrast-enhanced forms. Contrast enhancement was performed on the video display of the Ohio Nuclear Series 150 Data System by an observer without knowledge of the patient's history or other test data. Each image was read by 2 observers who did not know other data about the patient; interobserver agreement was 95% for positive or negative thallium image reading and 88% for defining which regions were abnormal. Results were drawn from readings after resolution of differences.

**Noninvasive criteria to identify patients with left main or 3-vessel CAD (Table I):** During the exercise test symptoms, heart rates, blood pressures, electrocardiograms, and thallium images were classified according to the criteria shown in Table I. The location of the transmural infarct was established by the pathologic Q waves of the electrocardiogram and confirmed by regional asynergy on the contrast left ventriculogram. We used criteria which correlate abnormalities of thallium images and the exercise response of the S-T segment of the electrocardiogram with the anatomic site of myocardial ischemia.[39,40] Although these correlations may be imperfect, we designated the following correspondence between electrocardiogram and coronary vascular distributions, in accordance with previous studies: leads II, III, and aVF, right coronary artery; I, aVL, $V_{5,6}$, circumflex artery; $V_1$ to $V_4$, left anterior descending artery.[39,40] Consistent with previous correlations of thallium images with cardiac catheterization data,[41] we designated the correspondence between thallium image regions, walls of the left ventricle, and coronary vascular distributions as illustrated in Figure 1. It should be noted that the apical portion of the left ventricle was not used to localize the coronary artery involved because it is difficult to assign this region to the vascular distribution of 1 coronary artery.[42] Two thallium-201 criteria to predict anatomically high-risk CAD after infarction are shown in Figure 2 (criterion IIIC was adapted from IIIB).

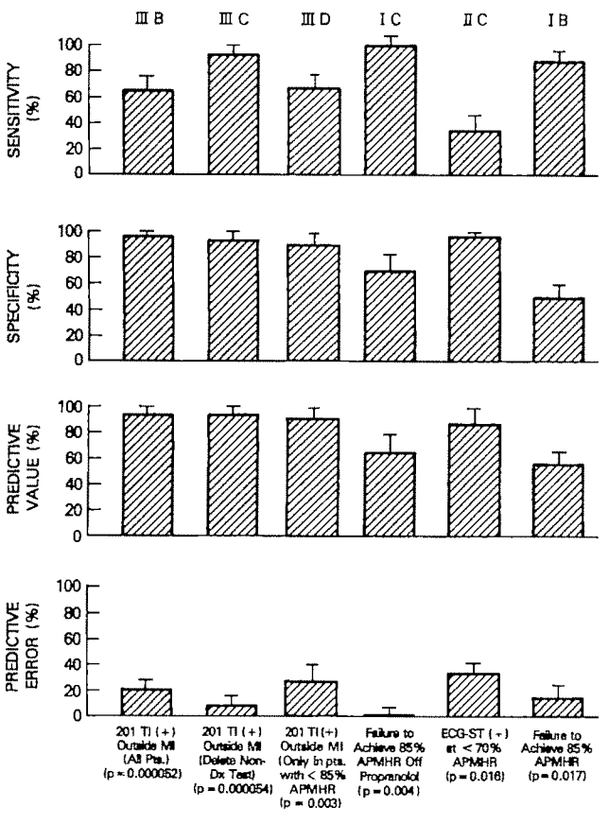

**FIGURE 3.** Exercise test criteria which successfully discriminate high-risk CAD after MI. The criteria are listed in order of the p value from Fisher's exact test for their ability to discriminate anatomically high-risk disease from less extensive disease, from the lowest p value on the **left** to the highest p values on the **right.** The p value is shown under the bar graph representing each criterion. The panels show sensitivity, specificity, predictive value, and predictive error. The population prevalence of high-risk disease was 43%. APMHR = age-predicted maximal heart rate; Dx = diagnostic; ECG-ST = electrocardiographic S-T; Pts. = patients; Tl = thallium.

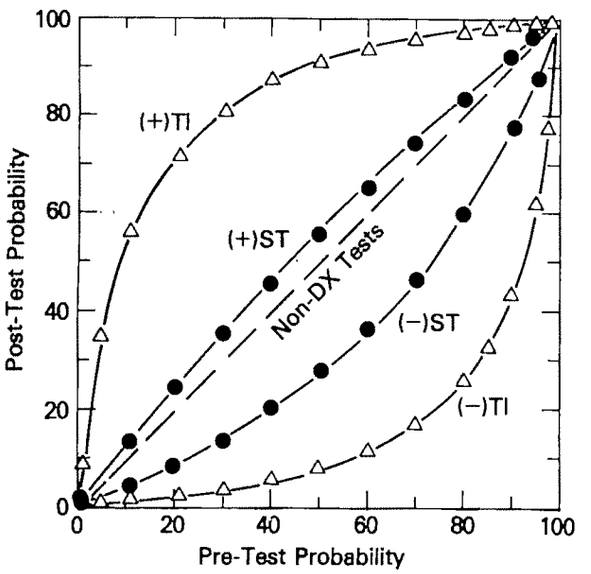
**Analysis of data:** Coronary angiography determined each patient's anatomic extent of CAD. Patients with left main or 3-vessel disease were classified for the purpose of this study as a high-risk subgroup of the population of patients after their first MI.[1,7,8] Each criterion in Table I was tested in each patient to determine whether the particular findings on exercise testing were present or absent. For each criterion, the result in each patient was defined as follows: true positive (TP) = a patient with left main or 3-vessel disease (that is, high-risk subgroup), and noninvasive criterion positive; true negative (TN) = noninvasive criterion negative in a patient without high-risk CAD; false negative (FN) = noninvasive criterion negative in a patient with high-risk CAD; and false positive (FP) = noninvasive criterion positive in a patient without high-risk CAD.[43,44]



In order to characterize fully all aspects of the ability of each criterion to identify high-risk subgroups of CAD, we calculated the following proportions as percentages: sensitivity = TP/(TP + FN); specificity = TN/(TN + FP); predictive error = FN/(FN + TN); predictive value = TP/(TP + FP). We estimated the standard deviation of each proportion (Pr) as $[(Pr)(1 - Pr)/n]^{1/2}$, where n is the number of observations as indi-

**TABLE I Exercise Treadmill Test Criteria to Identify Left Main Trunk or 3-Vessel CAD in Patients After Their First MI***

I. Clinical and hemodynamic criteria during exercise test
  A. Development of chest pain
  B. Failure to achieve 85% of age-predicted maximal heart rate (considering all patients)
  C. Failure to achieve 85% maximal heart rate (drop patients taking propranolol)
  D. Decreased blood pressure during exercise
II. Electrocardiographic criteria during exercise test
  A. Positive S-T segment response (all patients)
  B. Positive S-T response (drop patients with nondiagnostic tests)*
  C. Positive S-T segment response at heart rate <70% maximal heart rate
  D. Positive S-T segment response in lead not involved by infarct
III. Thallium-201 myocardial perfusion imaging criteria
  A. Defect on exercise image which disappears or improves on delayed rest image
  B. Any defect located in a vascular distribution outside the infarct (all patients)
  C. Defect outside infarct (drop patients with nondiagnostic tests)
  D. Defect outside infarct (considering only patients who failed to achieved 85% maximal heart rate)

* Criteria for diagnostic tests are to exclude patients with (A) electrocardiographic S-T segment response positive in a patient taking digitalis or with conduction defect, or with 1.0 mm S-T depression which is upsloping, or with S-T elevation; also, negative S-T response, but <85% maximal heart rate; (B) thallium-201 imaging normal in regions not involved by infarct, but <85% of the predicted maximal heart rate is achieved.

cated in Figure 3.[45] We tested the ability of each criterion to discriminate between the anatomically high-risk group and other patients by Fisher's exact test, the chi-square test with Yates' continuity correction, and a modification of the z statistic to compute confidence intervals.[45] We report the results of Fisher's exact test except where noted specifically. We used the chi-square test with Yates' correction for small numbers since the expected values were <5 in some tests. The modified z statistic was calculated to account for correlated proportions.[45] Results of these 3 statistical tests were similar. The p values were somewhat lower for the modified z statistic; for only 1 criterion did differences become significant ($p < 0.05$) by the modified z statistic but not by other tests. This 1 difference is indicated in the results. The z statistic does not account for small numbers and, thus, probably overestimates the significance of differences in small populations.[45]

| Criterion | Code | Sensitivity | Specificity | Non-DX |
|---|---|---|---|---|
| $^{201}$Tl(+) Outside MI (DX only) | △ | 92% | 92% | 16 |
| ECG-ST ↓ (DX only) | ● | 90% | 29% | 13 |

**FIGURE 4.** Influence of population prevalence (pretest probability) of anatomically high-risk disease on thallium (Tl) exercise imaging and exercise electrocardiographic S-T (ECG-ST) predictions after MI, using Bayes' theorem. Considering the number of patients, these curves represent clinical trends rather than precise calculations of the probability of high-risk CAD for a particular patient. If thallium-201 imaging is positive (+) outside the infarct region, the probability (posttest) that the patient has 3-vessel or left main coronary disease remains high over a wide range of pretest probabilities, as shown by the **top left curve.** If thallium-201 imaging is negative outside the vascular distribution of the infarct and heart rate is >85% of the age-predicted maximum, the probability (posttest) of anatomically high-risk disease is very low over a wide range of pretest likelihoods, as shown by the **lower right curve.** The curves calculated from Bayes' theorem show that the posttest probability of anatomically high-risk disease is higher when the pretest probability (or prevalence) is higher. The curves indicate that a positive thallium-201 image outside the infarct is more reliable than a positive exercise S-T response as an indicator of anatomically high-risk disease, and that a negative S-T response is less reliable than a negative thallium-201 image outside the infarct to exclude 3-vessel or left main coronary disease after a first MI. DX = diagnostic result.

More sophisticated statistical tests of multivariate analysis might have indicated some improvement in the predictive power of some exercise test criteria, and Tables II and III provide data for such analysis. We did not adopt this statistical approach because our goal was to assess the clinical usefulness of different exercise test criteria. The more sophisticated statistical tests using multivariate analysis might have indicated statistical significance in situations where clinical significance would be lacking. Thus, we ranked exercise test criteria in ascending order of their p values for discriminating anatomically high-risk disease, using Fisher's exact test. The rank order was the same using either chi-square or the modified z statistic.

We tested differences between group means by Student's $t$ test for unpaired variables.[45] We calculated the linear regression equations and correlation coefficients. One-way analysis of variance was used to test whether slopes of these regression lines differed significantly from zero.[45] A p value <0.05 was required for statistical significance.

We estimated the influence of different population prevalence rates (or pretest probabilities) of the high-risk subgroup CAD on the predictive value and predictive error of these noninvasive criteria by application of Bayes' theorem. We calculated the probability of high-risk CAD with a given result of the noninvasive criterion, using the values of sensitivity and specificity of each criterion found in our population as follows[44,46–48]: if the criterion is negative, then the probability of high-risk disease (predictive error) = [(100 − sensitivity %) (prevalence %)]/[(100 − sensitivity %) (prevalence %) + (specificity %) (100 − prevalence)]. If the criterion is positive, then the probability of high-risk CAD (predictive value) = [(sensitivity %) (prevalence %)]/[(sensitivity %) (prevalence %) + (100 − specificity %) (100 − prevalence %)].

These calculations in 40 patients seem justifiable because of the clinical implications of different population groups. Clearly, Figure 4 does not represent an exact calculation of the probability of left main or 3-vessel coronary disease in every patient, but it does indicate the influence of population prevalence of high-risk disease on the predictions by these criteria.

## Results

**Cardiac catheterization:** In the 40 patients with previously documented transmural MI, coronary angiography revealed disease involving 1 coronary vessel in 13, 2 vessels in 8, and 3 vessels in 17. Three of the 17 patients with 3-vessel disease also had left main coronary stenosis, and 2 patients had normal coronary angiograms. Left ventricular ejection fraction in patients with 3-vessel or left main disease (high-risk subgroup) was 51.2 ± 21.9% (mean ± standard deviation), which did not differ significantly from the patients with less extensive CAD, 56.2 ± 24.4%. The proportion of patients with ejection fraction <40% also was not significantly greater in patients in the high-risk subgroup (1 of 17) than in patients with less extensive CAD (1 of 23). Asynergic contraction was identified on the left ventriculogram in 36 of 40 patients; the location agreed with the pathologic Q waves on the electrocardiogram in 35 patients, and with the defects on delayed rest thallium imaging in 34 patients.

**Clinical and hemodynamic exercise test criteria (1A to 1D) (Tables II and III):** Development of chest pain during the exercise test did not distinguish patients with high-risk CAD from those with less extensive CAD

Abbreviations as in Table II.

($p > 0.577$) as shown in Table IV for criterion IA. Again, the p value seems most useful to identify criteria which fail the minimal expectation for any diagnostic test, that is, to distinguish 2 groups of patients with versus patients without high-risk disease. In contrast, criterion IB discriminated patients with high-risk disease ($p < 0.017$) by their failure to achieve 85% of age-predicted maximal heart rate. This heart rate criterion was sensitive (88%) (Fig. 3) but lacked specificity (48%), because of peak heart rates <85% of predicted values during propranolol therapy in several patients with less extensive disease (Tables II, III, and V). The heart rate criterion could not distinguish high-risk CAD in the 20 patients receiving propranolol (dose range 30 to 160 mg/day), but discriminated successfully between high-risk and less extensive disease in patients not re-

**TABLE IV Ranking Criteria Which Fail to Discriminate Anatomically High-Risk CAD After MI**

| | Criterion | Sensitivity | Specificity | p |
|---|---|---|---|---|
| ID | BP decrease | 18 ± 9 | 100 ± 5 | <0.069 |
| IIA | S-T (+) (All patients) | 71 ± 11 | 48 ± 10 | <0.199 |
| IIB | S-T (+) (Dx only) | 90 ± 9 | 29 ± 11 | <0.251 |
| IIIA | Tl-201 (+) Ex > Rest* | 47 ± 12 | 65 ± 10 | <0.323 |
| IID | S-T (+) outside MI | 35 ± 12 | 70 ± 12 | <0.504 |
| IA | Chest pain | 24 ± 10 | 74 ± 9 | <0.577 |

* Thallium-201 image positive with exercise defect worse than delayed rest defect.

Ranking is in ascending order of the p value for Fisher's exact test. Criteria with p >0.05 for the difference between groups failed the minimal requirement for any diagnostic test, that is, to distinguish 2 groups with versus without high-risk disease. BP = blood pressure; Dx = diagnosis; Ex = exercise.

**TABLE V Effects of Propranolol Therapy on the Prediction of Anatomically High-Risk Disease After MI by the Criteria Which Used Peak Heart Rate Achieved During the Exercise Test**

| | Low-Risk CAD | High-Risk CAD |
|---|---|---|
| Patients Not Taking Propranolol | | |
| >85% APMHR | 9 | 0 |
| <85% APMHR | 4 | 7 |
| | p = 0.004 | |
| Patients Receiving Propranolol, 40 to 160 mg/day | | |
| >85% APMHR | 2 | 2 |
| <85% APMHR | 8 | 8 |
| | p = 0.709 (not significant) | |

APMHR = age-predicted maximal heart rate.

ceiving propranolol (p <0.00052) (Table V). In 20 patients not taking propranolol, no patients with high-risk CAD achieved 85% of the predicted heart rate (criterion IC). The group with left main or 3-vessel disease achieved the same percentage of age-predicted maximal heart rate whether they were (73.3 ± 11.5%) or were not (72.0 ± 16.0%) receiving propranolol. On the other hand, in the group with 0-, 1-, or 2-vessel disease, the patients taking propranolol had a lower heart rate (69.4 ± 17.4%) than those not receiving the drug (86.2 ± 7.6%; p <0.05). During exercise testing, arterial blood pressure decreased in 3 patients with 3-vessel disease (1 also had left main disease). Criterion ID did not significantly discriminate the anatomically high-risk group by the Fisher's exact test (p = 0.069) because of its low sensitivity. The modified z statistic yielded p = 0.024, but this test fails to account for small numbers.[45]

**Exercise electrocardiographic data (criterion IIA to IID):** The S-T segment response of the electrocardiogram to exercise was positive in 12 of 17 patients with high-risk CAD, but also in 12 of 23 patients with less extensive disease. Thus, criterion IIA, which is widely used, could not distinguish the high-risk subgroup (p = 0.199). The 2 patients with positive S-T responses who were receiving digitalis were considered positive for high-risk CAD by criteria IIA, IIC, and IID. Criterion IIB classified as nondiagnostic the patients with these electrocardiographic readings and the patients with negative S-T responses but peak heart rate <85% of the predicted maximum. Despite dropping these 13 patients with nondiagnostic S-T responses, criterion IIB could not discriminate high-risk CAD (p = 0.251), primarily because of the low specificity of the S-T response (Table IV).

The electrocardiogram was positive and the heart rate was <70% of predicted in 6 of 17 high-risk patients (1 of whom had left main disease) and in only 1 of 23 patients with less extensive disease. Criterion IIC discriminated high-risk disease (p = 0.016) because of its high specificity. Criterion IID, which indicated the high-risk subgroup when S-T responses were positive in leads not involved by the MI, was positive in 6 of 17 patients with high-risk CAD (2 of 3 with left main disease), but also in 7 of 23 patients with less extensive disease, so that this criterion also failed to discriminate high-risk from less extensive CAD (p = 0.504) (Tables II and III).

**Thallium-201 myocardial imaging data (criteria IIIA to IIID):** Thallium imaging revealed defects during exercise, delayed resting imaging, or both, in 38 of 40 patients, and showed an increase in the apparent dimensions of the left ventricular cavity on the exercise image relative to the rest image in 1 of the 2 patients with no perfusion deficits visible on thallium imaging.

Figure 2 illustrates the criteria for reading the thallium images to identify left main or 3-vessel disease. Criterion IIIA was considered positive for high-risk CAD when a defect present on exercise disappeared or improved dramatically on the delayed rest image. Defects disappeared on delayed rest images in 16 patients, only half of whom had high risk CAD. Thus, this criterion alone could not discriminate 3-vessel or left main disease from less severe disease (p = 0.323) (Tables II and III).

In contrast, criterion IIIB required thallium imaging to be positive in the vascular distribution of a coronary artery which was not involved by the previous MI, defined by Q waves on the electrocardiogram, as shown in Figure 2. Criterion IIIB discriminated most successfully the patients with high-risk CAD (p = 0.00052), with 65 ± 12% sensitivity and 96 ± 4% specificity (Fig. 3).

Criterion IIIC used the same thallium reading but classified separately 16 patients as nondiagnostic because they had negative results on thallium imaging by this regional criterion; however, they had inadequate stress, that is, peak heart rate <85% of predicted. Criterion IIIC discriminated successfully between high-risk and less extensive CAD (p = 0.000054, Fig. 3). Sensitivity (92 ± 8%) and specificity (92 ± 8%) were excellent by criterion IIIC.

Criterion IIID applied the same thallium reading of defects outside the vascular distribution of the infarct to the 27 patients who failed to achieve 85% of maximal predicted heart rate. Sensitivity was 67 ± 12% and specificity was 92 ± 8% to allow discrimination of patients with left main or 3-vessel disease (p = 0.0029).

**Combined criteria:** It was possible to combine criteria to improve sensitivity and specificity. For example, we considered a test result positive for anatomically

high-risk CAD if any 1 of the following criteria was positive: IC, heart rate <85% of that predicted in a patient not taking propranolol; ID, a blood pressure decrease during exercise; or IIIB, thallium-201 imaging positive outside the vascular distribution of the myocardial infarction. This combined criterion test was 82 ± 8% sensitive and 83 ± 8% specific to discriminate left main or 3-vessel disease ($p = 0.000055$). The predictive value was 78 ± 10% and the predictive error was 14 ± 7%. This retrospectively defined combined criterion is not shown in Figure 3.

The sensitivity of thallium imaging for defects outside the infarct to identify high-risk CAD (criterion IIIB) was higher in patients with previous inferior wall infarction (100 ± 9%) than in patients with previous anterior wall infarction (45 ± 15%, $p = 0.037$, Table VI).

**Influence of left ventricular dysfunction on noninvasive test results:** Because of the possible influence of irreversible myocardial damage itself on the results of exercise test criteria, we correlated global left ventricular ejection fraction with the results of exercise test criteria to predict high-risk CAD. First, we used analysis of variance to determine that this group of patients after MI showed no relation between ejection fraction and the extent of CAD, confirming the previous reports from this laboratory.[40] Next, we found that 5 of the criteria showed no association between the ejection fraction and the noninvasive test results, using a 2 by 5 contingency table and chi-square test. We also found that the ejection fraction at rest did not correlate with the percentage of age-predicted maximal heart rate achieved during exercise testing: ($r = -0.11$, $p > 0.4$), using analysis of variance to compare the slope of the linear regression equation to zero.[45] Thus, using resting left ventricular ejection fraction as an index of the degree of irreversible damage resulting from the MI, we were not able to demonstrate any influence of the extent of myocardial dysfunction on either the extent of CAD or the noninvasive criteria to discriminate extensive CAD.

**TABLE VI Differential Detection of High-Risk CAD After Inferior Versus Anterior Wall MI**

| Patients With Anatomically High-Risk Disease | | |
|---|---|---|
| | Sensitivity | |
| Criterion | Inferior MI (n = 6) | Anterior MI (n = 11) |
| IA. Chest pain on treadmill | 17 ± 15% | 27 ± 13% |
| IB. Heart rate <85% of predicted | 100 ± 9% | 82 ± 12% |
| IIA. S-T positive (all patients) | 50 ± 20% | 82 ± 12% |
| IID. S-T positive outside infarct | 17 ± 15% | 45 ± 15% |
| IIIB. Thallium-201 positive outside infarct | 100 ± 9%* | 45 ± 15%* |
| **Patients Without High-Risk Disease** | | |
| | Specificity | |
| Criterion | Inferior MI | Anterior MI |
| IA. Chest pain on treadmill | 71 ± 17% | 79 ± 12% |
| IB. Heart rate <85% of predicted | 43 ± 19% | 50 ± 13% |
| IIA. S-T positive (all patients) | 29 ± 17% | 57 ± 13% |
| IID. S-T positive outside infarct | 57 ± 19% | 71 ± 12% |
| IIIB. Thallium-201 positive outside infarct | 86 ± 13% | 100 ± 6% |

* $p = 0.037$, comparing anterior versus inferior infarcts by Fisher's exact test. Other differences were not significant.

## Discussion

Management of patients after a first MI could be improved by a noninvasive prediction of which patients have a poor prognosis and, therefore, might be most likely to benefit from aggressive therapy.[1–3] It would be most desirable to identify patients at high risk specifically, because of extensive CAD which is potentially reversible by surgery[31,32,49–51] rather than those patients at high risk due to irreversible left ventricular damage.[5,6,52] We set out to identify patients with left main or 3-vessel disease by exercise test criteria because recent evidence suggests that coronary bypass surgery may improve prognosis in such patients.[1,2,31,32,49–51]

**Thallium imaging criteria:** The best criterion to distinguish high-risk CAD in this study was to detect thallium image defects outside the coronary vascular distribution of the MI (criterion IIIB). This finding is consistent with reports that exercise thallium imaging can identify jeopardized myocardium after MI[53] and can assess perfusion of specific coronary vascular distributions.[29,30,41,42] One preliminary report indicates that thallium imaging is not useful to detect multivessel disease after MI,[54] although another indicates that thallium imaging is moderately useful.[55] In the present study the sensitivity of thallium imaging in detecting high-risk CAD was greater after inferior wall infarction than after anterior wall infarction. This differential sensitivity of thallium imaging to detect ischemia of the anterior wall after inferior infarction is consistent with the finding in other patients from this laboratory that thallium imaging detects ischemia in the distribution of a stenotic left anterior descending coronary artery with greater sensitivity than in the distribution of a stenotic circumflex or right coronary artery; thallium imaging, however, detects infarcts (in contrast to ischemia) with equal sensitivity in the distribution of any 1 of the 3 vessels.[56] Thus, thallium detects infarcts with equal sensitivity regardless of location, but identifies transient hypoperfusion of noninfarcted myocardium supplied by a stenotic left anterior descending with greater sensitivity than other stenosed coronary arteries.

It should be noted that the only false-positive finding on thallium imaging in the present study occurred in the only patient who had an inferior wall infarct and 2-vessel disease involving the proximal left anterior descending artery. Such patients may be at higher risk than patients with other 2-vessel disease.[49] The greater sensitivity of thallium imaging to detect anterior wall ischemia after inferior wall infarction suggests that thallium imaging may detect this group reliably (Table VI). The sensitivity to thallium imaging to detect every diseased vessel in these patients was 48% (Tables II and III), lower than the 66% sensitivity reported by Massie et al[30] ($p < 0.02$). Massie et al required that a vessel be stenosed by 70% to be considered diseased, whereas we

required only 50% narrowing of luminal diameter in 2 views. Nine of our patients had 50 to 69% stenosis, and findings on thallium imaging were positive in the distribution of only 2 of these 9 vessels. Also, 66% of their patients achieved ≥85% of their predicted heart rate, while only 28% of our patients achieved this heart rate during exercise. Differences in criteria for coronary stenosis and peak heart rate achieved during exercise could explain the differences in the sensitivity of thallium imaging for identifying each abnormal vessel in this study and the study by Massie et al.[30]

Also, the overall sensitivity of thallium imaging to detect high-risk CAD by identifying defects outside the infarct was improved marginally from 65 ± 13 to 92 ± 8% ($p = 0.108$) by classifying separately 16 patients who had negative thallium imaging outside the infarct region but who had inadequate exercise stress, that is, who failed to achieve 85% of their predicted heart rate (Tables II and III).

Classifying these 16 test results as nondiagnostic increased sensitivity marginally with no decrease in specificity (96 ± 4 to 92 ± 8%), and represents the usual practice in calculating sensitivity and specificity for exercise electrocardiography.[15,17] It should be emphasized that sensitivity of our criteria to detect high-risk CAD was not the same as the sensitivity to detect any perfusion defect. Thus, findings on thallium imaging were abnormal in 38 of 40 patients, including the defects representing the MI. Thallium defects during exercise, which disappeared on the delayed rest image, did not distinguish high-risk CAD ($p = 0.323$) consistent with reports by others.[54] This criterion may have identified exercise-induced ischemia within the same coronary vascular distribution as the MI, since most of these patients had a history typical of angina pectoris. It has been found in dogs after infarction that the increase in blood flow during stress to noninfarcted tissue in the subepicardium which overlies the infarct is less than the flow increase to normal subepicardium; this could explain ischemia after MI even in single-vessel disease.[57]

**Exercise electrocardiographic criteria:** These data indicate that if the S-T segment response to exercise is positive at <70% predicted heart rate, there is a high probability (86 ± 13%) of left main or 3-vessel disease in this population where there was a 43% prevalence of high-risk CAD. This criterion IIC was specific (96 ± 4%) but not sensitive (33 ± 8%) for high-risk CAD (Fig. 3).

These data are consistent with the suggestion that a positive S-T segment response to a low cardiac work load indicates severe, extensive CAD.[19] All other S-T segment criteria failed to discriminate high-risk disease, as shown in Table IV. Even the diagnostic quality exercise electrocardiographic tests (criterion IIB) were not able to discriminate high-risk CAD because of low specificity (48 ± 10%), which may be related to the reported electrophysiologic effects of the old MI on the S-T segment response.[20,21] Others have also noted that the leads in which the S-T segment is positive during exercise do not correlate closely with the vascular distributions of stenotic coronary arteries.[58]

Weiner et al[15] reported a good predictive value (79%) of positive exercise electrocardiographic results for multivessel disease after infarction, where the population had a 59% prevalence, and patients with nondiagnostic test results were excluded (as in our criterion IIB). The predictive value of diagnostic exercise electrocardiography for multivessel disease was also 79% in our patients, not different from the results of Weiner et al. Another study by Chaitman et al[17] reported that the S-T response had a sensitivity of 76% and specificity of 61% to identify 3-vessel disease after a single inferior wall infarct. Chaitman et al excluded 39% of their patients for nondiagnostic tests, using the same guidelines as our criterion IIB. Our data support the conclusion of Chaitman et al[17] that exercise electrocardiography added little to the clinical history of chest pain to identify 2- or 3-vessel disease after infarction. Several reports indicate that exercise electrocardiography early after MI predicts short-term prognosis.[12–14] Many of the patients in these studies[12–14] achieved relatively low heart rates, so that these data may compare with our criterion IIC, positive S-T results at <70% of predicted heart rate.

The short-term mortality rate after MI, however, is probably related more closely to infarct size and the extent of left ventricular dysfunction than to the extent of CAD.[4,6] Coronary bypass surgery exerts little beneficial effect on resting left ventricular function[59] and appears most helpful in the presence of extensive CAD and normal left ventricular function.[31,50] Thus, it must be emphasized that studies which link S-T response early after infarction to the short-term prognosis[12–14] have not been shown to identify patients whose poor prognosis can be improved by therapy. The data in the present study suggest that exercise electrocardiography after infarction might actually be more useful if performed to a low work load, because a positive S-T result at a low work load (<70% age-predicted maximal heart rate) has a somewhat higher predictive value for 3-vessel or left main disease (86 ± 13%) than does a positive S-T at any heart rate (50 ± 15%).

**Clinical criteria during exercise testing:** The clinical criterion IB of failure to achieve 85% of predicted heart rate was useful in discriminating high-risk CAD ($p = 0.017$, Fig. 3). It was sensitive (88 ± 7%) but had limited specificity (48 ± 10%) in the entire group of patients because 20 to 40 patients were taking propranolol at the time of the test. In patients receiving propranolol, the heart rate criterion could not discriminate high-risk CAD (Table V) because beta blockade decreased the chronotropic response to exercise. In contrast, in 20 patients not receiving propranolol, failure to achieve 85% of predicted heart rate (criterion IC) was 100 ± 8% sensitive and 69 ± 13% specific in discriminating high-risk CAD ($p = 0.00052$). These data indicated that an exercise treadmill test limited by development of symptoms, hypotension, or 2 mm S-T depression can provide very useful data about the extent of CAD 3 to 24 months after MI, especially if the patient is not taking propranolol. This finding extends reports by others that chronotropic incompetence during exercise testing is a useful indicator of CAD.[60,61]

Blood pressure decreased during exercise in only 3 patients, but all 3 had 3-vessel disease, and 1 had additional left main disease (Tables III and IV). Thus, criterion ID failed to significantly discriminate the high-risk group ($p = 0.069$). These findings support the predictive value of exercise-induced hypotension as an indicator of severe, extensive CAD[62,63]; however, an increase in blood pressure during exercise, per se, has no value in ruling out severe CAD because of the low sensitivity of criterion ID (Table IV).

Chest pain during the exercise treadmill test was of no value in discriminating left main and 3-vessel disease from less extensive CAD ($p = 0.577$). As indicated earlier, ischemia could occur in the subepicardium that survives within the vascular distribution of the predominantly subendocardial infarction.[58] Consistent with this, 4 of 13 patients with single-vessel disease had chest pain during exercise and even more had a clinical history typical of angina. These data indicate that angina pectoris could occur after infarction in single-vessel disease as well in 3-vessel disease; further, no patient with left main disease had chest pain during the exercise test. Thus, neither chest pain during an exercise test nor a history typical of angina pectoris provides a reliable indicator of anatomically high-risk CAD. This finding in a population of 40 patients referred for cardiac catheterization for medical indications may not be true in all patients. Indeed, the presence of angina pectoris was a major factor leading physicians to refer most of these patients. Further, exertional angina may be an indication for coronary angiography and surgery for the purpose of relieving symptoms.

**Clinical implications: indications for coronary angiography:** The results of this study suggest guidelines for deciding whether or not to refer a patient for coronary angiography after a first MI. An important objective in the management of such patients is to identify those whose prognosis may be limited by potential ischemia of noninfarcted myocardium.[1,2] Coronary angiography seems indicated because of the high probability of left main trunk or 3-vessel disease in any patient who has 1 or more of the following findings: (1) a defect on thallium imaging outside the coronary vascular distribution of the MI, (2) a decrease in blood pressure during exercise testing, (3) a positive S-T segment response at <70% of predicted heart rate, or (4) failure to achieve 85% of predicted heart rate in patients not taking propranolol and in the absence of limiting noncardiac disease.

In contrast, if the physician managing a patient after MI is considering coronary angiography primarily to rule out left main or 3-vessel disease, then these tests may help him decide that there is such a low probability of high-risk CAD that angiography can be avoided in some patients. If a patient has all of the following findings: (1) negative thallium imaging results in vascular distributions outside the MI, (2) an increase in blood pressure during exercise, and (3) a peak heart rate >85% of the age-predicted maximum, then the chance of left main or 3-vessel disease should be very low (predictive error 14 ± 7% in our study population with a 43% prevalence of anatomically high-risk disease). In a patient without disabling symptoms, the indications for coronary angiography would be weak if the above normal findings were present.

The present study of primarily symptomatic patients, with a 43% prevalence of high-risk CAD shows a good predictive value for several of these criteria to detect high-risk CAD. Population prevalence influences predictive value and predictive error of a test.[43,44] The true prevalence of left main or 3-vessel disease after a first infarct is not certain, but the ranges of prevalence of multivessel disease, 3-vessel disease, or left main disease in the present study are similar to those in other studies.[7,8,10,11,15–17,31,32,39,40,49,51,53–55] It is likely that the prevalence of high-risk CAD in populations of patients who are selected by having a first infarct varies much less than does the prevalence of any CAD in different populations. Figure 4 indicates the effect of variation in the prevalence of high-risk CAD in a population on the predictions by defects on thallium imaging outside the infarct or by exercise electrocardiography. Considering the numbers of patients involved, these graphs serve to illustrate important clinical trends, but they cannot predict the exact probability of high-risk CAD in a particular patient. Thus, differences in prevalence of high-risk CAD within the range discussed would have only small effects on predictive value and predictive error of these tests. Even if asymptomatic patients have a lower prevalence, for example, 10 to 20%, a negative test would further reduce the likelihood of high-risk CAD. Conversely, positive findings on thallium imaging outside the infarct would indicate a 56 to 72% probability of high-risk CAD in the same patient population. Thus, these tests can probably help clinical management of patients who are completely asymptomatic after their first infarct.

The results of these exercise test criteria did not correlate with the resting left ventricular ejection fraction, suggesting that these exercise results were not determined by the extent of irreversible left ventricular damage 3 to 24 months after MI. This finding is important because it offers the first support for the premise that these criteria may predict the potentially reversible component of a poor prognosis after an infarct, and, thus, be quite useful when screening patients after a first MI to determine who might benefit from surgery. Noninvasive exercise tests with thallium imaging offer a more cost-effective way to identify patients who are at high risk due to extensive CAD after a first MI than would widespread use of coronary angiography in every patient. Furthermore, the present study indicates that exercise thallium imaging is more accurate than exercise electrocardiography to identify 3-vessel and left main coronary disease. These differences should be noted in considering recent reports of exercise electrocardiography after infarction.[64–67]

Patients in the present study had exercise tests 3 to 24 months after their first myocardial infarction (most between 3 and 6 months). Had we studied all patients 2 to 4 weeks after infarction, the results might have differed, particularly for the clinical observations (criteria IA to ID). The S-T response to exercise might have changed over time, 2 weeks to 2 years after infarction,

but it seems less likely that the results of thallium imaging of defects outside the infarct would change. More relevant to our study, it seems less likely that there would be major changes in noninvasive test results after a person had fully recovered from infarction for 3 months. Thus, the results of the present study are most applicable to patients who have fully recovered from a first infarct for 3 to 24 months.

Most deaths occur within the first 6 months after infarction,[1,4] and several studies have performed exercise tests 2 to 4 weeks after infarction in an attempt to identify these patients.[13,14,53,64–67] A major limitation of these studies is that most of the early deaths are related to electrical and mechanical complications of large infarcts, and it is not clear that medical or surgical therapy will alter the natural history for these patients. For this reason we were more interested in identifying patients who had extensive CAD jeopardizing noninfarcted myocardium since medical and surgical therapy should be more effective in this group.

**Cost-effectiveness of exercise testing after MI (Table VII):** It is extremely difficult to measure cost-effectiveness of medical diagnostic tests,[25,68] but the cost of exercise tests with electrocardiography and thallium imaging require justification. Estimation of effectiveness or quality of care is most difficult, but we made 3 assumptions for our population. First, we assumed that good quality of care would require identification of the maximal number of patients with left main or 3-vessel disease while performing the minimal number of cardiac catheterizations. The potential for poor quality of care due to suboptimal management of high-risk CAD seems more serious than does the small risk and inconvenience of extra cardiac catheterizations. Some patients would require angiography for other reasons such as intractable anginal symptoms. Calculating costs is also difficult, but we made several assumptions about our population and the relative costs of the tests, as shown in Table VII. A different diagnostic approach is shown in each panel, A to E. Panel A assumes that every patient needs every test after MI; this is the most expensive approach, as expected. Panel B assumes that every patient after infarction needs angiography, and noninvasive tests should be avoided as unreliable and costly. Widespread application of this approach would greatly increase the number of coronary angiograms. The approach does save 15% relative to approach A, but this saving may be misleading because of the need for angiography in every patient after MI. Panel C assumes that patients with typical angina after an infarct should all have angiography without noninvasive tests, and patients without angina should have exercise electrocardiography and be referred to catheterization if the S-T segment response is positive. This approach would fail to identify 1 of 17 patients with high-risk CAD,[2] but saves 23% relative to approach A.

Panel D assumes that all patients should have exercise electrocardiography, and those with a positive S-T response should have angiography. The 44% financial saving in this approach is offset by missing 5 of 17 (29%) patients with high-risk CAD because of the low sensitivity of the S-T response.

**TABLE VII Estimated Cost-Effectiveness of Screening Patients for Left Main or 3-Vessel CAD After MI by Exercise Tests With Electrocardiography (Ex-ECG) and Thallium-201 (Tl-201) Imaging and Coronary Angiography**

| | Cost × N (Pts) | = Total | Pts With Left Main/3-Vessel Disease Missed |
|---|---|---|---|
| **A. All Tests in Every Patient** | | | |
| ECG & Tl-201 | $450 × 40 | = $ 18,000 | |
| Angiography | $3,000 × 40 | = $120,000 | |
| | | = $138,000 | None missed |
| **B. Angiography in All Patients, No Exercise Tests** | | | |
| ECG & Tl-201 | $0 | = $0 | |
| Angiography | $3,000 × 40 | = $120,000 | |
| | | = $120,000 | None missed |
| **C. Exercise ECG (but no Tl-201) in Patients Without Typical Angina, Angiography if Patient Has Typical Angina or Positive Exercise ECG Results** | | | |
| ExECG | $150 × 10 | = $ 1,500 | |
| Angiography | $3,000 × 35 | = $105,000 | |
| | | = $106,500 | Misses 1 of 17 pts |
| **D. Exercise ECG in all Patients, Angiography if Positive ECG Results** | | | |
| ExECG | $150 × 40 | = $ 6,000 | |
| Angiography | $3,000 × 24 | = $72,000 | |
| | | = $78,000 | Misses 5 of 17 pts |
| **E. Exercise Tl-201 in all Patients; Angiography if Tl-201 is Positive Outside the Infarct Region, or if Blood Pressure Decreases During Exercise, or if a Patient Without Propranolol Fails to Achieve 85% of Predicted Heart Rate** | | | |
| Tl-201 | $300 × 40 | = $12,000 | |
| Angiography | $3,000 × 20 | = $60,000 | |
| | | = $72,000 | Misses 1 of 17 pts |

Cost = number (N) of patients tested × test fee. Fee = $150 for electrocardiography (ECG) and $300 for thallium-201. Pts = patients.

Panel E uses the approach suggested by our data: all patients should have exercise testing with thallium imaging and clinical observation. Electrocardiography would be used only to monitor for arrhythmias. Patients are referred for angiography if they have thallium defects outside the vascular distribution of the infarct, or if they have a decrease in blood pressure during exercise, or if patients not taking propranolol fail to achieve 85% of their age-predicted maximal heart rate during exercise. The small extra cost of thallium imaging is offset by the increased accuracy of the test when patients with negative thallium imaging at adequate heart rates are not referred for angiography. The financial saving is 48% relative to approach A, 40% relative to approach B (angiography in all patients after MI), 32% relative to approach C, and 8% relative to approach D. While only 1 of 17 patients with anatomically high-risk disease is missed by approach E, 5 of 17 high-risk patients were missed by approach D.

Again, these estimates of cost-effectiveness are not definitive; however, they illustrate the high cost of ex-

cessive tests, the potential decline in quality of care if an unreliable test such as the exercise electrocardiogram is relied upon too heavily, and an apparent justification of exercise testing with thallium imaging as a cost-effective approach to screening patients for high-risk CAD after MI. The population of the present study represented patients selected by their physicians for cardiac catheterization because of a probability of high-risk disease. If the general population of patients has a lower prevalence of high-risk CAD, then Figure 4 would predict a higher percentage of patients with negative findings on thallium imaging. This trend would reduce further the cost of approach E relative to performing angiography in all patients after MI.

**Acknowledgment:** The authors are grateful to Ken Miceli, RT, and Sue Strauss, RT, for assistance in acquiring the thallium-201 images. We also thank Maureen Baker for help in performing the exercise tests and Irma Rosenblatt for assistance in preparing the manuscript.

# Papillary Muscle Rupture Complicating Acute Myocardial Infarction: Analysis of 17 Patients

RICK A. NISHIMURA, MD, HARTZELL V. SCHAFF, MD, CLARENCE SHUB, MD, BERNARD J. GERSH, MB, ChB, DPhil, WILLIAM D. EDWARDS, MD, and ABDUL J. TAJIK, MD

**The records of 17 patients (10 men and 7 women) with the diagnosis of acute papillary muscle rupture secondary to acute myocardial infarction (AMI) were reviewed to determine the clinical course and pathologic features of this entity. Eight patients underwent operation after papillary muscle rupture had been diagnosed, and 9 had the diagnosis confirmed at autopsy without a prior surgical procedure. The ages were 44 to 80 years (mean 64). The site of AMI was inferolateral in 15 and anterior in 2. The recorded onset of mitral regurgitation ranged from <24 hours to 28 days after AMI (mean 6 days). Of the 11 patients presenting with pulmonary congestion alone, 6 remained stable and had subsequent mitral valve replacement and coronary artery bypass graft operation; however, 5 patients' condition initially stabilized with medical therapy and then suddenly deteriorated after a variable period (1 to 60 days), followed by death. Of the 6 patients who presented with systemic hypotension and pulmonary congestion, 4 were treated medically and died; 1 of the 2 who had surgical treatment survived. The extent of the AMI at autopsy was small and was limited to the subendocardium in half of the patients. Significant coronary artery disease was limited to a single vessel in 7 of 14 patients. The unpredictable and rapid clinical deterioration and the limited extent of coronary atherosclerotic disease and infarct size suggest that early surgical repair should be undertaken in patients with papillary muscle rupture after AMI.**

Papillary muscle rupture, a rare but well-documented complication of AMI, usually occurs 2 to 7 days after AMI and leads to acute mitral regurgitation (MR), pulmonary edema, cardiogenic shock, or some combination of these findings.[1] If this rupture is untreated, the prognosis is poor; an 80% mortality rate in the first week has been reported.[2] Wei et al[1] estimated that 0.4 to 5.0% of all deaths after AMI are associated with papillary muscle rupture. Prompt diagnosis, hemodynamic stabilization (with intraaortic balloon support, if necessary), and mitral valve replacement combined with coronary artery bypass operation may improve the poor natural history. We reviewed the records of patients diagnosed as having papillary muscle rupture at the Mayo Clinic from 1939 to 1981, with particular attention to the clinical course and pathologic features.

From the Mayo Clinic and Mayo Foundation, Rochester, Minnesota. Manuscript received June 29, 1982; revised manuscript received September 2, 1982, accepted September 3, 1982.

## Clinical Profile

Excluded from the analysis were patients with chordal rupture, papillary muscle dysfunction, and papillary muscle rupture unassociated with coronary heart disease. Seventeen patients (10 men and 7 women) had papillary muscle rupture secondary to AMI. Of these patients, 8 had undergone operation for papillary muscle rupture (Group 1), and 9 had the diagnosis confirmed at autopsy (Group 2) and had not undergone operation. The ages of the overall group ranged from 44 to 80 years (mean 64); the mean age was 58 years in Group 1 and 69 years in Group 2. Only 1 patient had a history of documented prior AMI that healed. Four patients had had stable exertional angina before the AMI, and 12 patients had no history of angina or AMI. Three patients had a history of systemic hypertension.

All patients had a recent AMI substantiated by electrocardiographic changes, postmortem examination, or both. Electrocardiograms were available in 14 patients; the site of AMI was inferior in 10, anterior in 1, and of undetermined location in 3. The AMI was subendocardial in 8 patients and transmural in 6 patients. The recorded onset of MR ranged from <24 hours to 28 days after clinical AMI (mean interval 6 days), occurring earlier than 24 hours in 3 patients and later

than 5 days in 4 patients (Tables I and II). A loud precordial holosystolic murmur was heard in all but 2 patients; these 2 patients had severe pulmonary edema with shock and died within 24 hours after the onset of papillary muscle rupture. One of these 2 patients had total rupture of the papillary muscle. Auscultatory evidence of pulmonary congestion was present in all patients. Eleven patients presented with pulmonary congestion alone, and 6 patients had pulmonary congestion in association with systemic hypotension (systolic blood pressure <90 mm Hg).

## Methods

**Noninvasive:** Of the 6 patients in Group 1 in whom papillary muscle rupture was diagnosed after 1972, 4 underwent M-mode echocardiography. Three studies demonstrated the typical flail mitral leaflet with systolic posterior motion, in combination with shaggy echoes and diastolic flutter; the remaining study demonstrated a hyperdynamic septum with increased D-E excursion of the mitral valve. The posterior left ventricular wall was hypokinetic in 2 studies, and normal wall motion was seen in the other 2 studies. Three patients underwent 2-dimensional echocardiography. Two patients had localized hypokinesia of the inferobasal wall, and the third patient had a large inferior akinetic area extending from the apex to the base. Partial rupture of the head of the posteromedial papillary muscle could be seen in 2 of the 3 patients; the muscle was attached to the chordae and "swinging" into the left atrium.

**Invasive:** Cardiac catheterization was performed in 6 patients, and bedside hemodynamic monitoring (Swan-Ganz catheterization) was done in 1 additional patient (Table I). The mean pulmonary arterial wedge pressure in these patients was 21 mm Hg (range 17 to 31), with a peak V wave mean of 55 mm Hg (range 38 to 66). The mean cardiac index was 2.4 liters/min/$m^2$ (range 1.9 to 2.8). In all 6 patients who underwent left ventricular cineangiography, dense opacification of the left atrium confirmed the presence of severe MR. Coronary cineangiography was performed in 5 patients; 2 had severe (>75% stenosis) 3-vessel disease, 1 had 2-vessel disease, and 2 had single-vessel right coronary artery disease (Fig. 1). Left ventriculography revealed ventricular dilatation and regional wall abnormalities in all 5 patients. One patient had global reduction in left ventricular function; the remaining 4 patients had normal ventricular function. The mean left ventricular ejection fraction was 51% (range 32 to 60%). In 1 patient, a radiolucent mass—thought to be the head of the ruptured papillary muscle—was noted to prolapse into the left atrium during systole.

**Course and management:** Operation was performed in 8 of 17 patients from 1968 to 1981. Seven had elective mitral valve replacement performed 76 to 155 days after AMI. All patients in whom elective operation was performed had satisfactory left ventricular function and a cardiac index ≥2.3 liters/min/$m^2$. One Ionescu-Shiley, 1 Smeloff-Cutter, and 6 Starr-Edwards prostheses were used. Concomitant coronary bypass grafting was performed in 3 patients; 1 had 3 grafts (right coronary, obtuse marginal, and left anterior descending arteries), 1 had 2 grafts (right coronary and left anterior descending arteries), and the third had a single graft (right coronary artery). All 7 patients survived the operative procedure. One patient died in the postoperative period from a pulmonary artery rupture from an occluding Swan-Ganz catheter balloon.

One patient underwent an emergency operation 18 days after a large transmural inferior AMI. This patient underwent operation because of sudden cardiogenic shock; because of hemodynamic deterioration, he could not be weaned from cardiopulmonary bypass. Preoperative 2-dimensional echocardiography had demonstrated a large akinetic inferior wall extending from the base to the apex of the left ventricle and rupture of the posteromedial papillary muscle. The cardiac index was 1.9 liters/min/$m^2$.

Of 11 patients who presented with congestive heart failure unaccompanied by hypotension, 6 remained stable preoperatively; however, 5 patients had sudden deterioration and death occurring at 1, 3, 6, 30, and 60 days, respectively, after the onset of mitral regurgitation (Fig. 2). Of 6 patients who presented with pulmonary edema and hypotension, 4 died within the first 24 to 48 hours. One patient's condition stabilized with use of vasodilators and an intraaortic balloon pump and a successful operation was performed 72 days later. In another patient, treatment with vasodilators resulted in a stabilized condition; 2-dimensional echocardiography disclosed a partial rupture of the papillary muscle. Seven days later, abrupt deterioration necessitated surgical intervention. At operation, complete rupture of the papillary muscle was found. The patient died.

**Pathologic material (Table II):** From 1939 to 1972, 9 patients who did not undergo an operation died after the onset of MR and had postmortem examinations. Five deaths occurred <48 hours after the onset of congestive heart failure.

The posteromedial mitral papillary muscle was involved in 8 patients; 1 patient had rupture of the anterolateral mitral papillary muscle. Among all specimens, 2 had complete dehiscence of the papillary muscle. The other 7 hearts demonstrated either partial rupture of the posteromedial papillary muscle (rupture of 1 of 2 or 2 of 5 heads) or incomplete rupture of a single trunk.

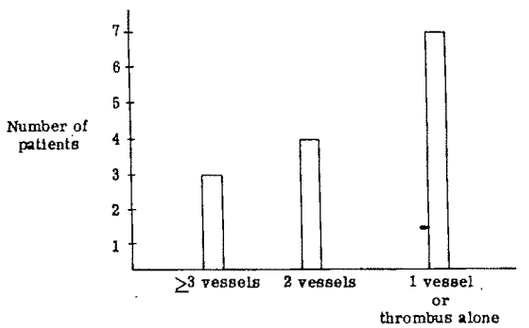

**FIGURE 1.** Extent of coronary artery disease in patients (from Groups 1 and 2) with papillary muscle rupture. Significant disease was defined as >75% stenosis of the cross-sectional diameter.

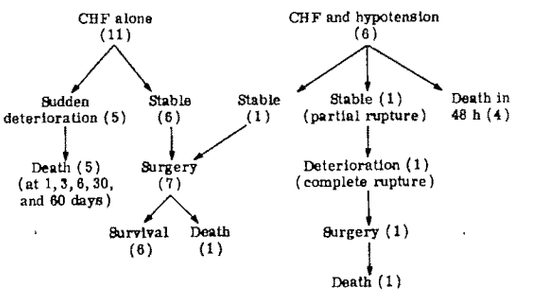

**FIGURE 2.** Clinical course of patients with rupture of papillary muscle. CHF = congestive heart failure.

Inferoposterior AMI was transmural in 4 patients and was limited to the subendocardium in 5 patients; 2 of the subendocardial infarctions were clinically suspected to have been transmural because of the presence of Q waves in the electrocardiogram. Five infarcts involved a relatively small area of the myocardium (<6 $cm^2$). Both total papillary muscle ruptures were associated with extensive transmural infarcts. Three patients had had previous AMI that healed.

The extent of coronary arterial disease was determined by examination of serial cross sections of the coronary arteries at 3-mm intervals. Obstruction of ≥75% of the cross-sectional area was considered significant (Fig. 1). Four patients had significant obstruction in 2 or 3 coronary arteries. Two patients had single-vessel disease. In the remaining 3 patients, a thrombus with no apparent underlying atherosclerotic lesion was present at the site of occlusion.

## Discussion

Cardiogenic shock after AMI can be caused by many factors but usually is the consequence of extensive myocardial damage; the prognosis for affected patients is dismal despite new therapeutic options.[3] Thus, the incentive to identify a potentially reversible cause of cardiogenic shock is great. Approximately 15% of all patients with fatal AMI have complications attributable to some degree of myocardial rupture and may be potentially salvageable.[1,4] In 1 reported series,[5] 85% of patients with myocardial rupture had rupture of the free wall of the left ventricle, 10% had a ventricular septal defect, and 5% had an acute papillary muscle rupture. The first antemortem diagnosis of a ruptured papillary muscle was reported in 1948[6]; since then, several series of papillary muscle rupture—totaling more than 160 patients—have been reported.[2,5,7–11]

The arterial supply to the papillary muscles consists of small coronary vessels derived from the large epicardial arteries, which in turn traverse the entire thickness of the left ventricular wall and the papillary muscles themselves. The excessive length of the arteries and their subendocardial location may account for the susceptibility to ischemia.[2,12] Because of a single blood supply from the posterior descending artery to the posteromedial papillary muscle, the latter is involved with ruptures 6 to 12 times more frequently than the anterolateral muscle, which has a dual blood supply from the left anterior descending and left circumflex coronary arteries.[1,2,5,12]

The clinical course is characterized by the onset of pulmonary edema or hypotension (or both), usually 2 to 7 days after an AMI.[1] A systolic murmur is usually heard but may seem inconsequential because of the dynamics of acute MR and resultant pressure equalization between the left atrium and the left ventricle.[13] In the setting of an AMI, ventricular septal defect[14–16] and papillary muscle dysfunction[17] must be considered when a new systolic murmur appears in association with clinical deterioration.

The 2-dimensional echocardiogram has been shown to be useful in this differential diagnosis. Direct visualization of a ventricular septal defect has been demonstrated by 2-dimensional echocardiography.[15,16] The echocardiogram may also be useful in distinguishing papillary muscle dysfunction from rupture.[9] Papillary muscle dysfunction is usually found in conjunction with large transmural AMI and major wall motion abnormalities. The papillary muscle itself may appear echodense and notably hypokinetic; these factors result in improper coaptation of the mitral leaflets.[18] Alternatively, papillary muscle rupture may result in a flail mitral leaflet and extension of a portion of the flail leaflet into the left atrium during systole. Coarse diastolic or systolic fluttering of the flail leaflet may be seen.[19,20] In 2 previous reports,[9,21] the belly of the papillary muscle itself had ruptured and could be directly visualized as a mass attached to the chordae, as was seen in 2 of the 3 patients described in our study.

Treatment of papillary muscle rupture has consisted of medical and surgical management. Medical treatment alone has been unsuccessful in most of these patients. Studies in the presurgical era showed a poor prognosis: 33% of the patients died immediately, 50% died within the first 24 hours, and only 6% survived longer than 2 months.[2] Vasodilator therapy, intraaortic balloon pumping, and surgical procedures with improved myocardial protection have increased the number of survivors with this previously fatal complication.[7,8,11,22,23] Replacement of the mitral valve in a patient with papillary muscle rupture was first performed successfully by Austen et al[10] in 1965. With a satisfactorily functioning left ventricle, patients have survived rupture of the entire trunk of the papillary muscle with surgical intervention.[22] Recently, mitral valve repair has been successful in this situation.[24]

The optimal timing of surgical intervention remains unclarified. Patients with acute MR after AMI have a reported 35 to 50% mortality when an operation is performed within 30 days after the acute event.[4,8] If operation is delayed for more than 3 months after AMI, operative mortality is reported to be lowered to 15 to 25%.[4,8] This delay in surgical intervention results in a selection process whereby patients with relatively good ventricular function and less severe MR eventually become candidates for valve replacement or repair. This strategy may result in excellent surgical survival; however, overall salvage of patients with acute MR due to papillary muscle rupture might be improved by proceeding with valve replacement (and coronary artery bypass grafting, if necessary) early after the diagnosis is made, even in patients whose symptoms are controlled. With the use of diuretic drugs and the newer afterload reduction agents, stabilization for 1 to 3 months may be possible; nonetheless, the labile course with rapid clinical deterioration and death seen even after stabilization in our series shows that this delay is not without risk.

The pathologic features of coronary artery disease associated with the papillary muscle rupture in this study are of important clinical relevance. Half of the postmortem examinations showed small areas of myocardial infarction limited to the subendocardium, surrounding the papillary muscle. This relatively small area of infarction associated with papillary muscle rupture has been reported by others.[1] Conceivably, patients with smaller infarctions may be more prone to ruptures, as their relatively good ventricular function may result in a greater "shearing" force at the site of potential ruptures. The extent of coronary artery disease seen in

patients undergoing angiography or at autopsy was also, in most cases, not extensive. Seven of 14 had either single-vessel disease or the absence of significant coronary artery disease (Fig. 1). Both the relatively minimal involvement of the myocardium and the moderate extent of coronary artery disease portend a good prognosis if the hemodynamic abnormality itself can be corrected.

Mortality in the postoperative period is primarily due to inadequate myocardial function and recurrent myocardial infarction.[7] Concomitant coronary artery bypass grafting should be considered. Because 2-dimensional echocardiography provides regional and global assessment of left ventricular function, it may eliminate the need for left ventricular angiography, especially in those patients who remain hemodynamically unstable. We do, however, recommend early coronary cineangiography to delineate the coronary anatomy before valve replacement or repair.

Although papillary muscle rupture is an uncommon complication of AMI, it is life-threatening and may be potentially curable. When a new systolic murmur develops in the setting of an AMI, the pathogenesis may be elucidated by 2-dimensional echocardiography. An early surgical approach seems reasonable in patients with acute papillary muscle rupture; this will probably result in an increase in surgical mortality but may improve overall patient salvage. In stable patients, deterioration may be sudden and unpredictable, and thus delay in the timing of operation is risky. In patients with hypotension, mortality with medical therapy is high; no patient in our study survived on medical therapy alone. This prompts us to consider early surgical intervention in all patients with papillary muscle rupture, irrespective of their clinical presentation.

# Comparative Rates of Resolution of QRS Changes After Operative and Nonoperative Acute Myocardial Infarcts

DAVID E. ALBERT, MS, ROBERT M. CALIFF, MD, DAVID A. LeCOCQ, RAY A. McKINNIS, PhD, RAYMOND E. IDEKER, MD, PhD, and GALEN S. WAGNER, MD

**An independently developed and previously validated QRS scoring system for estimating myocardial infarct size has been used to compare the development and regression of changes associated with myocardial infarcts occurring in 2 different clinical settings. It is known that QRS changes suggesting myocardial infarction occur after coronary artery bypass grafting. This study compares the magnitudes and time courses of these QRS changes in 40 patients with the QRS changes observed in a control group of 46 patients with nonoperative acute myocardial infarcts. Only patients in both groups who had a baseline electrocardiogram (ECG) with no evidence of previous myocardial infarcts, ventricular hypertrophy, or bundle branch block were included. Both groups attained similar peak QRS scores during the acute phase but different rates of resolution of scores were observed. During the subsequent 2 months, regression of QRS changes occurred more rapidly in the perioperative group than in the control group (43 versus 19%). Rates of regression were similar in both groups during the remainder of the follow-up period, attaining total decreases of 62% in the operative group and 37% in the nonoperative group by 18 months. These results could mean either that factors other than acute infarction are responsible for the perioperative QRS changes or that the infarct healing process in the 2 clinical settings are quite different.**

Many studies have used the ECG to estimate the incidence of perioperative myocardial infarction. This has been complicated by observations that in some patients there is rapid resolution of QRS changes[1] or that new Q waves are due to the "unmasking" of old infarcts.[2] These observations have led to questions regarding the comparability of perioperative with nonoperative myocardial infarcts as diagnosed by the ECG.

Changes in the QRS complex of the standard 12-lead ECG have been shown to correlate with both the size of infarcts as determined at postmortem examination[3–5] and the extent of damage as determined by radionuclide ventriculography[6] during the first year after acute infarction. This study examines the hypothesis that QRS changes suggestive of perioperative myocardial infarction that persist until hospital discharge will undergo a subsequent rate of resolution which exceeds that of nonoperative infarcts. Infarct size calculated from the QRS score may appear similar to that in the nonoperative infarcts initially, but subsequent variations in resolution of the QRS changes would indicate that ultimately the perioperative infarcts involved less myocardium.

| | R ≥60 (2) | | |
| | R ≥50 (1) | R/S ≥1.5 (1) | 4 |
| $V_3$ | Any Q or R ≤30 (1) | | 1 |
| $V_4$ | Q ≥20 (1) | R/Q or R/S ≤0.5 (2) | |
| | | R/Q or R/S ≤1 (1) | 3 |
| $V_5$ | Q ≥30 (1) | R/Q or R/S ≤1 (2) | |
| | | R/Q or R/S ≤2 (1) | 3 |
| $V_6$ | Q ≥30 (1) | R/Q or R/S ≤1 (2) | |
| | | R/Q or R/S ≤3 (1) | 3 |

* The number of points awarded for meeting each criterion is in parentheses.

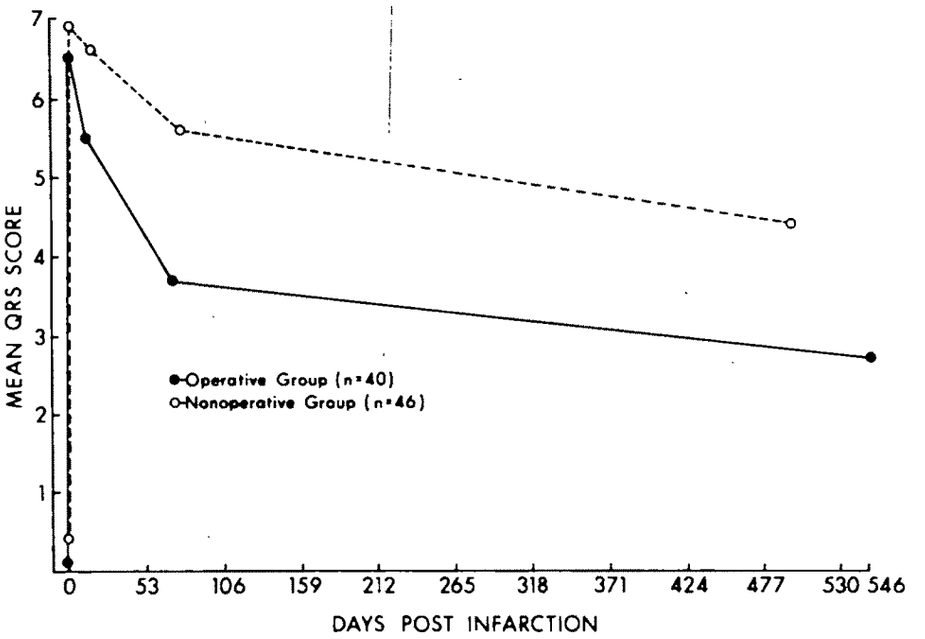

**FIGURE 1.** These curves illustrate the resolution of mean QRS scores in the operative and nonoperative groups. The points indicated on both curves represent the scores obtained on the 12-lead ECG from baseline (preoperative or admission), day 1 to 5 (maximum score), day 14, day 60, and 18 months.

## Methods

**QRS scoring method:** Points were assigned on the basis of absolute duration of Q and R waves and amplitude ratios of the QRS components in 10 leads of the standard 12-lead ECG (Table I). This system consists of a total of 29 points and a score of >2 has a 98% specificity for identification of a myocardial infarct in the absence of confounding cardiac problems.[3]

**Patient population:** Twelve-lead ECGs were reviewed from all patients who underwent coronary artery bypass grafting at Duke University Medical Center or who were admitted to the Duke University Medical Center coronary care unit between 1972 and 1978. Patients with a previous myocardial infarct, a persistent intraventricular conduction abnormality (left anterior or posterior fascicular block, left or right bundle branch block), or ventricular hypertrophy by the Estes (left ventricular hypertrophy)[7] or Sokolow (right ventricular hypertrophy)[8] criteria were eliminated from the study. The effect of these conditions on the QRS complex could limit its ability to indicate myocardial infarct size. Patients were included in the study only if they had a baseline ECG with <3 points and a subsequent ECG that gained at least 2 additional points. In the nonoperative group, the baseline ECG usually was obtained in the emergency room and in the operative group it was acquired during the 24 hours before surgery. A patient from the operative group was included in the study only if QRS changes indicative of an acute infarct appeared within 24 hours after the surgical procedure. Also, only patients with a QRS score which remained greater than that of the baseline ECG for at least 14 days were included.

ECGs from the following intervals were analyzed: baseline; daily through day 5; and closest to day 14, to day 60, and to 18 months after the acute infarct. ECGs were obtained successfully in 100% of the baseline, day 0 to 5, and day 14 intervals. Follow-up ECGs were obtained at 60 days in 95% of the operative group and 96% of the nonoperative group. At 18 months, ECGs were obtained in 75% of the operative group and 86% of the nonoperative group.

Total resolution of the QRS score was defined as a return of the QRS score to the baseline level. Near-total resolution was defined as return of the QRS score to within 1 point of baseline.

**Statistical methods:** A linear regression line was fitted for the natural log of the scores of each patient against the square root of time. The 2 groups were compared using the individual slopes (rate of change) and intercepts of the regression lines with the Wilcoxon ranked sums test. Thus, the initial value and the rate of resolution of the QRS changes were compared rather than the static scores around each particular time interval.

The percentage of patients with complete resolution of the QRS score was compared using Fisher's exact test.

**TABLE II Anatomic Distribution of Acute Myocardial Infarcts**

| Infarct Location | Operative Group (n = 40) | Nonoperative Group (n = 46) |
|---|---|---|
| Anterior | 19 | 15 |
| Inferior | 14 | 25 |
| Posterolateral | 2 | 3 |
| Multiple | 5 | 3 |

## Results

There were 40 patients in the operative group and 46 patients in the nonoperative group. The anatomic distribution of their infarcts by ECG is shown in Table II. According to the ECG, all patients in the operative group had infarcts in the distribution of a grafted coronary artery.

The development and regression of mean QRS scores in both groups are illustrated in Figure 1. The mean baseline level of QRS scores was similar in the groups (0.2 points in the operative group and 0.4 points in the nonoperative group). During the first 5 days after the

acute event, the scores increased to similar mean peaks of 6.5 in the operative group and 6.9 in the nonoperative group ($p = 0.85$). The distribution of peak QRS scores within the 2 groups was also similar. Between days 5 and 60, the slope of the curve relating QRS score to time was steeper in the operative group than in the nonoperative group ($p = 0.03$). While QRS scores continued to decrease between day 60 and 18 months in both groups, the slopes of the curves were similar. In the operative group, the mean QRS score at 18 months was closer to the baseline score than to the peak score, having decreased by 62%. The mean decrease in QRS score by 18 months in the nonoperative group was 37%.

Table III depicts the number of patients in each group who had total or near-total resolution of their QRS changes during follow-up. At 60 days, 11% of the operative group had total resolution compared with none of the nonoperative group ($p = 0.05$). At 18 months, no significant difference in total resolution could be found between the 2 groups. At both time periods, however, more operative patients had near-total resolution than nonoperative patients ($p = 0.02$ at 60 days; $p = 0.03$ at 18 months).

## Discussion

The QRS scoring system developed by Selvester et al[9] and simplified and modified by Wagner et al[3] is based on the computer simulation of the human myocardial activation sequence documented by Durrer et al.[10] It achieves high specificity in normal controls[3] and correlates with the anatomic extent of single infarcts in the anterior[4] and inferior[5] aspects of the left ventricle. In the present study, the peak QRS score of the group with operative infarcts was similar to that of the nonoperative group, suggesting either that similar extents of infarction developed in both groups or that the initial extent of infarction was not as large as indicated by the QRS score in the operative group.

QRS changes tend to resolve gradually after acute infarcts.[11–13] In the studies that compared the QRS score with the anatomic infarct size,[4,5] the correlation between the size estimated from the final ECG before death and the observed size was similar when the necrosis was acute and when there was a fibrotic scar. This observation suggests that the reason for QRS resolution is the "resolution" of the infarct itself. The "healing" process results in the resolution of edema and cellular infiltration of the inflammatory response and retraction of the scar tissue. This is accompanied by hypertrophy of adjacent myocardium. Thus, the percentage of left ventricle that contains nonviable tissue may be greater during the necrotic stage than in the fibrotic stage of myocardial infarction.

**TABLE III Resolution of QRS Changes in Patient Groups**

| | 60 Days | | 18 Months | |
|---|---|---|---|---|
| | Total* | Near-Total† | Total* | Near-Total† |
| Operative group | 4/38 (11%) | 13/38 (34%) | 7/30 (23%) | 16/30 (53%) |
| Nonoperative group | 0/44 (0%) | 4/44 (9%) | 5/39 (13%) | 7/39 (18%) |
| | $p = 0.05$ | $p = 0.02$ | $p = 0.26$ | $p = 0.03$ |

* Return to baseline QRS score; † return to within 1 point of baseline QRS score.

Perioperative infarcts are marked by contraction-band necrosis, indicating that a period of occlusion has been followed by reperfusion.[14] Intraoperative studies indicate that these infarcts frequently begin early during the operative procedure.[15–18] The infarcts are located in areas supplied by patent grafts in 80% of instances.[19–22] These infarcts are frequently not followed by significant wall motion abnormality[23,24] and, as documented in the present study, are accompanied by a more rapid and complete resolution of QRS score than are nonoperative infarcts. These studies suggest that the myocardial infarcts occurring during coronary artery bypass grafting may serve as an experimental model by which reperfusion of a developing area of necrosis could be evaluated.

Blood flow is essential[25] for wound healing. Thus, reperfusion after the onset of an acute myocardial infarct might facilitate the healing process and result in a decreased ratio of infarcted to noninfarcted myocardium. Shaw et al[26] have demonstrated that the wound produced by a left ventricular venting during coronary bypass surgery results in akinesis or dyskinesis when the blood supply to the area is impaired, but causes no detectable wall motion abnormality when flow is unimpaired. Therefore, it is possible that the operative and nonoperative groups had infarcts which were initially of similar size, but the resolution or healing of the operative infarcts was augmented by prompt reperfusion. This would result in a subsequent decrease in the ratio of infarcted to normal myocardium.

It is important to consider possible alternate explanations for the differences observed in QRS resolution between the operative and nonoperative groups. The rapid decrease in QRS score in the operative group during the first 2 months (Fig. 1) might be caused by an initial overestimation of infarct size with subsequent disappearance of the confounding factor. Bresnahan et al[27] found that reperfusion vastly increases the fluid in infarct tissue. Ganz et al[28] observed prompt increase in Q-wave size immediately after intracoronary streptokinase infusion in patients with acute infarcts. A study by Bassan et al[2] demonstrated the reappearance of Q waves indicative of remote preoperative infarcts immediately after aortocoronary bypass surgery. Since all of the QRS changes in the operative group indicated infarction in the distribution of a grafted vessel, the increase in fluid caused by operative infarct reperfusion may have exaggerated the peak QRS scores. The subsequent reabsorption of the fluid could explain the accelerated rate of QRS resolution in the operative group.

It is possible that the QRS changes in the operative group were produced or augmented by operative events other than myocardial infarction. Salem et al[1] have observed new Q waves appearing transiently after cardiac surgery in patients with large posterior pericardial

effusions. However, inclusion in the present study required persistence of the new operative QRS changes until hospital discharge. Therefore it is unlikely that such transient events could have been responsible for the QRS changes observed.

The QRS changes which appear after aortocoronary bypass surgery resolve during the subsequent 2 months at a significantly more rapid rate than do similar appearing changes in nonoperative patients. This suggests that use of the ECG for evaluation of either the presence or the extent of perioperative myocardial infarcts would be better performed at this later time. It has been demonstrated[29] that postoperative creatine kinase isoenzyme measurements overestimate the amount of myocardial damage. It is also possible that immediate postoperative QRS changes may overestimate either the initial extent of the operative infarct or the final extent which will be present when the healing process has been completed.

# Evaluation of a QRS Scoring System for Estimating Myocardial Infarct Size

## III. Correlation With Quantitative Anatomic Findings for Inferior Infarcts

STEVEN F. ROARK, MD, RAYMOND E. IDEKER, MD, PhD, GALEN S. WAGNER, MD, DANIEL R. ALONSO, MD, SANFORD P. BISHOP, DVM, PhD, COLIN M. BLOOR, MD, DEAN A. BRAMLET, MD, JESSE E. EDWARDS, MD, JOHN T. FALLON, MD, PhD, GEOFFERY J. GOTTLIEB, MD, DONALD B. HACKEL, MD, HARRY R. PHILLIPS, MD, KEITH A. REIMER, MD, PhD, WILLIAM J. ROGERS, MD, WAYNE K. RUTH, MD, ROBERT M. SAVAGE, MD, RICHARD D. WHITE, MD, and RONALD H. SELVESTER, MD

**This study evaluated by quantitative autopsy correlation a previously developed scoring system for estimating the size of myocardial infarcts based on the QRS complex of the electrocardiogram. This system was tested using electrocardiograms from patients with infarcts shown by autopsy to predominate in the inferior third of the left ventricle. The study was limited to patients whose electrocardiogram did not indicate left or right ventricular hypertrophy, left or right bundle branch block, or left anterior or posterior fascicular block. Thirty-one patients from 6 medical centers met these criteria.**

**In the electrocardiogram of 28 of the 31 patients (90%), lead aVF exhibited a Q wave of at least 30 ms. The correlation coefficient between the total QRS score and the percent infarction of the left ventricle was 0.74. In patients without confounding factors in the electrocardiogram and with single infarcts, the electrocardiogram provides a marker for infarcts in the inferior third of the left ventricle and a quantitative QRS scoring system provides an estimate of infarct size.**

While several new, sophisticated methods are potentially capable of determining the size of myocardial infarcts, it is still important to evaluate the standard 12-lead electrocardiogram because it is readily available, inexpensive, and noninvasive. Although changes in the QRS complex are recognized for their ability to document the presence of various locations of myocardial infarcts, relatively little has been determined about their ability to indicate infarct size. Recent studies from a multicenter collaboration have demonstrated that a simplified version of a previously developed scoring system based on quantitative aspects of the QRS complex attains a correlation of 0.80 with the size of anatomically documented anterior infarcts.[1,2] Previous studies have suggested that the electrocardiogram might be less capable of defining infarcts in the other principal locations in which they occur, that is, inferior and posterolateral aspects of the left ventricle.[3] It is important that the capability of any method for indication of infarct size be evaluated for all infarct locations. Accordingly, this study was performed to determine the correlation between the simplified version of the QRS scoring system and anatomically documented inferior myocardial infarcts.

### Methods

**Criteria for inclusion:** Deceased patients from the Massachusetts General Hospital, Cornell University Medical College, the University of Alabama at Birmingham, the University of California at San Diego, United Hospitals of St. Paul, and Duke University Medical Center were included in the study if they met the following criteria: (1) quantitative postmortem examination revealed a myocardial infarct primarily in the inferior third of the left ventricle (Fig. 1). It was required that this infarct either be the only infarct present or

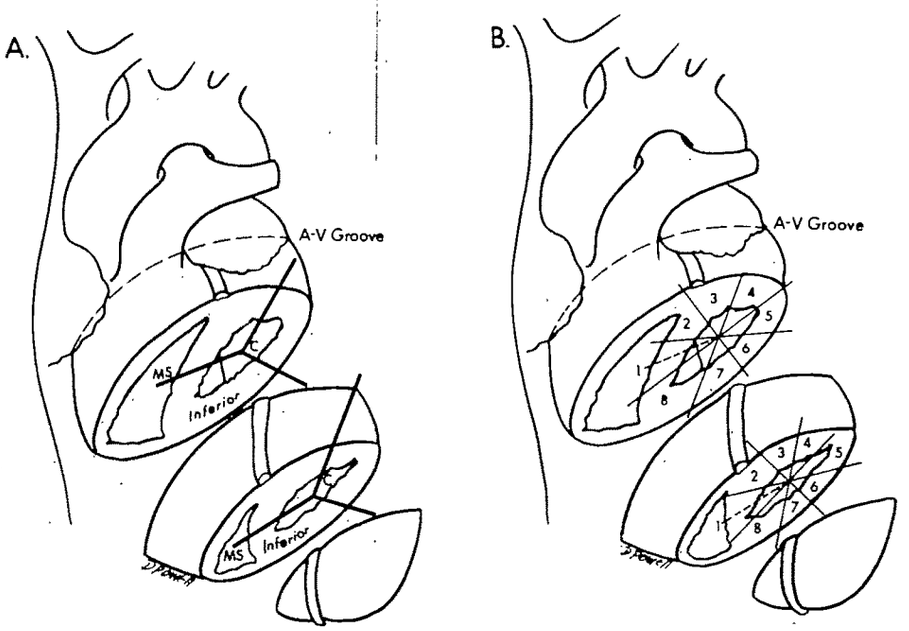

**FIGURE 1.** Division of the left ventricle into thirds (**A**) and octants (**B**). This study includes all cases in which the inferior third of the left ventricle had the largest percent infarction. C = centroid of the outline of the left ventricular epicardium and right septal border; MS = point in the mid-septum halfway between the anterior and posterior endocardial insertions of the right ventricle into the septum. **B**, the **dashed line** MS to C bisects octant 1.

that it be fibrotic and clearly distinguished from a second and fatal acute infarct. In this latter instance only the fibrotic infarct was considered for this study. (2) An electrocardiogram was available that was taken when only the infarct considered in the study was present. This electrocardiogram could not exhibit left or right ventricular hypertrophy, left or right bundle branch block, or left anterior or posterior fascicular block as defined by the IBM program for electrocardiographic analysis.[4] The electrocardiogram must have been taken within 1 year of the paient's death. The final available electrocardiogram was used for the study.

**Quantitative anatomic evaluation:** The hearts, all obtained between 1969 and 1979, were initially dissected by similar protocols at the 6 institutions. The ventricles were cut transverse to the long axis into 5 to 7 slices of approximately equal thickness. Coronary dominance, amount of atherosclerotic coronary arterial disease, and transmural extent of infarction were determined as previously described.[2] To be considered transmural, an infarct had to extend from the endocardium to involve at least 1 cm of the epicardial surface.[2]

The size of the infarct was quantified by computer-assisted planimetry as described previously.[5] Infarct size excludes viable muscle within the infarcted region. For infarcts at least 1 week old at the time of the patient's death, the method includes a correction for estimated wall thinning caused by the infarct. No correction was made for wall thinning in infarcts <1 week old because such thinning was assumed to be caused by expansion and stretching of the infarcted tissue[6] rather than by phagocytosis and scar contraction.

The dominant location of the infarct was determined by comparing the percent infarction of the anterior, posterolateral, and inferior thirds of the left ventricle (Fig. 1A). This study includes all hearts in which the greatest percent infarction was in the inferior third. The percent infarction for each of 24 sectors of the left ventricle was also calculated. The sectors divide the heart into octants in the transverse plane (Fig. 1B) for basal, middle, and apical thirds of the left ventricle as described in the second study in this series.[2]

**Electrocardiographic evaluation:** The point score to estimate infarct size developed by Selvester et al[7-9] and simplified and modified by Wagner et al[1] (Table I) was determined for each electrocardiogram. Points are awarded for duration of Q or R waves and for R to Q and R to S ratios from 10 of the 12 standard leads. R to Q ratio points may only be awarded if Q-wave duration criteria have been satisfied for that lead. However, R to S ratio points may be awarded without consideration of any other criteria for that lead. If there are multiple criteria of a single type (such as Q-wave duration) for a lead, the points achieved by the maximal satisfied criterion are awarded.

## Results

Thirty-one patients met the criteria for inclusion in the study. Twenty-seven were men (mean age 56) and 4 were women (mean age 65). Eighteen of the infarcts were >30 days old when the patient died, 6 between 7 and 30 days old, and 7 were <7 days old. Of the 18 patients with infarcts >30 days old, 10 had a second, fatal infarct.

**TABLE I Simplified QRS Scoring System**

| Lead | Duration (ms) | | Amplitude Ratios | | Maximal Points |
|---|---|---|---|---|---|
| I | Q ≥30 | (1) | R/Q ≤1 | (1) | 2 |
| II | Q ≥40 | (2) | | | |
| | Q ≥30 | (1) | | | 2 |
| aVL | Q ≥30 | (1) | R/Q ≤1 | (1) | 2 |

**TABLE II Transmural Extent of Infarcts**

| | Number of Hearts | | | | |
|---|---|---|---|---|---|
| Level of LV | TM | SEn | SEp | IM | Zero |
| Base | 12 | 19 | 0 | 0 | 0 |
| Middle | 17 | 12 | 1 | 1 | 0 |
| Apex | 4 | 12 | 5 | 6 | 4 |

IM = intramural; LV = left ventricle; SEn = subendocardial; SEp = subepicardial; TM = transmural; zero = no infarct in that level.

**Anatomic evaluation:** The mean total heart weight was 462 g. The right coronary artery was dominant in 29 hearts. Maximal narrowing in the dominant coronary artery was 90 to 100% in all cases. The percentage of the left ventricle that was infarcted ranged from 4 to 41% (mean 15).

Eighteen hearts had transmural involvement in at least 1 level of the left ventricle. Sixteen of 18 infarcts involving >10% of the left ventricle had transmural involvement in at least 1 level. Eleven of 13 infarcts involving ≤10% of the left ventricle had no levels with transmural involvement. Infarcts were more often transmural in the basal and middle thirds than in the apical third (Table II). Eleven of the 13 (85%) nontransmural infarcts in the basal and middle thirds were subendocardial. In the apical third, however, 11 of the 23 (48%) nontransmural infarcts were intramural or subepicardial. Four hearts had no apical involvement.

The inferior free wall (octant 7) was the most commonly involved area with the basal and middle levels containing infarct in 100 and 97% of the hearts, respectively (Table III). The infarcts involved the inferior aspect of the septum and immediately adjacent free wall (octant 8) in 94% of the hearts. Involvement of the midseptum (octant 1) was uncommon, with only 2 infarcts reaching all 3 levels. Many infarcts extended laterally into octant 6 but fewer infarcts extended more laterally into the middle of the "free wall" (octant 5) (Table III). In contrast to anterior infarcts,[2] no infarct predominating in the inferior third had circumferential apical involvement.

**Electrocardiographic evaluation:** Q waves in leads II, III, and aVF are commonly considered indicative of inferior infarcts. Table IV indicates the Q wave durations observed in these 3 leads in the study patients. Q waves of ≥30 ms were present in leads II, aVF, and III in 20, 28, and 22 electrocardiograms, respectively. Forty ms or greater Q waves were present in leads II, aVF, and III in 3, 19, and 14 electrocardiograms, respectively. Thus, 28 of the 31 patients (90%) had a 30 ms Q wave in at least 1 inferiorly oriented electrocardiogram lead, while only 19(61%) had a 40 ms Q wave in at least 1 of these leads.

The mean QRS score for the 31 patients was 5 points, with a range of 0 to 11 (Fig. 2). All but 1 of the patients received points and 26 patients (84%) received >2 points. Of the total of 150 points received by all 31 patients, 119 points (80%) were gained from leads aVF and II. Three patients had no QRS points from either leads aVF or II. One of these patients had no points and 2 had only 1 point, contributed by a Q wave in lead $V_1$. The anatomic size of these infarcts varied from 4 to 10% of the left ventricle and the 2 with a Q wave in $V_1$ did not have more anteroseptally located infarcts.

Five of the 31 patients (16%) received points for increased duration or amplitude of the R wave in leads $V_1$ or $V_2$ (Fig. 2) which has been reported to indicate "true posterior" infarction.[10–12] Ten other patients (32%) received points for a Q wave in lead $V_1$ or a diminished R wave in leads $V_2$ or $V_3$, which have been reported to indicate "anteroseptal" infarction.[13] Eleven of the 31 patients (35%) met criteria for points in leads $V_4$, $V_5$, or $V_6$ which have been reported to indicate apical infarction.[1,14,15] None of the patients met criteria for points from leads I or aVL, which have been reported to indicate "high lateral" infarction.[14,15]

**Comparison of antomic and electrocardiographic estimated infarct size:** A diagram of the location of the infarct and the electrocardiogram is shown for 1 representative patient in Figure 3. The percent infarction of the left ventricle versus the total point score is plotted for all patients in Figure 4. For the 26 patients in whom the electrocardiograms scored >2 points, the mean infarct occupied 17% of the left ventricle (range 4 to 41%). For the 5 patients with electrocardiogram scores of ≤2 points, the mean infarct occupied 7% of the left ventricle (range 4 to 10%).

The correlation coefficient between the number of points and infarct size was 0.74. The slope of the regression line was 2.5, indicating that each QRS point represents infarction of 2.5% of the left ventricle. The standard error of the estimate was 6.6%.

Twenty-seven of the 31 hearts contained infarcts in the apical third of the left ventricle, although only 11 electrocardiograms received points for leads $V_4$ to $V_6$ (Fig. 2). In many patients, however, the amount of apical infarction was small. In the 11 patients receiving points in leads $V_4$ to $V_6$, the mean infarct extent in the apical third of the left ventricle was 12%, significantly greater

**TABLE III Number and Percentage of Hearts With Infarction of Each Octant**

**FIGURE 2.** QRS point scores for each patient. Anatomically estimated infarct size is at the right of the figure. MI = myocardial infarct; LV = left ventricle.

than the mean infarct size of 5% in the 26 patients not receiving such points.

Eleven of the 31 hearts contained infarct in ≥1 level of octant 1 within the mid-septum, although only 8 electrocardiograms received points for Q waves or diminished R waves in leads $V_1$ to $V_3$. The amount of the middle third of octant 1 infarcted in the 8 patients receiving points for Q waves or diminished R waves in leads $V_1$ to $V_3$ (mean infarction of 0%) was not significantly greater than the mean amount infarcted for the 23 patients not receiving these points (mean infarction of 4%).

## Discussion

**Terminology of infarct location:** The inferior aspect of the left ventricle is the site of approximately 40% of all myocardial infarcts. This incidence is similar to that for anterior infarcts, but both the anatomic location and electrocardiographic changes for inferior infarcts are less well understood than for anterior infarcts. The term *inferior* or *diaphragmatic* is applied when the frontal plane leads II, III, and aVF are involved, and the term *true posterior* is applied when the right precordial leads are involved. However, it has not been clear pre-

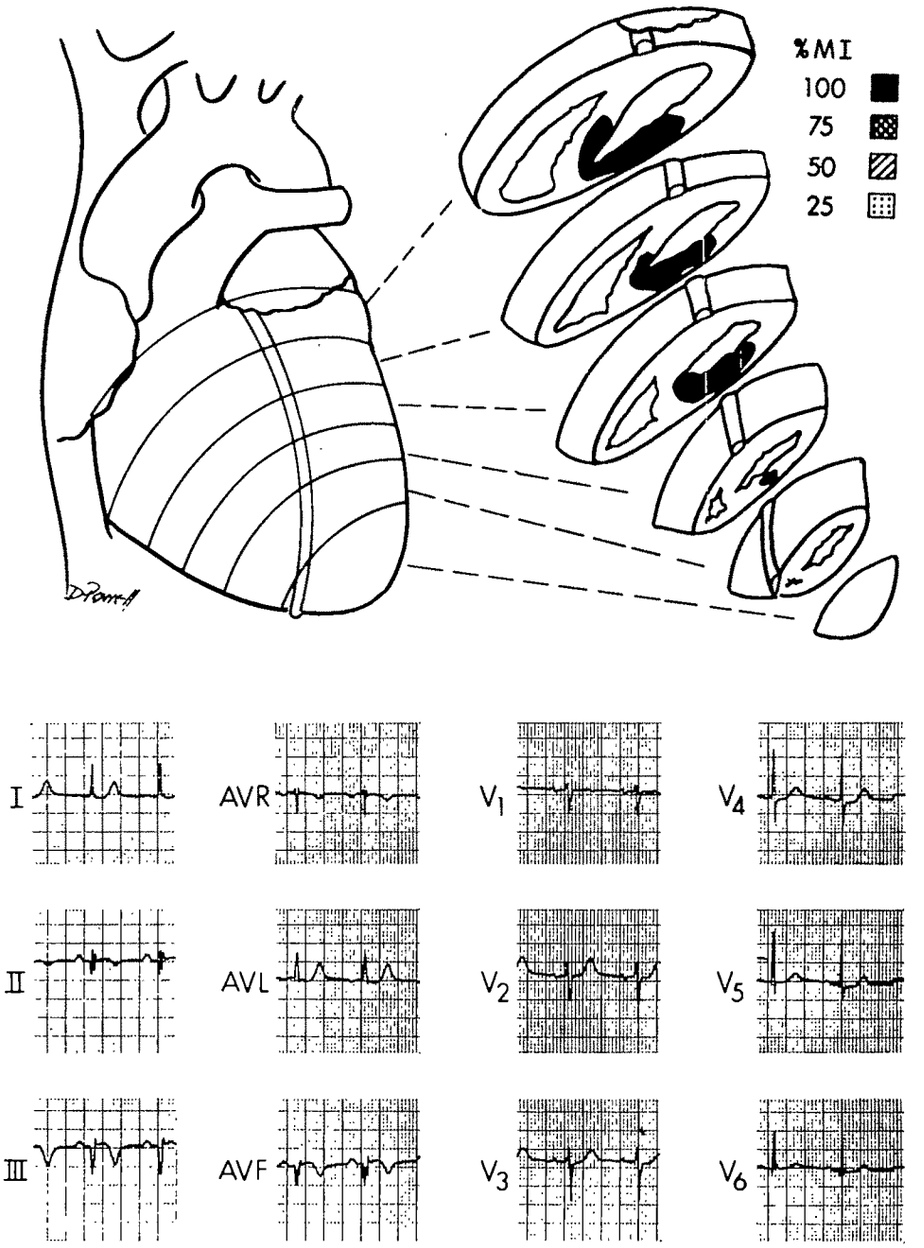

**FIGURE 3.** Myocardial infarct (MI) location and electrocardiogram for Patient 22. The infarct was acute, solid, and occupied 13% of the left ventricle. Six QRS points were awarded; Q ≥50 ms and R/Q ≥1 in lead aVF, and a Q ≥30 ms in lead II.

cisely which areas of the myocardium lie in the inferior versus the true posterior locations.

Originally, infarcts now called inferior were called posterior and those now called true posterior were called lateral. Barnes and Ball,[16] in a series of 1,000 consecutive necropsies, delineated 3 primary locations of infarcts: (1) infarcts in the anterior septum, adjacent free wall, and apex, ascribed to disease of the left anterior descending coronary artery, (2) infarcts in the posterior septum and adjacent free wall, usually due to right coronary artery disease, and (3) infarcts in the free wall opposite the septum resulting from disease in the circumflex coronary artery. A series of studies during the late 1940s by Myers[13,14,17-21] presented electrocardiographic criteria for the localization of myocardial infarcts based on pathological correlation. More recent studies have extended these qualitative observations by quantifying the pathologic and electrocardiographic aspects of myocardial infarcts.[22-26]

Sayen[27] showed that optimal evaluation of the relation between the electrocardiogram and anatomic extent of myocardial infarcts requires division of the left ventricle circumferentially into thirds that correspond roughly to the vascular beds of the 3 major coronary arteries. These locations are termed *anterior*, *inferior*, and *posterolateral*, respectively, in this report. In a previous study from Duke, only anterior and posterior locations were considered and, because of the small number of patients, no attempt was made to distinguish inferior from posterolateral.[3] Acquisition of additional patients from other medical centers permitted separation of the general group with posterior infarcts into those with primarily inferior location included in this study and primarily posterolateral location included in a subsequent study. The pathologists working with the Myocardial Infarction Research Units and the Specialized Centers of Research in Ischemic Heart Disease adopted a common protocol for evaluation of the hearts of patients with coronary disease.[28] The hearts had been carefully evaluated and preserved and were thus available for inclusion in this collaborative project.

A QRS scoring system has been proposed by Selvester et al[7-9] from computer simulation of human heart activation. This has been described extensively elsewhere. A previous study documented both the specificity of the QRS scoring system in normal control subjects and the intra- and interobserver variability of performing the scoring on a standard 12-lead electrocardiogram.[1]

Through collaboration, the anatomical extent of a large number of single infarcts in the distributions of each of the major coronary arteries was correlated with the changes in the QRS complex which had been proposed for infarct sizing by Selvester et al. Patients with infarcts primarily in the anterior third of the left ventricle have been the subject of a previous study.[2] This study considers those 31 patients with infarction primarily involving the inferior third of the left ventricle as indicated in Figure 1.

**Quantitative anatomy of inferior infarcts:** This study confirms quantitatively the location of these infarcts previously reported by Barnes[16,29,30] and by Sayen et al.[27] All of the infarcts involve the basal third of octant 7 in the inferior free wall, and all but 1 include the middle third of this octant (Table III). These are the 2 regions least commonly involved by infarcts predominating in the anterior third of the left ventricle.[2]

The transmural extent of inferior infarcts varies. Large infarcts tend to be transmural while small infarcts tend to involve primarily the subendocardial region. As noted previously,[3] some infarcts that are only subendocardial at the base become transmural in the middle third and intramural or subepicardial near the apex. They become intramural or subepicardial because the distal portion of the anterior descending branch of the left coronary artery supplies the more endocardial aspects of the inferior apex. The posterior descending artery supplies the more superficial aspects.[31] Though it is often assumed clinically that inferior or diaphragmatic infarcts are primarily apical, the opposite is true. Inferior infarcts involve more of the base and middle of the left ventricle than of the apex (Fig. 3). Large infarcts form a wedge pointing toward the apex, with their widest portion at the base of the left ventricle (Table III). Inferior infarcts do not involve the apex circumferentially as do anterior infarcts.[2] Many of the infarcts extend more into the lateral wall than into the septum at the base. They rarely involve more than the posterior one-third of the interventricular septum because of the much longer septal perforating vessels from the anterior descending branch of the left coronary artery.[31]

**QRS identification of inferior infarcts:** Askenazi et al[32] and Starr et al[33] determined that Q waves in lead aVF alone were as sensitive as Q waves in leads II, III, and aVF together. The present study further determines that a 30 ms Q wave rather than a 40 ms Q wave in lead aVF is a sensitive indicator of infarction in the inferior third of the left ventricle. A 30 ms Q wave is present in aVF in 90% of the patients, including all of those with transmural infarcts and 9 of the 12 with nontransmural involvement. Only 19 of the 31 patients (65%) had at least a 40 ms Q wave in lead aVF. The specificity of a 30 ms Q wave in lead aVF has been de-

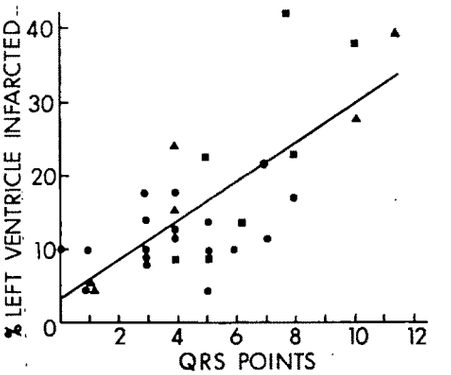

**FIGURE 4.** Comparison of the point score for electrocardiogram sizing of infarcts predominating in the inferior third of the left ventricle with the percent infarction of the left ventricle. Those infarcts <7 days old at the time of the patient's death are shown by **squares**, those 7 to 30 days old by **triangles**, and those >30 days old by **circles**. The regression line is shown (% infarct − 2.5 × points + 2.9; r = 0.74; standard error of the estimate = 6.6).

termined for normal individuals and for patients with anterior infarcts.[1,2,34] A study from this series found only a 2.6% prevalence of a 30 ms Q wave in aVF in 349 normal subjects.[1] None of the 21 patients with single infarcts located predominantly in the anterior third of the left ventricle had a 30 ms Q wave in lead aVF.[2] Therefore, a 30 ms Q wave in lead aVF provides a better criterion for identification of inferior myocardial infarcts since it achieves a sensitivity in this study of 90% and has a previously proven specificity of 97%.

The 90% sensitivity of a 30 ms Q wave in lead aVF can be reconciled with other reports that many infarcts are not associated with Q waves[35,36] by considering the design of the present study. Patients were excluded if >1 infarct was present at autopsy or if criteria for left or right ventricular hypertrophy, left or right bundle branch block, or left anterior or posterior fascicular block were present on the electrocardiogram. The electrocardiogram may be less sensitive and specific if these confounding factors are present.

**Correlation of QRS points and infarct location:** The computer simulation developed by Selvester et al[9] indicated the following. An increase in R-wave size in the right precordial leads should indicate involvement extending more laterally into the posterior free wall of the left ventricle. QRS changes in the left precordial leads should indicate involvement of the posterior and lateral aspects of the apex. Loss of R waves or the development of Q waves in the right precordial leads should indicate involvement in the middle aspect of the interventricular septum.

More than half of the patients in this study had infarcts which extended posterolaterally into ≥1 level of octant 5 (Table III). This involvement was somewhat underestimated by the point score as only 5 of the patients received points for increased R waves in the right precordial leads. However, the mean amount of infarct in octant 5 in these 5 patients (32%) was significantly greater than the mean amount infarcted in the remaining 26 patients (5%).

The posterolateral aspect of the left ventricle lies between the insertions of the anterior and posterior fascicles of the left bundle and therefore would be activated later than other aspects of the left ventricle.[37] Though R- and S-wave dimensions are not usually considered for diagnosis of myocardial infarcts, additional scoring criteria based upon them may be important for determining infarct size in this area of the left ventricle.

The average amount of apical involvement in patients with QRS points from the left precordial leads was greater than for patients without such QRS changes. However, the electrocardiograms of some patients with substantial apical involvement did not receive points from leads $V_4$ to $V_6$. Thus, the relation between the amount of apical involvement and the QRS score from leads $V_4$ to $V_6$ is not as close for inferior infarcts as for anterior infarcts.[2] The anterior infarcts usually have much greater involvement of even the inferior aspect of the apex and these anterior infarcts tend to involve the subendocardium which activates earlier than the subepicardium.[37] Therefore, that part of the apex supplied by the posterior descending coronary artery might, if infarcted, cause changes later in the QRS complex. As with posterior free wall involvement, extension into the inferior apex might be better described by criteria considering those later aspects of the QRS complex which are not evaluated in this study.

The QRS scoring system did not correlate well with more anterior involvement of the interventricular septum. The 2 patients with the largest amount of septal involvement did not have Q waves in lead $V_1$ or $V_2$. However, both infarcts also involved the posterior free wall opposite the septum (octant 5). As suggested by Myers et al,[18] the loss of electrical activity in the septum might be cancelled by loss of electrical activity in the opposite wall.

The 8 patients who received points for Q waves or diminished R waves in the right precordial leads did not have involvement of the septum which extended more anteriorly than was typical for patients with inferior infarcts. One possible explanation for loss of R waves in the right precordial leads is right ventricular involvement. The right ventricles had previously been removed from some of the hearts in this study. A second series of hearts is now being acquired with right ventricles still attached to permit evaluation of the correlation between the loss of R waves in the right precordial leads and the extent of both anterior septal and right ventricular infarction.

**Conclusions:** The simplified version of the QRS point score developed by Selvester et al[7–9] correlates significantly (r = 0.74) with the size of infarcts predominating in the inferior one-third of the left ventricle. Each point represents infarction of 2.5% of the left ventricle. Correlation between the electrocardiogram and the anatomic size is similar, regardless of the age of the infarct, that is, fibrotic, organizing, and acute. Most (90%) of these infarcts can be identified by ≥30 ms Q wave in lead aVF. The relatively large standard error of the estimate should be considered when the point score is used for an individual patient; the 95% confidence limits are ±13% of the left ventricle. While the QRS score has been shown to correlate (r = 0.80) with left ventricular ejection fraction in 12 patients with combined anterior and inferior infarcts,[38] further anatomic studies are needed to determine the limitations of the scoring system when applied to patients with >1 infarct or with a complex electrocardiogram exhibiting ventricular hypertrophy or intraventricular conduction delay.

# Segmental Right Ventricular Function After Acute Myocardial Infarction: Two-Dimensional Echocardiographic Study in 63 Patients

JOSE LOPEZ-SENDON, MD, MIGUEL ANGEL GARCIA-FERNANDEZ, MD, ISABEL COMA-CANELLA, MD, MAR MORENO YANGÜELA, MD, and FERMIN BAÑUELOS, MD

**Right ventricular (RV) segmental contraction was studied in 63 patients with acute myocardial infarction (MI), using 2-dimensional (2-D) echocardiography. Group A included 32 patients with ischemic RV dysfunction: 19 had a disproportionate increase in right atrial pressure at the time of the examination (Group AI) and in 13 patients, right atrial pressure was normal when the echocardiogram was obtained (Group AII). Group B included 31 patients without ischemic RV dysfunction. Akinesia or dyskinesia of the RV wall was found in 30 patients: 19 from Group AI, 8 from Group AII, and 3 from Group B. Asynergy could be identified in all segments of the RV wall including the outflow tract, RV apex, and anterior wall, but was more frequently found in the posterior wall (29 patients), best seen in the transversal subcostal short-axis view. A significant difference was found either in the frequency of wall motion abnormalities or in the number of segments with asynergy among the 3 groups ($p < 0.001$). However, asynergy of the RV wall may be present in some patients with normal right heart hemodynamic function, suggesting that asynergy may be more sensitive than hemodynamic function in the diagnosis of acute RV infarction. Paradoxical septal motion was found in 8 patients, all in Group AI, and all had a right atrial pressure equal to or greater than pulmonary capillary pressure.**

A strong correlation between segmental left ventricular contraction abnormalities and myocardial ischemia or infarction has been demonstrated by several techniques including cineangiography,[1] radioisotopic ventriculography,[2] and 2-D echocardiography.[3,4] For this reason, regional abnormalities of left ventricular wall motion have become a hallmark of both acute and chronic coronary artery disease. Although ischemic RV involvement and primary RV dysfunction are common findings in patients with acute MI, little attention has been paid to the study of regional RV contraction. Asynergy of the RV free wall has been demonstrated in patients with acute MI using radionuclide[2,5–7] or angiographic techniques,[7] but very few studies with 2-D echocardiography have been reported.[8,9] However, the identification of such abnormalities may constitute an important clue in the diagnosis of RV MI.

This report describes a prospective study of regional RV performance in acute transmural MI using 2-D echocardiography. The goals of the study were (1) to identify the abnormalities in segmental RV function after acute MI, and (2) to compare both hemodynamic and 2-D echocardiographic criteria of ischemic RV involvement.

## Methods

**Patients:** We studied 70 patients admitted to the coronary care unit with the diagnosis of acute transmural MI according to recognized clinical, electrocardiographic, and laboratory data. Location of the MI was defined as "posterior" by the presence of abnormal Q waves (>0.04 second) in leads $D_2$, $D_3$,

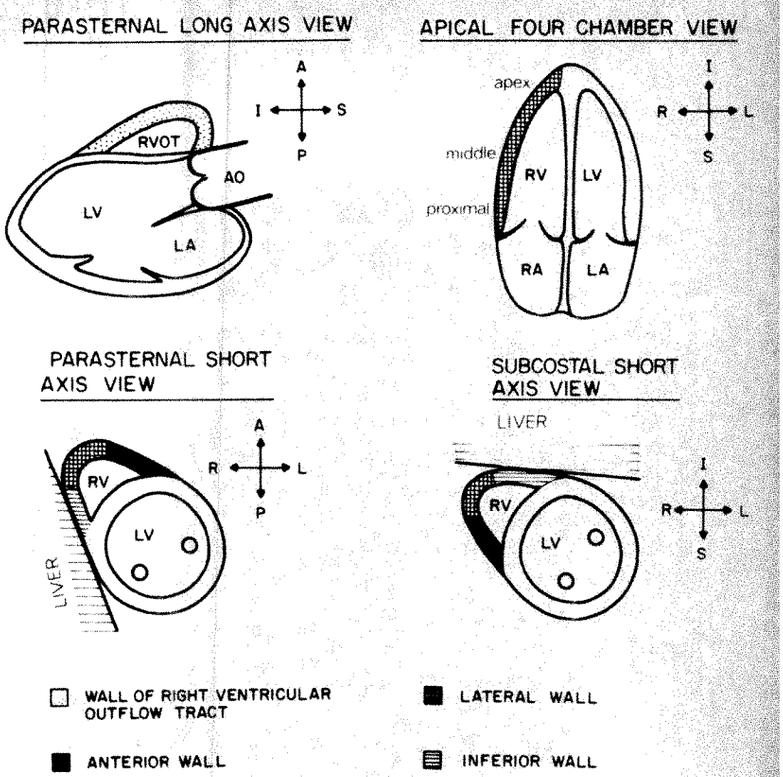

**FIGURE 1.** Schematic representation of the different echocardiographic views studied. A = anterior; AO = aorta; I = inferior; L = left; LA = left atrium; LV = left ventricle; P = posterior; R = right; RA = right atrium; RV = right ventricle; RVOT = right ventricular outflow tract; S = superior.

and aVF. "Anterior" MI was defined by the presence of abnormal Q waves in 2 or more adjacent precordial leads ($V_1$-$V_6$).

The study was initially begun including only those patients with acute posterior MI in whom hemodynamic monitoring had been performed. However, because 2 patients with acute anterior MI were found to have hemodynamic criteria of ischemic RV dysfunction, a group of 5 additional unselected patients with acute anterior MI were included.

Patients with acute MI without hemodynamic monitoring were not included. Patients with previously known MI, chronic congestive failure, pericardial disease, valvular heart disease, or chronic obstructive lung disease were not included. Of the initial 70 patients, 7 were excluded because of failure to obtain satisfactory 2-D echocardiograms of the right ventricle in at least 1 transversal plane (parasternal or subcostal short-axis views). Thus, a total of 63 patients (52 men, and 11 women, aged 36 to 78 years) were included.

**Hemodynamic monitoring:** Hemodynamic monitoring was performed in all patients. Right atrial, pulmonary artery, and pulmonary capillary wedge pressures were recorded in millimeters of mercury with a Hewlett-Packard 1280 transducer on a Siemens Elema Mingograph 34 through a Swan-Ganz thermodilution catheter.

Hemodynamic determinations were made at least every 8 hours. Monitoring was begun at admission and maintained for 3 to 5 days, being discontinued when the condition of the patient was considered as stable (subset I or II according to Forrester[10]) and had no hemodynamic variations for at least 24 hours.

**Criteria of RV dysfunction:** The diagnosis of ischemic RV dysfunction was made when the relation between right atrial and pulmonary capillary pressure was indicative of primary RV dysfunction, according to the results of a previous study.[11] Although this relation varies according to the level of pulmonary capillary pressure, for practical purposes right atrial mean pressure must be >10 mm Hg and either greater than, equal to, or not more than 5 mm Hg less than pulmonary capillary pressure. This criterion was found sensitive (73%) and very specific (100%) for the diagnosis of acute RV MI.[11] In patients with a right atrial pressure <10 mm Hg in the absence of pulmonary congestion, a volume loading test with dextran 40 was performed to identify ischemic RV dysfunction not present in basal conditions.[11,12]

**Echocardiographic examination:** Real-time 2-D echocardiographic examination was performed with the patient in the supine position or 30° to 60° left lateral decubitus using a wide angle (90°) mechanical sector scanner (Mark III, Advanced Technology Laboratory) and a 3 MHz transducer. Echocardiograms were obtained 3 to 12 hours after the last hemodynamic determination. In this period of time, the clinical condition of the patients included in the study was considered stable, without episodes of pain, dyspnea, arrhythmias, or variations in blood pressure.

Visualization of the ventricles and the ventricular septum in the long-axis, 4-chamber, and short-axis planes was obtained from parasternal, apical, and subcostal positions. Transverse planes were obtained from both parasternal and subcostal positions. All echocardiographic recordings were obtained in normal (90°) and amplified (45°) dimensions, and stored on a Sanyo VJC 7100 tape recording system. Individual frames selected for the figures were photographed using a Polaroid® film from the videotape. There was significant degradation of the stop frame image because only 1 of the 2 fields could be visualized.

A simultaneous electrocardiogram was recorded. The initiation of the QRS complex was used as an end-diastolic marker, and the end of systole was assumed to correspond to the end of the T wave. Imaging of the endocardial outline was obtained by playing through preceding and succeeding beats, using both real-time and slow motion playback.

Only RV free wall and ventricular septal motion were considered. The RV wall was divided into several segments (Fig. 1), and each was analyzed for wall motion abnormalities. Wall motion was qualitatively classified as *normal* (inward motion of the endocardium during systole) (Fig. 2), *akinetic* (absence of motion) (Fig. 3), or *dyskinetic* (outward motion of the endocardium during systole) (Fig. 4 and 5). Ventricular septal motion was considered as normal when the septum was displaced toward the left ventricular cavity in systole, akinetic when no septal movement could be appreciated, and dyskinetic or paradoxical when both sides of the septum were displaced toward the RV cavity during systole (Fig. 4 and 5).

All echocardiograms were interpreted independently by 2 observers, without previous knowledge of the hemodynamic data of each patient. In case of discrepancy, the studies were reviewed and an agreement was reached.

**Groups:** The patients were classified into 2 groups: *Group A* included 32 patients with definite ischemic RV dysfunction in at least 1 hemodynamic determination during the monitoring period. Nineteen of the 32 patients had a relation between right atrial and pulmonary capillary pressures indicative of ischemic RV dysfunction at the time of the echocardiographic examination (Group AI); The 13 remaining patients had transient ischemic RV dysfunction with a normal pressure relation at the time of the echocardiographic study (Group AII). Twenty-two patients had electrocardiographic evidence of posterior MI, 2 of anterior MI, and 8 of posterior plus anterior MI. *Group B* included 31 patients without hemodynamic criteria of ischemic RV dysfunction during the entire period of hemodynamic monitoring. Acute MI was posterior in 20 patients, anterior in 5, and posterior plus anterior in 6.

**Statistical analysis:** All statistical analyses were performed using nonparametric tests: chi-square test and Fisher's exact test. Significant values were considered those corresponding to $p < 0.05$. Only hemodynamic data corresponding to the last hemodynamic determination before the echocardiographic examination were considered for statistical analysis.

## Results

**Hemodynamic findings:** By definition, only Group A patients had a right atrial-pulmonary capillary pressure relation indicative of ischemic RV dysfunction. In all patients from Group AI, ischemic RV dysfunction was spontaneous, whereas in 5 patients from Group B it was observed only after volume loading.

**Two-D echocardiographic findings: Right ventricular segmental wall motion:** The number of patients with asynergy and the number of segments with abnormal wall motion found in each group in the different echocardiographic views are shown in Table I.

*Transverse plane:* Regional abnormalities in segmental wall motion were observed in 29 patients: 19 in Group AI, 7 in Group AII, and 3 in Group B. (Fig. 3 and 4).

When subcostal and parasternal views were compared, no difference was found in either the number of patients with wall motion abnormalities, the number of segments with asynergy, or the type of asynergy, between both short-axis views obtained. However, 2 patients had akinesia of the inferior RV wall in the subcostal short-axis view although the movement of these segments was considered normal in the parasternal short-axis view. Good quality images of the subcostal transversal plane were obtained in 62 patients; adequate imaging of the parasternal transversal plane could only be obtained in 42 patients.

In the longitudinal parasternal view, dyskinesia of the RV outflow tract was observed in 1 patient (Group AI). In the remaining 50 patients in whom good quality echocardiographic images were obtained, contraction of the RV outflow tract was normal.

In the *apical 4-chamber view*, asynergy of the lateral RV wall occurred in 9 patients (Fig. 5), 8 of whom were in Group AI. In the other patient, included in Group AII, akinesia of the RV apex was the only abnormality.

**Ventricular septal motion:** In Group A, septal motion was normal in 18 patients (56%), akinetic in 5 (16%), and dyskinetic in 9 (28%). Paradoxical motion of the ventricular septum was always accompanied by some alteration in the movement of the RV posterior wall ($p < 0.001$) (Fig. 4). In group B, septal motion was normal in 24 patients (77%), and akinetic in the remaining 7 (23%).

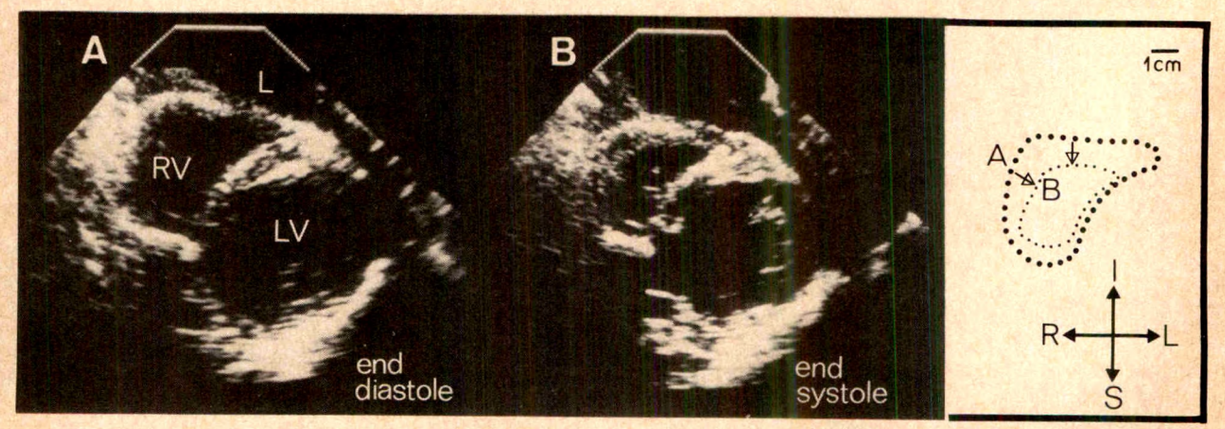

**FIGURE 2.** Subcostal short-axis view of both ventricles. Normal motion of the RV wall and interventricular septum. L = liver or lateral; other abbreviations as in Figure 1.

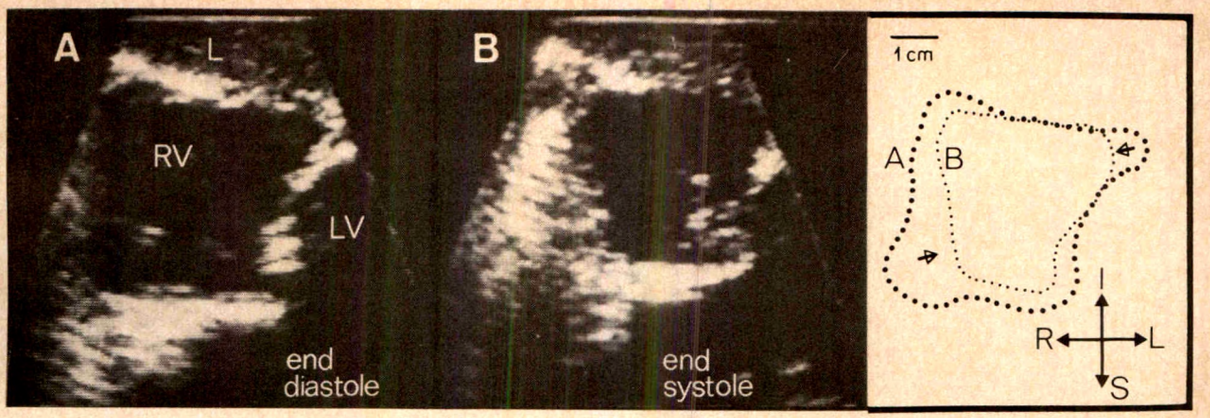

**FIGURE 3.** Subcostal short-axis view: akinesia of the inferior RV wall. Abbreviations as before.

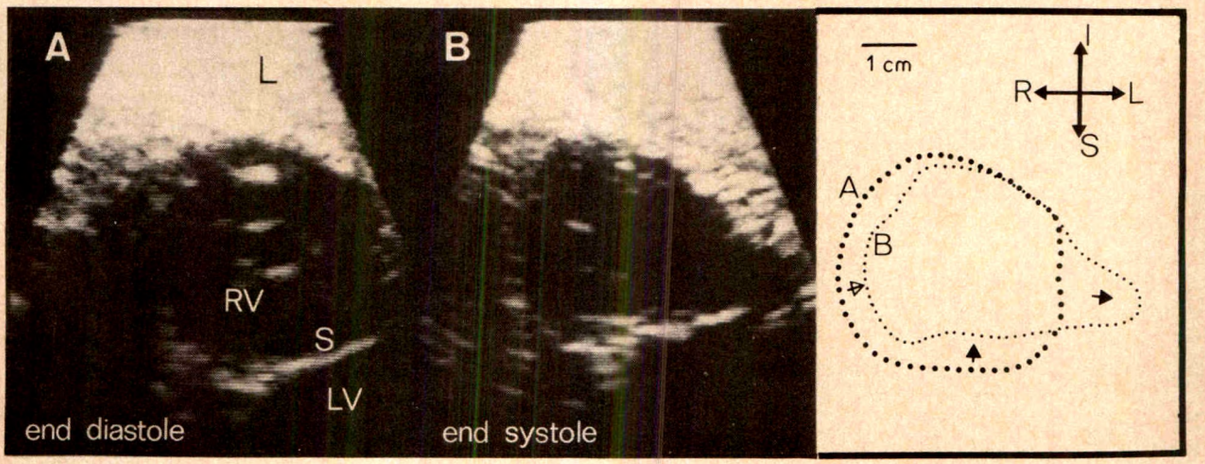

**FIGURE 4.** Subcostal short-axis view: dyskinesia of the inferior RV wall adjacent to the interventricular septum. Paradoxical septal motion. **Open arrows,** normal contraction. **Solid arrows,** dyskinesia. S = interventricular septum or superior; other abbreviations as before.

**Correlation between hemodynamics and 2-D echocardiographic findings:** *Right ventricular wall:* A significant relation was found between hemodynamic data of ischemic RV dysfunction and alterations in segmental RV wall motion. A highly significant difference was found either in the frequency of wall motion abnormalities or the number of segments with asynergy among the 3 groups of patients ($p < 0.001$) (Table I). Furthermore, a highly significant difference was also found between the incidence and number of segments with abnormal wall motion and the presence of a right atrial pressure equal to or greater than the pulmonary capillary pressure ($p < 0.001$) (Table II), indicating that the severity of asynergy is related to the severity of ischemic RV dysfunction.

*Ventricular septum:* A significant relation was found between the presence of dyskinetic or paradoxical septal motion and the hemodynamic data indicative of ischemic RV dysfunction ($p < 0.001$). All 9 patients with paradoxical septal motion were included in Group AI and all had a right atrial pressure equal to or higher than pulmonary capillary pressure. However, 2 patients without paradoxical septal motion also had a right atrial pressure equal to or greater than pulmonary capillary pressure when the echocardiographic examination was performed.

**TABLE II Frequency of Asynergy in Relation to Hemodynamic Data**

| | Number of Segments With Asynergy | | |
|---|---|---|---|

PCP = pulmonary capillary pressure; RAP = right atrial pressure.

## Discussion

**Segmental RV contraction in acute MI:** Asynergy of the RV wall has been reported in patients with RV MI.[2,5–9] Our results demonstrate that abnormalities in segmental RV wall motion are common in patients with acute MI and can easily be appreciated by 2-D echocardiography. The actual frequency of such abnormalities cannot be accurately defined from this study because not all patients with acute MI admitted to the coronary care unit were included.

Although acute RV infarction is generally associated with posterior left ventricular infarction,[11,13] a small number of patients with anterior MI also had RV asynergy, correlating well with hemodynamic alterations consistent with ischemic RV dysfunction.

Asynergy may be identified in all segments of the RV wall, including the outflow tract, ventricular apex, and the anterior wall, but is, in general, specifically located in the posterior RV wall. Asynergy of other regions without posterior wall involvement is rare, and in this study was found in only 1 patient. Moreover, anatomicopathologic studies indicate that in most cases, RV infarctions are confined to the posterior RV wall[11,13] which can be identified only in the transversal plane. The transversal plane is the most useful echocardiographic view for the identification of such abnormalities.

The greater frequency of wall motion abnormalities in the long-axis and 4-chamber planes reported in previous studies[8,9] can be attributed to a more rigid criteria of patient selection, inclusion being restricted to patients with strong clinical evidence of RV infarction.

**Segmental RV contraction and RV infarction:** Recent echocardiographic and anatomic studies[3,4] demonstrated that necrotic segments of the left ventricle almost always present motion abnormalities, but the latter far less frequently imply MI, and a number of nonnecrotic myocardial segments show segmental wall motion abnormalities. In the absence of transmural

MI, asynergy has been attributed to local ischemia,[3,4] small inlands of infarcted tissue,[4] and myocardial dysfunction due to mechanical tethering in zones adjacent to the MI.[14]

These findings indicate that wall motion abnormalities found in 2-D echocardiography are very sensitive but not very specific for MI. On the basis of these previous studies performed on the left ventricle, one can hypothesize that regional abnormalities of RV contraction may be sensitive for the detection of RV infarction, but may be present in patients with right RV ischemia without MI.

**Correlation between hemodynamics and wall motion abnormalities:** We found a strong relation between the hemodynamic alterations indicative of ischemic RV dysfunction and the presence and extent of abnormalities in regional wall motion demonstrated by 2-D echocardiography. All Group AI patients had some contraction abnormalities; those patients with the most severe ischemic RV dysfunction (right atrial pressure equal to or higher than pulmonary capillary pressure) presented a higher number of RV wall segments with abnormal motion (Table II). The same results have been found in 2 previous studies. Yung-Dae et al[8] presented 13 patients with severe RV dysfunction and wall motion abnormalities; 10 patients reported by D'Arcy et al[9] with clinical or anatomic evidence of RV infarction had RV asynergy.

Nevertheless, the hemodynamic criteria of right ventricular dysfunction followed in this study were less rigid, and considering the aforementioned hemodynamic changes as sensitive and specific for right ventricular infarction, there are certain discrepancies between hemodynamic and wall motion abnormalities that deserve further comment.

*Abnormal wall motion and transient ischemic RV dysfunction:* In an important number of patients (8 of the 13 from Group AII), abnormalities in RV wall motion were still present after normalization of the hemodynamic variables of ischemic RV dysfunction. The same results were found by Yung-Dae et al[8] in 5 patients with clinical data of RV infarction. This finding may be of interest when considering ischemic right ventricular involvement in subacute or chronic heart disease.[15] However, further studies are needed to evaluate the long-term evolution of RV wall dynamics after acute myocardial infarction.

*Normal wall motion and transient ischemic RV dysfunction:* From another point of view, some patients with transient RV dysfunction (5 of 13 patients from Group AII) had normal RV wall motion. When one considers that the hemodynamic alterations, even if transient, are highly specific of RV infarction,[11] this finding may be explained by several mechanisms: (1) Although asynergy usually persists for several days or weeks after acute MI,[2,16] some wall motion abnormalities can be transient, even in the presence of transmural MI,[2] if some islands of normal tissue are preserved, and may be manifested only under stress conditions such as exercise.[15] (2) Hypokinesia has not been evaluated in this study, and although it is less specific for MI than akinesia or dyskinesia,[3] it cannot be completely forgotten. Also, small abnormalities in ventricular motion can only be identified studying the complete cardiac cycle.[17] Further methodologic refinement and the application of computer-aided techniques would allow a more precise evaluation and quantification of regional wall motion and endocardial thickening, the latter being a sensitive and specific variable of ventricular function in acute MI.[4] (3) Small defects can be occult to the echocardiographic examination if several transverse planes are not obtained.[3] (4) There is always the possibility that the transient and borderline hemodynamic changes in ischemic RV dysfunction may be due to ischemia rather than necrosis. This hypothesis is supported by the fact that 3 of 5 patients from Group AII with normal regional wall motion showed hemodynamic alterations of ischemic RV dysfunction only after dextran administration, and asynergy may not be found when the hemodynamic condition of the patient improves.

*Abnormal wall motion and normal hemodynamic function:* Three patients had abnormal RV motion without primary RV dysfunction during the hemodynamic monitoring. Abnormal wall motion can be the result of transient ischemia rather than infarction.[3,4] Two patients from Group B with RV asynergy presented a QS pattern and S-T segment elevation in leads $V_{3R}$ and $V_{4R}$ in the absence of anterior necrosis, a finding highly indicative of acute RV infarction.[18] This finding strongly suggests that wall motion abnormalities can be more sensitive than hemodynamics in detecting acute RV necrosis. This may be especially true when left ventricular function is impaired, preventing a close relation between right atrial and pulmonary capillary pressures suggestive of RV involvement.[11] This may have occurred in 2 of the 3 patients in this study, who had severe pulmonary congestion and a normal right atrial/pulmonary capillary pressure relation.

**Ventricular septal motion:** Paradoxical motion of the ventricular septum is a common finding in patients with acute RV infarction[7-9,19-21] and may be attributed to RV volume overload, tricuspid regurgitation, or alterations in RV compliance. In these circumstances, RV diastolic pressure equals or exceeds simultaneous left ventricular pressure, producing an inversion of the ventricular septum toward the left ventricle during diastole (Fig. 5), whereas during systole the septum moves toward the right ventricle because of the higher left ventricular systolic pressure. This behavior of the septal motion may distort the left ventricular geometry, impairing left ventricular function.[19]

## CAPOTEN controls blood pressure without the following usual antihypertensive side effects†:

- No cardiac depression
- No glucose intolerance
- No bradycardia
- No mental depression
- No sleep disturbances
- No nasal congestion
- No hypokalemia
- Rare impotence/loss of libido
- Rare bronchospasm
- Rare tachycardia
- Rare fatigue

## CAPOTEN is appropriate therapy when coexisting disorders complicate hypertension management

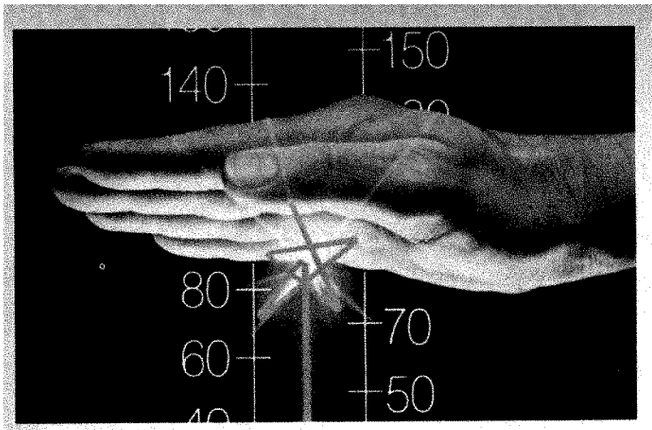
Unlike some other antihypertensive agents, CAPOTEN is appropriate for use in the presence of a wide range of cardiovascular and metabolic disorders that often coexist with hypertension.

- Bronchospastic disease
- Cardiac arrhythmias
- Congestive heart failure
- Diabetes mellitus
- Hepatic disease

## CAPOTEN is effective in controlling many kinds of hypertension when conventional multidrug regimens have proven inadequate

- Essential hypertension
- Hypertension resistant to standard triple therapy (STT)
- Hypertension associated with low, normal, and high plasma renin levels
- Renovascular hypertension

ACE* INHIBITOR



# CAPOTEN®

## (captopril tablets)

**CAPOTEN has been associated with the development of neutropenia, agranulocytosis, or proteinuria.† These serious side effects are more likely to occur in patients with predisposing conditions, such as renal impairment or autoimmune disease, or in patients receiving therapy known to suppress the autoimmune response.**

**The following precautionary guidelines are recommended for all patients receiving CAPOTEN:**

- **Obtain urinary protein level estimates prior to initiating therapy, at monthly intervals for the first nine months of treatment, and periodically thereafter.**
- **Obtain WBC counts at the initiation of therapy, at two-week intervals for the first three months of treatment, and periodically thereafter.**
- **Carefully review the WARNINGS and ADVERSE REACTIONS sections in the complete prescribing information, with particular attention to the patient at increased risk.**
- **The most frequently occurring adverse reactions are skin rash and taste alteration; both effects are generally mild, reversible, or self-limited.**

SQUIBB®

*Angiotensin Converting Enzyme

†Please see brief summary of prescribing information, for INDICATIONS AND USAGE, WARNINGS, and ADVERSE REACTIONS.

**CAPOTEN® TABLETS**
**Captopril Tablets**

**INDICATIONS: Hypertension** — Because serious adverse effects have been reported (see WARNINGS), CAPOTEN is indicated for treatment of hypertensive patients who on multidrug regimens have either failed to respond satisfactorily or developed unacceptable side effects.
**Heart Failure:** CAPOTEN (captopril) is indicated in patients with heart failure who have not responded adequately to or cannot be controlled by conventional diuretic and digitalis therapy. CAPOTEN is to be used with diuretics and digitalis.
**WARNINGS: Proteinuria** — Total urinary proteins >1 g/day were seen in 1.2% of patients on captopril; the nephrotic syndrome occurred in about ¼th of these cases. About 60% of affected patients had evidence of prior renal disease; the remainder had no known renal dysfunction. In most cases, proteinuria subsided or cleared within 6 months whether or not captopril was continued. The BUN and creatinine were seldom altered in proteinuric patients.

Membranous glomerulopathy was found in nearly all the proteinuric patients on captopril who were biopsied and may be drug related. Most cases of proteinuria occurred by the 8th month of therapy. Patients should have urinary protein estimates (dip-stick on 1st morning urine, or quantitative 24-hr urine — the latter provides greater precision when proteinuria is persistent and/or at low levels) before therapy, at approx. monthly intervals for the 1st 9 months of therapy, and periodically thereafter. For patients who develop proteinuria >1 g/day, or increasing proteinuria, the benefits and risks of continuing captopril should be evaluated.

**Neutropenia/Agranulocytosis** — Neutropenia (<300/mm³) associated with myeloid hypoplasia (probably drug related) occurred in about 0.3% of captopril treated patients. About half of the neutropenic patients developed systemic or oral cavity infections or other features of agranulocytosis. Most of the neutropenic patients had severe hypertension and renal function impairment; about half had systemic lupus erythematosus (SLE), or another autoimmune/collagen disorder; multiple concomitant drug therapy was common, including immunosuppressive therapy in a few cases. Daily doses of captopril in the leukopenic patients were relatively high, particularly in view of their diminished renal function. The neutropenia appeared 3 to 12 weeks after starting captopril; it developed relatively slowly, taking 10 to 30 days to have white blood count fall to its nadir; neutrophils returned to normal in about 2 weeks (other than 2 patients who died of sepsis).

**Use captopril with caution in patients with impaired renal function, serious autoimmune disease (particularly SLE), or who are exposed to other drugs known to affect the white cells or immune response. In patients at particular risk (as noted above), perform white blood cell and differential counts prior to therapy, at about 2-week intervals for about the 1st 3 months of therapy, and periodically thereafter.**

The risk of neutropenia in patients who are less seriously ill or who receive lower dosages appears to be smaller. In these patients white blood cell counts should be performed every 2 weeks for the 1st 3 months of therapy, and periodically thereafter. Perform differential counts when leukocytes are <4000/mm³ or the pretherapy white count is halved. All patients treated with captopril should be told to report any signs of infection (e.g., sore throat; fever); if infection is suspected, perform counts without delay. Since discontinuation of captopril and other drugs has generally led to prompt return of the white count to normal, upon confirmation of neutropenia (neutrophil count <1000/mm³) withdraw captopril and closely follow the patient's course.
**Hypotension** — Excessive hypotension was rarely seen in hypertensive patients but is a possibility in severely salt/volume-depleted persons such as those treated vigorously with diuretics (see PRECAUTIONS [Drug Interactions]).

In heart failure, where blood pressure was either normal or low, transient decreases in blood pressure >20% were recorded in about ½ the patients. This transient hypotension may occur after any of the first several doses and is usually well tolerated, although rarely it has been associated with arrhythmia or conduction defects. A starting dose of 6.25 or 12.5 mg tid may minimize the hypotensive effect. Patients should be followed closely for the first 2 weeks of treatment and whenever the dose of captopril and/or diuretic is increased.

**BECAUSE OF THE POTENTIAL FALL IN BLOOD PRESSURE IN THESE PATIENTS, THERAPY SHOULD BE STARTED UNDER VERY CLOSE MEDICAL SUPERVISION.**
**PRECAUTION: General:** *Impaired Renal Function,* Hypertension — Some hypertensive patients with renal disease, particularly those with severe renal artery stenosis, have developed increases in BUN and serum creatinine. It may be necessary to reduce captopril dosage and/or discontinue diuretic. For some of these patients, normalization of blood pressure and maintenance of adequate renal perfusion may not be possible. Heart Failure — About 20% of patients develop stable elevations of BUN and serum creatinine >20% above normal or baseline upon long-term treatment. Less than 5% of patients, generally with severe preexisting renal disease, required discontinuation due to progressively increasing creatinine. See DOSAGE AND ADMINISTRATION, ADVERSE REACTIONS [Altered Laboratory Findings]. *Valvular Stenosis* — A theoretical concern, for risk of decreased coronary perfusion, has been noted regarding vasodilator treatment in patients with aortic stenosis, due to decreased afterload reduction.
*Surgery/Anesthesia* — If hypotension occurs during major surgery or anesthesia, and is considered due to the effects of captopril, it is correctable by volume expansion.
**Drug Interactions:** *Hypotension: Patients on Diuretic Therapy* — Precipitous reduction of blood pressure may occasionally occur within the 1st 3 hours after administration of the initial captopril dose in patients on diuretics, especially those recently placed on diuretics and those on severe dietary salt restriction or dialysis. This possibility can be minimized by either discontinuing the diuretic or increasing the salt intake about 1 week prior to initiation of captopril therapy. Alternatively, provide medical supervision for at least 3 hours after the initial dose in hypertensive patients.
*Agents Having Vasodilator Activity:* In heart failure patients vasodilators should be administered with caution.
*Agents Causing Renin Release* — Captopril's effect will be augmented by

(Continued on next page.)

(continued from preceding page)

antihypertensive agents that cause renin release.

*Agents Affecting Sympathetic Activity* — The sympathetic nervous system may be especially important in supporting blood pressure in patients receiving captopril alone or with diuretics. Beta-adrenergic blocking drugs add some further antihypertensive effect to captopril, but the overall response is less than additive. Therefore, use agents affecting sympathetic activity (e.g., ganglionic blocking agents or adrenergic neuron blocking agents) with caution.

*Agents Increasing Serum Potassium* — Give potassium-sparing diuretics or potassium supplements only for documented hypokalemia, and then with caution, since they may lead to a significant increase of serum potassium.

**Drug/Laboratory Test Interaction:** Captopril may cause a false-positive urine test for acetone.

**Carcinogenesis, Mutagenesis, and Impairment of Fertility:** Two-year studies with doses of 50 to 1350 mg/kg/day in mice and rats failed to show any evidence of carcinogenic potential. Studies in rats have revealed no impairment of fertility.

**Usage in Pregnancy:** There are no adequate and well-controlled studies in pregnant women. Embryocidal effects were observed in rabbits. Therefore, captopril should be used during pregnancy only if the potential benefit outweighs the potential risk to the fetus.

**Nursing Mothers:** Captopril is secreted in human milk. Exercise caution when administering captopril to a nursing woman, and, in general, nursing should be interrupted.

**Pediatric Use:** Safety and effectiveness in children have not been established although there is limited experience with use of captopril in children from 2 months to 15 years of age. Dosage, on a weight basis, was comparable to that used in adults. Captopril should be used in children only if other measures for controlling blood pressure have not been effective.

**ADVERSE REACTIONS:** Reported incidences are based on clinical trials involving about 4000 patients.

*Renal* — One to 2 of 100 patients developed proteinuria (see WARNINGS). Renal insufficiency, renal failure, polyuria, oliguria, and urinary frequency in 1 to 2 of 1000 patients.

*Hematologic* — Neutropenia/agranulocytosis occurred in about 0.3% of captopril treated patients (see WARNINGS). Two of these patients developed sepsis and died.

*Dermatologic* — Rash (usually mild, maculopapular, rarely urticarial), often with pruritus and sometimes with fever and eosinophilia, in about 10 of 100 patients, usually during the 1st 4 weeks of therapy. Pruritus, without rash, in about 2 of 100 patients. A reversible associated pemphigoid-like lesion, and photosensitivity have also been reported. Angioedema of the face, mucous membranes of the mouth, or of the extremities in about 1 of 100 patients — reversible on discontinuance of captopril therapy. One case of laryngeal edema reported. Flushing or pallor in 2 to 5 of 1000 patients.

*Cardiovascular* — Hypotension in about 2 of 100 patients. See WARNINGS (Hypotension) and PRECAUTIONS (Drug Interactions) for discussion of hypotension on initiation of captopril therapy. Tachycardia, chest pain, and palpitations each in about 1 of 100 patients. Angina pectoris, myocardial infarction, Raynaud's syndrome, and congestive heart failure each in 2 to 3 of 1000 patients.

*Dysgeusia* — About 7 of 100 patients developed a diminution or loss of taste perception; taste impairment is reversible and usually self-limited even with continued drug use (2 to 3 months). Gastric irritation, abdominal pain, nausea, vomiting, diarrhea, anorexia, constipation, aphthous ulcers, peptic ulcer, dizziness, headache, malaise, fatigue, insomnia, dry mouth, dyspnea, and paresthesias reported in about 0.5 to 2% of patients but did not appear at increased frequency compared to placebo or other treatments used in controlled trials.

**Altered Laboratory Findings:** Elevations of liver enzymes in a few patients although no causal relationship has been established. Rarely cholestatic jaundice and hepatocellular injury with secondary cholestasis have been reported. A transient elevation of BUN and serum creatinine may occur, especially in volume-depleted or renovascular hypertensive patients. In instances of rapid reduction of longstanding or severely elevated blood pressure, the glomerular filtration rate may decrease transiently, also resulting in transient rises in serum creatinine and BUN. Small increases in serum potassium concentration frequently occur, especially in patients with renal impairment (see PRECAUTIONS).

**OVERDOSAGE:** Primary concern in correction of hypotension. Volume expansion with an I.V. infusion of normal saline is the treatment of choice for restoration of blood pressure. Captopril may be removed from the general circulation by hemodialysis.

**DOSAGE AND ADMINISTRATION:** CAPOTEN should be taken one hour before meals. Dosage must be individualized; see DOSAGE AND ADMINISTRATION section of package insert for detailed information regarding dosage in hypertension and in heart failure. Because CAPOTEN (captopril) is excreted primarily by the kidneys, dosage adjustments are recommended for patients with impaired renal function.

**Consult package insert before prescribing CAPOTEN (captopril).**

**HOW SUPPLIED:** Available in tablets of 25, 50, and 100 mg in bottles of 100, and in UNIMATIC® unit-dose packs of 100 tablets.

## What is CARDIOLOGY 1982?

- The second in an annual series to be published in the SPRING each year
- A review of the year's newest and most important developments in cardiology — **665 papers**
- A multidisciplinary approach to clinical and applied research based on an exhaustive search of the year's literature
- A unique, cohesive summary of the state-of-the-art, written, not edited, by those making outstanding developments in the field
- A practical approach to a complicated and fast-moving subject designed to be read and used daily

## CARDIOLOGY:1982 is NOT

- A collection of unrelated reviews
- An abstracting service
- A rehash of materials readily available elsewhere

***"It is more than merely a reference book, since it explains what to the average physician may be obscure....a treasure house of 1980 publications. It is highly recommended."*** Philip Reichert, M.D. New York State Journal of Medicine, September, 1981

***"...recommend...to any reader interested in the literature of cardiology."*** Irwin R. Callen, M.D. JAMA, November, 1981

**SPECIAL DISCOUNT OFFER**

Place a standing order to receive each edition of CARDIOLOGY: 1982 on 30 day approval and receive a 10% discount on this and all future editions.

☐ **YES,** please enter my standing order for CARDIOLOGY: 1982. I understand that each edition (published once a year) will be automatically shipped to me on 30 day approval, and I will receive a 10% discount on this and all future editions. (1982 edition discount price $40.50)

**Yorke Medical Books,** Box C-757, Brooklyn, NY 11205 AJCB3

# Dialog of the Hearts –by Hemingway:

"And she smiled and from no distance said, 'Hello, my Inglés.'

'I'm not an Inglés', he said very lazily.

'Oh yes, you are', she said. 'You're my Inglés', and reached and took hold of both his ears and kissed him on the forehead.

'There', she said. 'How is that? Do I kiss thee better?'

Then they were walking along the stream together and he said, 'Maria, I love thee and thou art so lovely and so wonderful and so beautiful and it does such things to me to be with thee that I feel as though I wanted to die when I am loving thee'.

'Oh', she said. 'I die each time. Do you not die?'

'No. Almost. But did thee feel the earth move?'

'Yes. As I died. Put thy arm around me, please'.

'No. I have thy hand. Thy hand is enough".

The Dialogue of Robert Jordan and Maria from "For Whom the Bell Tolls".

# Variable Threshold Exertional Angina in Patients With Transient Vasospastic Myocardial Ischemia

## Repeat Exercise Test Results and Therapeutic Implications

STEFANO DE SERVI, MD, GIUSEPPE SPECCHIA, MD, COLOMBA FALCONE, MD, ANTONELLO GAVAZZI, MD, ANTONIO MUSSINI, MD, LUIGI ANGOLI, MD, EZIO BRAMUCCI, MD, DIEGO ARDISSINO, MD, LAURA VACCARI, MD, JORGE SALERNO, MD, and PIERO BOBBA, MD

**Thirty-five of 70 patients with vasospastic angina at rest complained of chest pain during exercise or during usual daily activity. In 22, the angina threshold was described as variable during exercise: that is, the amount of exertion that induced angina was not always the same. In 12 patients with variable threshold exertional angina, 3 exercise tests performed in the morning on different days yielded different results, because chest pain and ischemic electrocardiographic changes occurred at different work loads with a wide range in heart rate-systolic pressure product. Two patients, in whom great cardiac vein flow was measured during exercise before and after taking nifedipine, tolerated heavier work loads after receiving the drug, with a more marked increase in flow during exercise. It is concluded that variable threshold exertional angina can be objectively demonstrated by repeat exercise tests in patients with vasospastic angina. Variability of the angina threshold may be due to a functional mechanism that causes myocardial ischemia in addition to the increased myocardial metabolic requirements provoked by exercise. Because in such patients fluctuations in coronary arterial tone play an important role in determining the response to exercise, calcium antagonistic drugs, which lower coronary tone and prevent the occurrence of coronary spasm, are effective in increasing exercise capacity.**

Patients with vasospastic angina at rest may also have chest pain during exercise or during usual daily activity.[1,2] In these patients the angina threshold may vary from time to time; a few patients have recently been described[3-5] in whom repeated exercise tests induced myocardial ischemia at different values of heart rate-systolic blood pressure product, an index of myocardial oxygen consumption.[6] However, the incidence of this phenomenon is not yet appreciated, and it is not clear whether the clinical suspicion of variable threshold exertional angina can always be confirmed by repeated exercise tests.

From the Divisione di Cardiologia, Cattedra di Fisiopatologia Cardiorespiratoria, Policlinico S. Matteo, Pavia, Italy. Manuscript received March 30, 1982; revised manuscript received July 20, 1982; accepted July 23, 1982.

Address for reprints: Stefano de Servi, MD, Divisione di Cardiologia, Policlinico S. Matteo, 27100 Pavia, Italy.

This study describes the results of repeated exercise tests in patients with vasospastic angina presenting with this clinical manifestation. We believe that the recognition of variable threshold exertional angina may have important therapeutic implications.

### Methods

**Patients: Criteria of selection:** Between October 1979 and October 1981 we observed 70 patients with vasospastic angina at rest without evidence of previous transmural myocardial infarction. Coronary vasospasm was considerd responsible for the occurrence of chest pain at rest on the basis of the following criteria: Sixty patients showed transient S-T segment elevation during at least 1 episode of chest pain at rest,[7] whereas the remaining 10 patients showed S-T segment depression repeatedly during chest pain as well as after the administration of intravenous ergonovine maleate in the coronary care unit.[14,15] Thirty-five patients also complained of chest pain during exercise or usual daily activity. In 22 of these patients the angina threshold was described as variable dur

Ang = angina; ECG = electrocardiographic; Exh = exhaustion; RPP = heart rate-systolic pressure product, mm Hg × beats/min × $10^{-2}$; ↑S-T = S-T segment elevation; ↓ST = S-T segment depression; — = no electrocardiographic changes.

exercise; these patients could not recognize a critical amount of exertion they could perform before experiencing angina but the level of activity that determined the symptoms varied from time to time. Twelve of these 22 patients were selected for this study. The selection was not done in a random fashion but depended on the clinical characteristics of the patients. We excluded patients with more than 3 episodes of chest pain at rest per day or with severe ventricular arrhythmias or left ventricular failure during anginal attacks.[16] In the 12 patients studied, drug therapy consisting of nitrates and nifedipine could be suspended 12 hours before exercise tests without any manifestation of withdrawal phenomena, such as accelerated angina or other coronary events. No patient was receiving beta-adrenergic blocking agents or digitalis.

**Exercise testing:** The 12 patients selected performed 3 bicycle exercise tests in the morning (8:30 to 11:00 A.M.) on different days during hospitalization. The mean interval between the first and the third exercise test was 7.8 ± 6 days. Two of these patients were described recently.[3] The exercise tests were performed in the supine position with an initial work load of 50 W and subsequent increments of 25 W every 3 minutes. Exercise was stopped when angina, dyspnea, exhaustion, S-T segment elevation ≥2 mm, or S-T segment depression >3 mm occurred. A 12-lead electrocardiogram was taken before and at the end of exercise, and every minute during recovery; leads $V_4$, $V_5$, and $V_6$ were monitored during exercise. Cuff blood pressure was measured at 3-minute intervals. The criteria for a positive exercise test were a horizontal or downsloping S-T segment depression ≥1 mm for 0.08 second compared with the resting tracing and S-T segment elevation ≥1 mm at 0.04 second after the J point compared with *the baseline* electrocardiogram. An estimate of myocardial oxygen consumption was made from the double product, obtained by multiplying systolic arterial pressure and heart rate.[6]

**Coronary arteriography:** The 12 patients studied underwent coronary arteriography using the Sones technique after premedication with 10 mg of diazepam. Left ventriculography was performed in the right anterior oblique projection before arteriography. Narrowing >50% of 1 or more coronary arteries was considered evidence of significant coronary artery disease. When a significant lesion was noted, the vessel was filmed again after sublingual administration of nitroglycerin.

**Coronary flow study:** In 2 patients with isolated left anterior descending artery disease, exercise tests were performed before and 20 minutes after sublingual administration of 20

**TABLE II Electrocardiographic (ECG) Changes During Chest Pain at Rest and Coronary Arteriographic Findings**

| Case | Age (yr) & Sex | ECG Changes (Spontaneous Angina) | Coronary Arteriographic Findings |

mg of nifedipine; the tests were done with the patient in the supine position with an initial work load of subsequent increments of 25 W every 3 minutes. A triple thermistor thermodilution catheter (Wilton Webster Laboratories, Altadena, California) was inserted into the coronary sinus with the tip advanced to the great cardiac vein, so that the flow recorded was entirely from the great cardiac vein.[17] Its position was confirmed with fluoroscopy and frequently checked throughout the procedure. Flow measurements were obtained in basal conditions and at peak exercise[15,18] by injecting physiologic saline solution at 24° per 30 seconds using a pump at a rate of 56 ml/min. The left brachial artery was punctured to measure intraarterial pressure.

An interval of 30 minutes was allowed to elapse between the end of the first exercise test and the administration of nifedipine. Great cardiac vein flow (GCVF) was calculated using the following formula: $GCVF = V_i \times [(T_b - T_i)/(T_b - T_m) - 1] \times 1.08$, where $V_i$ represents the volume of injectate (ml/min) and $T_b$, $T_i$, and $T_m$ the temperatures of blood, injectate, and mixture of blood and injectate; 1.08 is a constant of the saline solution.

Informed consent was obtained from all patients before each test. No complications were observed during the procedures.

## Results

**Clinical features:** Eleven patients were men and 1 a woman, with an average age of 52.7 years (range 38 to 62). In 8 patients, anginal attacks at rest were associated with S-T segment elevation, occurring in the anterior leads in 4 patients and in the inferior leads in 4, whereas 1 patient had episodes associated with either S-T segment elevation or depression in the anterior leads. Three patients showed S-T segment depression in the anterior leads during chest pain at rest. In 6 patients, angina was of recent onset (<3 months).

**Exercise tests (Table I):** Four patients (Cases 2, 4, 7, and 10) had 1 negative test and 2 positive tests; 1 patient (Case 3) had 2 negative tests and 1 positive test. Seven patients had all 3 positive tests. Chest pain occurred during all 3 exercise tests in 3 patients, while 8 patients had at least 1 exercise test ended because of exhaustion. In 1 patient the end point was angina in 2 tests and S-T segment depression >3 mm without angina in the third test.

S-T segment elevation was observed in 2 patients (Cases 3 and 4) during 1 exercise test and in 1 patient (Case 5) during 2 tests. In 6 patients (Cases 1, 6, 8, 9, 11, and 12) all 3 exercise tests induced S-T segment depression. In 5 of these patients, S-T segment depression occurred at different work loads with a wide range of values of double product. One illustrative case is shown in Figure 1. In 1 patient (Case 8) exercise tolerance did not change substantially during the 3 tests; however S-T depression was more marked during the first than during the second exercise test although a higher value of double product was attained during the latter.

**Angiographic features:** No patient had akinetic or dyskinetic areas of the left ventricle. The average ejection fraction was 59 ± 7 and the average left ventricular end-diastolic pressure was 12.5 ± 5 mm Hg. Coronary

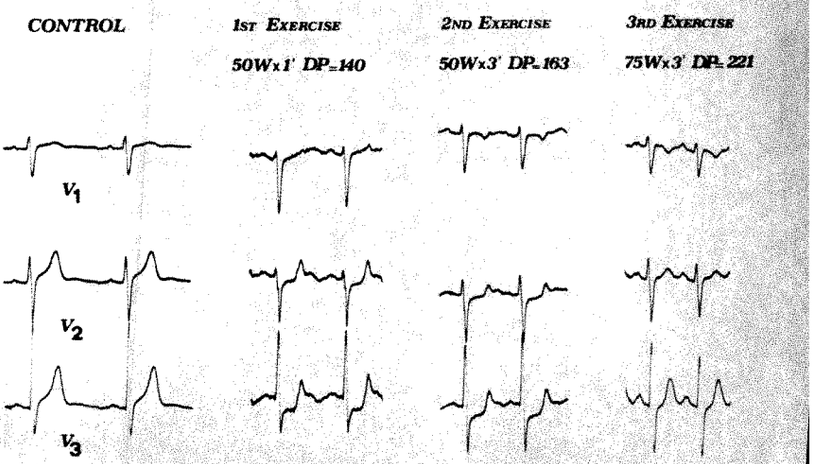

**FIGURE 1.** Case 11. Three exercise tests performed in the morning on different days yielded different results. The first and second tests induced chest pain and S-T segment depression, whereas the third test was negative despite a higher double product. DP = double product (mm Hg × beats/min × $10^{-2}$).

**TABLE III Great Cardiac Vein Flow During Exercise Tests Before and After Administration of Nifedipine**

| | Work Load | End-point | ECG Changes | Double Product (mm Hg beats/min $10^{-2}$) | GCVF (ml/min) |
|---|---|---|---|---|---|
| Case 11 | | | | | |
| Control | | | | | 72 |
| Peak exercise | 75 W × 3 min | Ang | ↓S-T 1 mm $V_4$-$V_6$ | 208 | 152 |
| After nifedipine | | | | | 64 |
| Peak exercise | 100 W × 2 min | Exh | — | 269 | 194 |
| Case 12 | | | | | |
| Control | | | | | 103 |
| Peak exercise | 25 W × 2 min | Ang | ↓S-T 4 mm $V_3$-$V_6$ | 131 | 105 |
| After nifedipine | | | | | 116 |
| Peak exercise | 75 W × 2 min | Ang | ↓S-T 4 mm $V_3$-$V_6$ | 183 | 164 |

Ang = angina; ECG = electrocardiographic; Exh = exhaustion; GCVF = great cardiac vein flow; ↓S-T = S-T segment depression; — = no electrocardiographic changes.

arteriography (Table II) showed normal coronary arteries in 2 patients. Seven patients had single-vessel disease with involvement of the left anterior descending artery in 5, of the right coronary artery in 1 and of the circumflex branch in 1.

Three patients had 2-vessel disease. During the procedure, 2 patients exhibited a spontaneous spasm of the right coronary artery and 1 of the left anterior descending artery. One patient had an ergonovine-induced spasm of the left anterior descending artery.

**Great cardiac vein flow measurements (Table III):** Both patients showed an increase in flow at peak exercise. After administration of nifedipine they tolerated heavier work loads than before and attained higher values of double product. Despite that, electrocardiographic signs of ischemia did not appear in 1 patient and occurred at far greater values of double product in the other. The increase in flow in the great cardiac vein at peak exercise was more marked after than before administration of nifedipine (Fig. 2).

## Discussion

**Variability of angina threshold during exercise:** Stable exertional angina is caused by increased myocardial oxygen consumption in the presence of fixed stenoses of the large coronary arteries. The concept that coronary lesions are fixed implies that myocardial ischemia occurs reproducibly at a given level of myocardial oxygen consumption. Epstein and Talbot[19] recently challenged this concept, because it does not explain several clinical characteristics often observed in patients with angina pectoris. For instance, "... it does not explain why angina threshold should vary markedly during different times of the day, different times of the week, or different seasons of the year."[19] This lack of reproducibility and predictability has been reported in classic descriptions of angina of effort.[20,21] Friedberg,[20] observing that some patients have only occasional seizures at intervals of days, weeks, or months, comments that "these intervals depend to some extent on avoidance of the factors which elicit the anginal attacks."

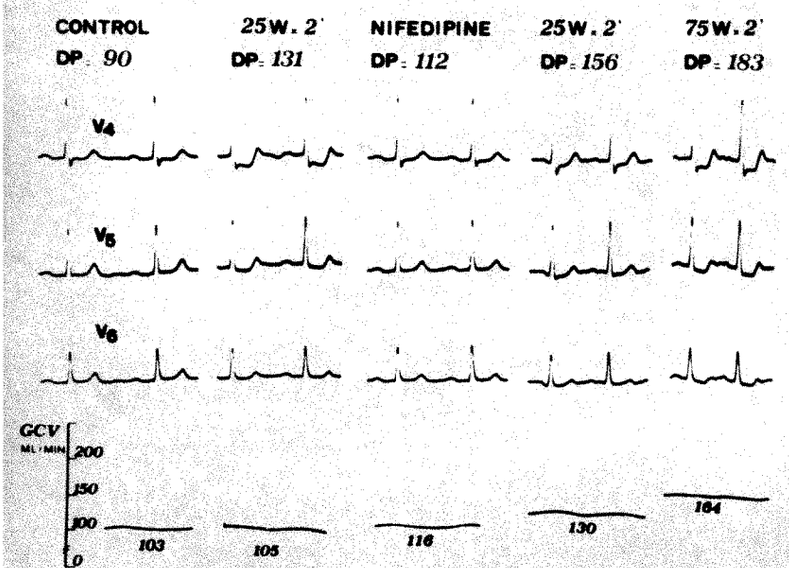

**FIGURE 2.** Case 12. In this patient with disease of an isolated left anterior descending artery, measurements of great cardiac vein flow were performed during exercise, before and after administration of nifedipine. After the drug, the patient tolerated a greater work load and attained a higher value of double product. This beneficial effect was achieved by an increase in great cardiac vein flow. DP = double product (mm Hg × beats/min × $10^{-2}$); GCVF = great cardiac vein flow measurements (ml/min).

Braunwald[21] ascribes this unpredictability to a "complex interplay of factors relating to the physiological and emotional set of a patient." However, a good reproducibility of exercise test results, repeated at short- or long-term intervals, has been shown in patients with stable exertional angina.[22,23] Moreover, when occasional patients showing a variation in their exercise tolerance were studied,[24] angina always occurred at a constant level of heart rate-systolic pressure product, an indirect index of myocardial oxygen consumption.

All 12 patients in our study had vasospastic angina at rest and clinical evidence of variable threshold exertional angina. Repeat exercise testing objectively demonstrated the variation in exercise tolerance and the variable occurrence of angina that was not dependent on the achievement of a critical level of heart rate-systolic pressure product. Other determinants of myocardial oxygen consumption not reflected by the double product, such as contractility or left ventricular size, may be operative in producing the variation in exercise tolerance in our patients. However the double product is well correlated with myocardial oxygen consumption during exercise,[25] and in patients with stable effort angina chest pain occurs when a critical level of double product is achieved.[24,26] Thus, there is no reason to assume that changes in other factors, not included in the double product, could play a major role in determining the wide variation in exercise capacity observed in our patients with vasospastic angina.

**Role of dynamic coronary tone in exertional angina:** Variability of the angina threshold may be due to a functional mechanism that causes myocardial ischemia in addition to the increased myocardial metabolic requirements provoked by exercise. It has been shown by us[15,27] and others[28,29] that in patients with variant angina, exercise-induced S-T segment elevation is caused by coronary spasm. Recently, Yasue et al[29] reported a circadian variation of exercise capacity in patients with variant angina. These investigators showed that the treadmill exercise test induced repeated attacks in the early morning but not in the afternoon of the same day, even though the exercise was heavier in the afternoon than in the morning. In their patients, coronary angiography revealed that the diameter of the coronary vessels was smaller in the morning than in the afternoon. Under conditions of increased coronary tone, exercise can readily induce spasm and result in an attack. Furthermore, it has been demonstrated that the exercise test is frequently positive in patients with active variant angina[16,30] but may become negative if the patient is in a latent phase of his disease. Thus, the fluctuating susceptibility of the coronary vessels to vasoconstriction may be responsible for the large variability of responses to the same exertion. Epstein and Talbot[19] recently developed the hypothesis that subtle alterations in coronary tone may account for the spontaneous changes in angina threshold during exercise. They developed the concept that there is a spectrum of coronary tone in dynamic large vessels that can significantly alter angina threshold. We believe that our results support this hypothesis. When coronary tone is low, patients can perform heavy exercise because myocardial oxygen supply is impaired only by the eventual presence of organic coronary stenoses. On the contrary, when coronary tone is high, oxygen supply is decreased and even moderate physical activities may induce chest pain and myocardial ischemia. In some patients, exercise-induced coronary spasm may supervene, as in patients showing S-T segment elevation during exercise and probably in those showing unexpected S-T segment depression at very light work loads.

**Clinical implications:** Our data show that variable threshold exertional angina is clinically observed in about one third of patients with vasospastic angina and can be objectively demonstrated by repeat exercise testing. In this study we did not test patients with a fixed limitation of exercise tolerance or without effort angina. Thus, it is not possible to establish in those patients a correlation between the clinical history and the repeat exercise test results.

Coronary tone changes seem the most likely explanation for the variable occurrence of chest pain and myocardial ischemia during exercise in patients with vasospastic angina. In such patients, calcium-channel blocking agents, which lower coronary tone[31,32] and prevent the occurrence of coronary spasm,[33] may have beneficial effects, whereas propranolol may be ineffective and even detrimental, as demonstrated by Yasue et al.[34] An increase in exercise capacity was observed in 2 of our patients to whom nifedipine was administered. After drug administration, both patients tolerated heavier work loads. Ischemic electrocardiograpic changes were no longer observed in 1 patient and occurred at higher values of double product in the other patient. We documented that this salutary effect was achieved by an increase in coronary flow during exercise. These results lend further support to the hypothesis that changes in coronary tone may account for the variability of angina threshold observed during exercise in some patients with vasospastic angina. Further studies should also focus on the recognition of this clinical manifestation in patients without vasospastic angina, and should assess the role of dynamic coronary tone in stable exertional angina.

mg of nifedipine; the tests were done with the patient in the supine position with an initial work load of subsequent increments of 25 W every 3 minutes. A triple thermistor thermodilution catheter (Wilton Webster Laboratories, Altadena, California) was inserted into the coronary sinus with the tip advanced to the great cardiac vein, so that the flow recorded was entirely from the great cardiac vein.[17] Its position was confirmed with fluoroscopy and frequently checked throughout the procedure. Flow measurements were obtained in basal conditions and at peak exercise[15,18] by injecting physiologic saline solution at 24° per 30 seconds using a pump at a rate of 56 ml/min. The left brachial artery was punctured to measure intraarterial pressure.

An interval of 30 minutes was allowed to elapse between the end of the first exercise test and the administration of nifedipine. Great cardiac vein flow (GCVF) was calculated using the following formula: $GCVF = V_i \times [(T_b - T_i)/(T_b - T_m) - 1] \times 1.08$, where $V_i$ represents the volume of injectate (ml/min) and $T_b$, $T_i$, and $T_m$ the temperatures of blood, injectate, and mixture of blood and injectate; 1.08 is a constant of the saline solution.

Informed consent was obtained from all patients before each test. No complications were observed during the procedures.

## Results

**Clinical features:** Eleven patients were men and 1 a woman, with an average age of 52.7 years (range 38 to 62). In 8 patients, anginal attacks at rest were associated with S-T segment elevation, occurring in the anterior leads in 4 patients and in the inferior leads in 4, whereas 1 patient had episodes associated with either S-T segment elevation or depression in the anterior leads. Three patients showed S-T segment depression in the anterior leads during chest pain at rest. In 6 patients, angina was of recent onset (<3 months).

**Exercise tests (Table I):** Four patients (Cases 2, 4, 7, and 10) had 1 negative test and 2 positive tests; 1 patient (Case 3) had 2 negative tests and 1 positive test. Seven patients had all 3 positive tests. Chest pain occurred during all 3 exercise tests in 3 patients, while 8 patients had at least 1 exercise test ended because of exhaustion. In 1 patient the end point was angina in 2 tests and S-T segment depression >3 mm without angina in the third test.

S-T segment elevation was observed in 2 patients (Cases 3 and 4) during 1 exercise test and in 1 patient (Case 5) during 2 tests. In 6 patients (Cases 1, 6, 8, 9, 11, and 12) all 3 exercise tests induced S-T segment depression. In 5 of these patients, S-T segment depression occurred at different work loads with a wide range of values of double product. One illustrative case is shown in Figure 1. In 1 patient (Case 8) exercise tolerance did not change substantially during the 3 tests; however S-T depression was more marked during the first than during the second exercise test although a higher value of double product was attained during the latter.

**Angiographic features:** No patient had akinetic or dyskinetic areas of the left ventricle. The average ejection fraction was 59 ± 7 and the average left ventricular end-diastolic pressure was 12.5 ± 5 mm Hg. Coronary

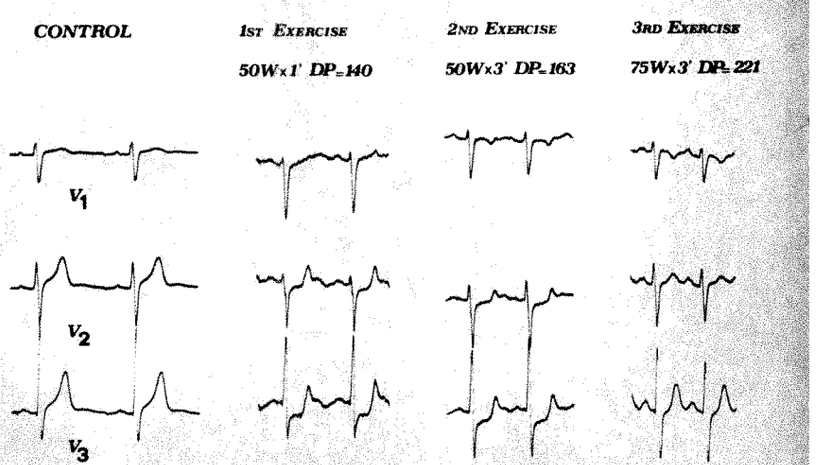

**FIGURE 1.** Case 11. Three exercise tests performed in the morning on different days yielded different results. The first and second tests induced chest pain and S-T segment depression, whereas the third test was negative despite a higher double product. DP = double product (mm Hg × beats/min × $10^{-2}$).

# Cardiovascular Disease in the Very Elderly

## Analysis of 40 Necropsy Patients Aged 90 Years or Over

BRUCE F. WALLER, MD and WILLIAM C. ROBERTS, MD

**Clinical and necropsy observations are described in 40 patients (29 women) aged 90 years and older. The majority (21 patients [57%]) died during the 4 coldest months, and 12 (30%), during the 4 warmest months. At necropsy, 39 had ≥1 major cardiac abnormalities, the most frequent being calcific deposits in the major epicardial coronary arteries in 37 (92%). In 28 patients (70%), 1 or more of the 4 major arteries was narrowed 76 to 100% in cross-sectional area (XSA) by atherosclerotic plaques, an average of 1.9/4.0 per patient: the 12 patients with clinical events compatible with myocardial ischemia (angina pectoris or myocardial infarction) had an average of 2.2/4 and the other 28 patients an average of 1.0/4.0. In 36 patients, a histologic section was examined from each 5 mm long segment from each of the 4 major coronary arteries: of the 1,789 segments, only 6 (<1%) were narrowed 96 to 100% in XSA by plaques; 147 (8%), 76 to 95%; 339 (19%), 51 to 75%; 930 (52%), 26 to 50%, and 367 (21%), 0 to 25%. The average amount of XSA narrowing for the 1,789 segments was about 42%. In 10 patients with clinical evidence of myocardial ischemia, the average amount of narrowing per segment was approximately 55%; in the 26 patients without clinical ischemia, the average was about 38%. Of the 40 patients, 18 (45%) had left ventricular transmural foci of fibrosis or necrosis or both. Of 14 patients with transmural scars, only 1 had a clinical event compatible with acute myocardial infarction; of the 10 with acute myocardial infarction at necropsy, only 4 had typical clinical features of infarction.**

**Calcific deposits were present in ≥1 aortic valve cusps in 22 patients (55%), causing aortic valve stenosis in 2, and in the mitral anulus in 19 (47%), probably causing mitral valve stenosis in 1.**

**Amyloid deposits were present in the heart in at least 9 patients; they were grossly visible and caused fatal cardiac dysfunction in 4, and microscopically visible only in 5, causing no cardiac dysfunction. Eight patients (20%) had chronic congestive heart failure; 27 of 39 (69%) had either a history of systemic hypertension or blood pressure >140/90 mm Hg during their final year of life. Precordial murmurs were recorded in 25 (62%) patients—systolic only in 24 and both systolic and diastolic in 1. Data from electrocardiograms were available in 30 patients: 12 (40%) had atrial fibrillation; 12 (40%), abnormal axis; 12, complete bundle branch block; 1, criteria for left ventricular hypertrophy (despite increased cardiac mass in 67%); and 1, low voltage.**

**All patients had fairly extensive atherosclerosis of the aorta, with aneurysmal formation in 5 with fatal rupture in 3. Five had strokes, which were fatal in 4. At least 5 had leg claudication. Two had massive pulmonary emboli superimposed on chronic obstructive pulmonary disease.**

**Thus, cardiovascular disease was present at necropsy in 39 of our 40 patients, but frequently it was not diagnosed clinically.**

Although the average age at death has increased dramatically during this century, the maximal length of life has not changed.[1] The percentage of individuals surviving for 90 years and beyond, however, is increasing.[2] In 1980, about 1% of the population in the United States was aged 90 years or older.[2] Very few necropsies are performed in patients dying after age 90 years (frequency about 4%)[3] and, therefore, little attention has been focused on the clinical and morphologic frequencies and types of cardiovascular disease observed in these very elderly persons. This report describes the types of cardiovascular disease found at necropsy in 40 patients aged 90 years or over.

From the Pathology Branch, National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland. Manuscript received and accepted September 24, 1982.

### Patients

**General observations:** Clinical and morphologic observations in the 40 patients are detailed in Table I. The patients died and underwent necropsy at 12 different hospitals (10 in the Washington, D.C. area [37 patients]); subsequently the heart and frequently the aortas were examined in all 40 patients by 1 of us (WCR). The year of death in 37 patients was between

1967 and 1982; the other 3 patients had been studied both clinically and at necropsy at the National Institutes of Health in 1954, 1966, and 1967, respectively. The month of death was known in 37 patients: death occurred during 4 cold months (November to February) in 21 (57%); during 4 warm months (June to September) in 11 (30%), and during intermediate weather months in 5 (13%) ($p < 0.05$). (The data throughout this study were analyzed using the $t$ test for paired and unpaired data and linear regression tests to determine correlation coefficients.) The ages of death in the 40 patients ranged from 90 to 103 (mean 94); 29 (72%) were women and 11 (28%) were men; 31 (78%) were white and 9 (22%) were black.

**TABLE II Morphologic Cardiac Observations in 40 Necropsy Patients Aged 90 to 103 Years**

| | Patients | |
|---|---|---|
| | n | % |
| Coronary arterial disease | | |
| Calcium | 37 | 92 |
| Luminal narrowing 76 to 100% in XSA by atherosclerotic plaques of ≥1 major coronary arteries | 28 | 70 |
| Acute myocardial infarction | 10 | 25 |
| Healed myocardial infarction | 14 | 35 |
| Aortic valve disease | | |
| Calcium | 22 | 55 |
| Stenosis | 2 | 5 |
| Mitral anular disease | | |
| Calcium | 19 | 47 |
| Cardiac amyloidosis (fatal) | 4 | 10 |
| Dilated cardiomyopathy | 1 | 3 |
| Obliterative pericardial disease | | |
| Idiopathic | 1 | 5 |
| Iatrogenic | 1 | 5 |

*Heart weights and body weights:* The weight of the heart was increased (>350 g in women and >400 g in men) in 27 (67%) patients. The hearts in the 29 women ranged from 220 to 630 g (mean 408), and those in the 11 men, from 335 to 660 g (mean 490). The body weights in the 23 women ranged from 41 to 85 kg (mean 52) and the heart weight-body weight ratio, from 0.003 to 0.013 (mean 0.007). Thus, the mean heart weight was 0.7% of the body weight (normal value for younger women is approximately 0.4%[4]). The body weights in 7 men ranged from 47 to 68 kg (mean 50) and the heart weight-body weight ratios, from 0.006 to 0.013 (mean 0.009). Thus, the mean heart weight was 0.6% of the mean body weight (the normal value for younger men is approximately 0.45%[4]).

**Necropsy observations (Table II):** *Coronary arterial calcification (Fig. 1 to 6):* Calcific deposits within atherosclerotic plaques were observed grossly in the epicardial coronary arteries in 37 (92%) patients. In 28 patients, radiograms of the heart or of the excised coronary arteries were performed; all patients had calcific deposits in the coronary arteries: 23 (82%), in the left anterior descending, left circumflex, and right coronary arteries, and the other 5 patients, in 2 of these 3 major

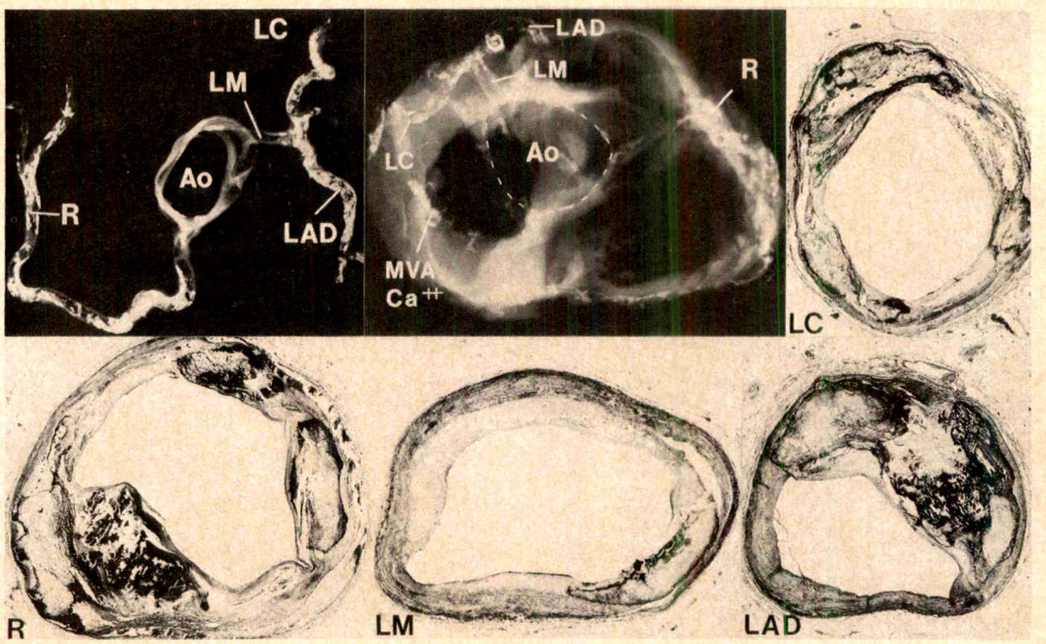

**FIGURE 1.** Patient 29 (SH #A80-74). Tortuous and heavily calcified coronary arteries in a 95-year-old woman who never had symptoms of cardiac dysfunction and who died from a perforated gastric ulcer. **Top left,** postmortem radiogram of the excised right (R), left main (LM), left anterior descending (LAD), and left circumflex (LC) coronary arteries. **Top center,** radiogram of a portion of the heart after removing the walls of the atria and most of the walls of the ventricles. MVA = mitral valve anulus. **Top right and lower panels,** photomicrographs of coronary arteries at sites of maximal narrowing by calcified atherosclerotic plaques. (Movat stains; magnification ×17, reduced 40%.) This case illustrates extensive calcific deposits in the coronary arteries without significant luminal narrowing.

coronary arteries. In 23 of the 28 patients, the left main coronary artery was studied radiographically: 18 (78%) had calcific deposits. Thus, of 112 major epicardial coronary arteries studied radiographically in 28 patients, 97 (87%) were seen to contain calcific deposits. Of the 37 patients with demonstrated calcific deposits in the epicardial coronary arteries, 26 (70%) also had calcific deposits in either aortic valve cusps or mitral anulus or both. Of the 3 patients without calcium in the coronary arteries, none had calcific deposits in either aortic valve cusps on mital anulus (Fig. 7 and 8).

*Coronary arterial atherosclerosis (qualitative studies):* At necropsy, 39 of the 40 patients had ≥1 significant cardiac conditions on *gross* examination. One or more of the 4 major (right, left main, left anterior descending, left circumflex) epicardial coronary arteries was narrowed 76 to 100% in XSA by atherosclerotic plaques in 28 (70%) patients; 37 (92%) had grossly palpable calcific deposits in ≥1 major coronary arteries. None of the 28 patients had significant (>75% in XSA) narrowing in the left main coronary artery. Of the other 3 major coronary arteries, 1 was significantly narrowed in 8 patients (29%), 2 were narrowed 76 to 100% by plaques in 15 patients (53%), and 3 arteries were so narrowed in 5 patients (18%). Of the 112 major coronary arteries in these 28 patients, 53 were significantly narrowed, an average of 1.9/4 major coronary arteries per patient. Of the 160 major coronary arteries in the 40 patients, the average number narrowed per patient was 1.3.

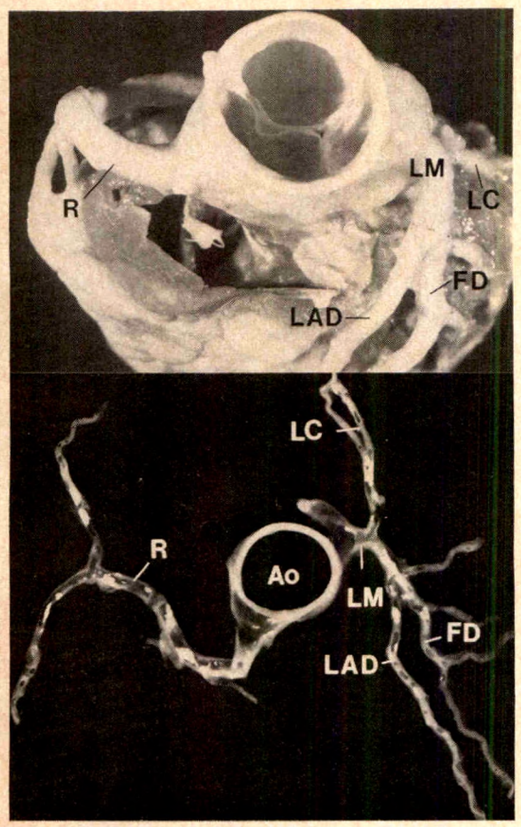

**FIGURE 2.** Patient 28 (SH #A79-77). Coronary arteries in a 95-year-old man who never had symptoms of cardiac dysfunction and who died from cancer. **Top,** aorta and coronary arteries from above. **Bottom,** radiograms of aortic root (Ao) and excised coronary arteries which contain calcific deposits. FD = first diagonal; LAD = left anterior descending; LC = left circumflex; LM = left main; R = right.

Of the 12 patients *with clinical evidence of myocardial ischemia* (angina pectoris or a clinical event diagnosed as or compatible with acute myocardial infarction or both), at least 1 of the 4 major coronary arteries was narrowed 76 to 100% in XSA by plaques: in 10 patients, 2 arteries (right, left anterior descending, or left circumflex) were so narrowed and in the other 2 patients, 3 arteries. Thus, of the 48 major coronary arteries (4 per patient) in these 12 patients, 26 arteries were significantly narrowed, an average of 2.2/4.0 per patient.

Of the 28 patients *without clinical evidence of myocardial ischemia*, at least 1 of the 4 major coronary arteries was narrowed 76 to 100% in XSA by atherosclerotic plaques in 16 patients (57%): in 8 patients, only 1 artery was so narrowed; in 5 patients, 2 arteries; and in 4 patients, 3 arteries. In 12 patients (43%), none of the 4 major coronary arteries was significantly narrowed. Thus, of the 112 major coronary arteries in these 28 patients, 27 (24%) were significantly narrowed, an average of 1.0/4.0 per patient.

*Coronary arterial atherosclerosis (quantitative studies):* In 36 patients, including 26 of the 28 in whom 1 or more of the 4 major coronary arteries were significantly narrowed and in 10 of the 12 in whom none of the 4 arteries was significantly narrowed, each of the 4 major coronary arteries was decalcified and cut into 5 mm long segments. Each segment was processed in alcohols and xylene, and imbedded in paraffin. At least 1 histologic section was cut and stained by the Movat method from each segment. Of the 1,789 5 mm segments from the 36 patients (an average of 49 segments per patient [range 30 to 75]), 6 (<1%) were narrowed 96 to 100% in XSA by atherosclerotic plaques; 147 (8%), 76 to 95%; 339 (19%), 51 to 75%; 930 (52%), 26 to 50%; and 367 (21%), 0 to 25%.

*A scoring system* was utilized to indicate the severity of the coronary narrowing. Every 5 mm long segment was assigned a score of 1 to 4 based on the amount of XSA narrowing by atherosclerotic plaques as follows: 1 = 0 to 25%, 2 = 26 to 50%, 3 = 51 to 75%, and 4 = 76 to 100% narrowing. A total score was obtained for each patient. The mean score per 5 mm segment was then calculated by dividing the total score per patient by the number of segments examined. The total scores for the 36 patients ranged from 53 to 170 (average 107) and the mean score per 5 mm segment, from 1.28 to 3.08 (average 2.15) (Fig. 9). This mean score indicates that each of the 1,789 5 mm segments was narrowed on an average of about 42% in XSA (Fig. 9).

Of the 40 patients, 12 had clinical evidence of myocardial ischemia. Of these 12 patients, the 4 major epicardial coronary arteries were available in their entirety for quantitative studies in 10. Of 467 5 mm coronary segments in these 10 patients, 2 (<1%) were narrowed 96 to 100% in XSA by atherosclerotic plaques; 90 (19%), 76 to 95%; 135 (29%), 51 to 75%; 198 (43%), 26 to 50%;

and 42 (9%), 0 to 25% (Fig. 10). The total score for each of the 10 patients ranged from 88 to 159 (average 120) and the mean score per 5 mm segment of coronary artery, from 2.20 to 3.08 (average 2.59), indicating that each 5 mm segment was narrowed an average of approximately 55% in XSA.

Of the 28 patients without clinical evidence of myocardial ischemia, the 4 major coronary arteries were available for quantitative studies in 26. Of 1,322 5 mm coronary segments examined in these patients, 4 (<1%) were narrowed 96 to 100% in XSA by atherosclerotic plaques; 63 (5%) were narrowed 76 to 95%; 206 (16%), 51 to 75%; 727 (55%), 26 to 50%; and 322 (24%), 0 to 25% (Fig. 10). The total score for each patient ranged from 53 to 170 (average 98) and the mean score per 5 mm segment, from 1.28 to 2.85 (average 2.01) (Fig. 9), indicating that each of the 1,322 5 mm segments was narrowed an average of about 38% in XSA. Of these 26 patients, ≥1 of the 4 major coronary arteries was significantly narrowed in 16. Of the 857 5 mm coronary segments examined in the 26 patients, 4 segments (<1%) had lumens narrowed 96 to 100% in XSA by plaques; 63 (7%), 76 to 95%; 183 (22%), 51 to 75%; 464 (54%), 26 to 50%; and 143 (17%), 0 to 25%. The total score for each of the 16 patients ranged from 56 to 170 (average 111) and the mean score per 5 mm segment, from 1.77 to 2.85 (mean 2.20). Thus, each of the 857 5 mm segments was narrowed an average of approximately 44% in XSA. In

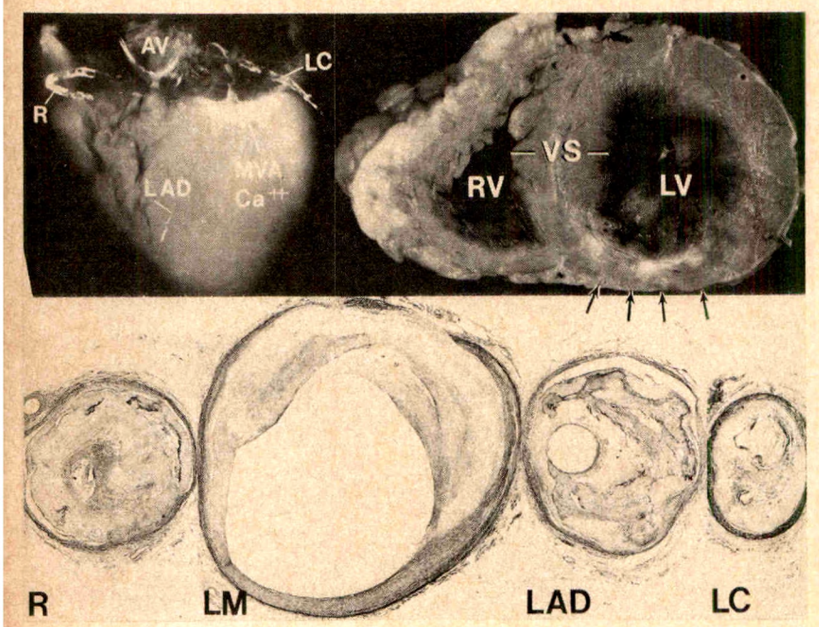

**FIGURE 3.** Patient 22 (LRC #5). Heart and coronary arteries in a 93-year-old woman who was hospitalized with worsening chronic congestive heart failure. **Top left,** postmortem radiogram showing calcific deposits in the right (R), left anterior descending (LAD), and left circumflex (LC) coronary arteries and in the mitral valve anulus (MVA) and aortic valve. **Top right,** view of right (RV) and left (LV) ventricles and ventricular septum (VS) showing a transmural scar (**arrows**). **Bottom,** coronary arteries at sites of maximal narrowing. LM = left main. (Movat stains; magnification ×17, reduced 40%.)

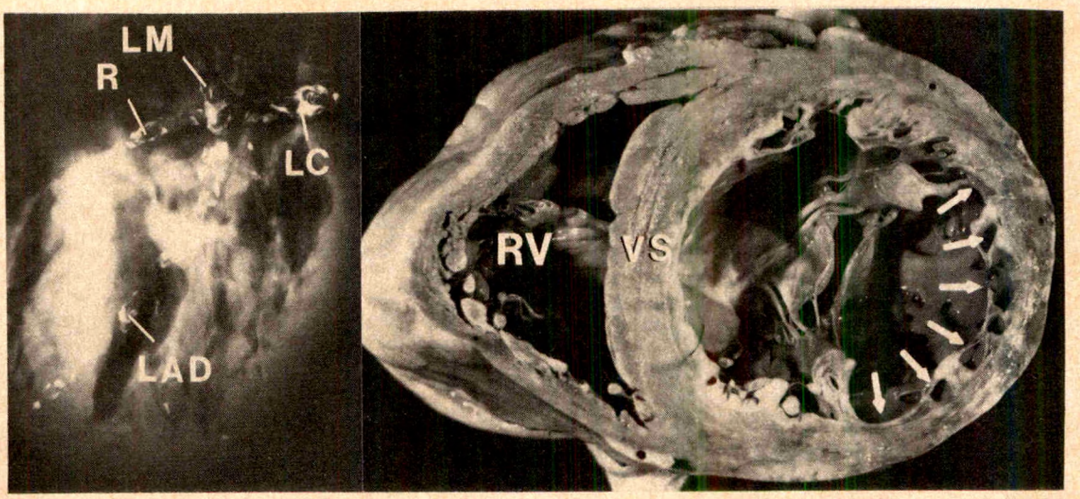

**FIGURE 4.** Patient 13 (LRC #3). This 91-year-old woman had a "typical" clinical acute myocardial infarct, which was fatal. **Left,** postmortem radiogram showing calcific deposits in the right (R), left main (LM), left anterior descending (LAD), and left circumflex (LC) coronary arteries. **Right,** view of left and right (RV) ventricles showing transmural necrosis and fibrosis (**arrows**) and dilated ventricles. VS = ventricular septum.

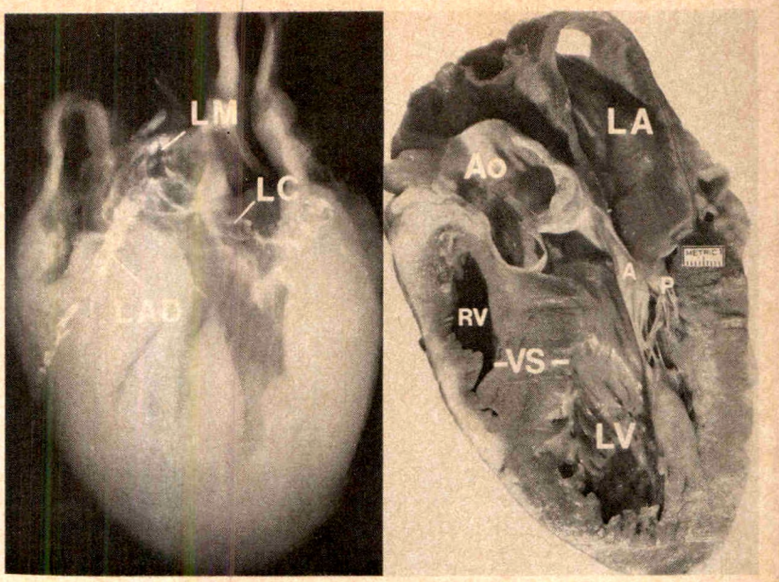

**FIGURE 5.** Patient 8 (SH #A82-1). This 90-year-old woman had no symptoms of cardiac dysfunction and died from a ruptured fusiform abdominal aortic aneurysm. **Left,** postmortem radiogram of the entire heart showing calcific deposits in the left anterior descending (LAD), left circumflex (LC), and left main (LM) coronary arteries. **Right,** view of heart cut in an anteroposterior fashion (M-mode or long-axis 2-dimensional echocardiographic view) showing a dilated left atrium (LA) and left ventricle (LV). A and P = anterior and posterior mitral valve leaflets; Ao = aorta; RV = right ventricle; VS = ventricular septum.

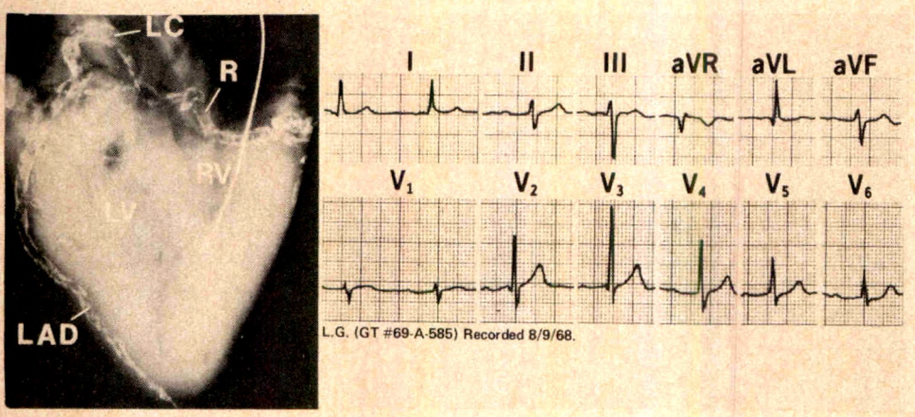

**FIGURE 6.** Patient 34 (GT #69A-585). This 97-year-old man had complete heart block and had a pacemaker inserted when he was 91 years old. **Left,** radiogram of heart at necropsy showing calcific deposits in the left anterior descending (LAD), left circumflex (LC), and right (R) coronary arteries, and a pacemaker wire in the right ventricle (RV). LV = left ventricle. **Right,** electrocardiogram.

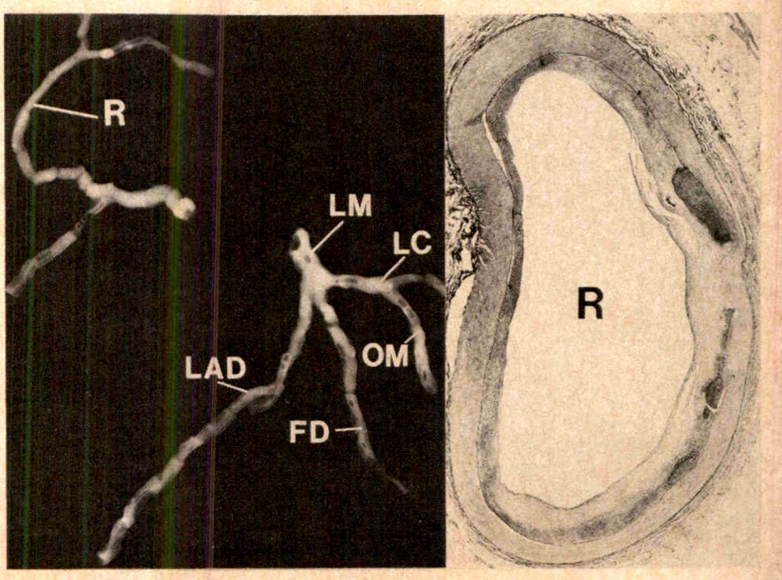

**FIGURE 7.** Patient 30 (DCGH #68A80). This 96-year-old woman had chronic congestive heart failure from dilated cardiomyopathy. Her total serum cholesterol level was 108 mg/dl. **Left,** postmortem radiogram of the right (R), left main (LM), left anterior descending (LAD), left circumflex (LC), first diagonal (FD), and left obtuse marginal (OM) coronary arteries showing no calcific deposits. **Right,** right coronary artery section devoid of calcium or narrowing. (Movat stain; magnification ×16, reduced 23%.)

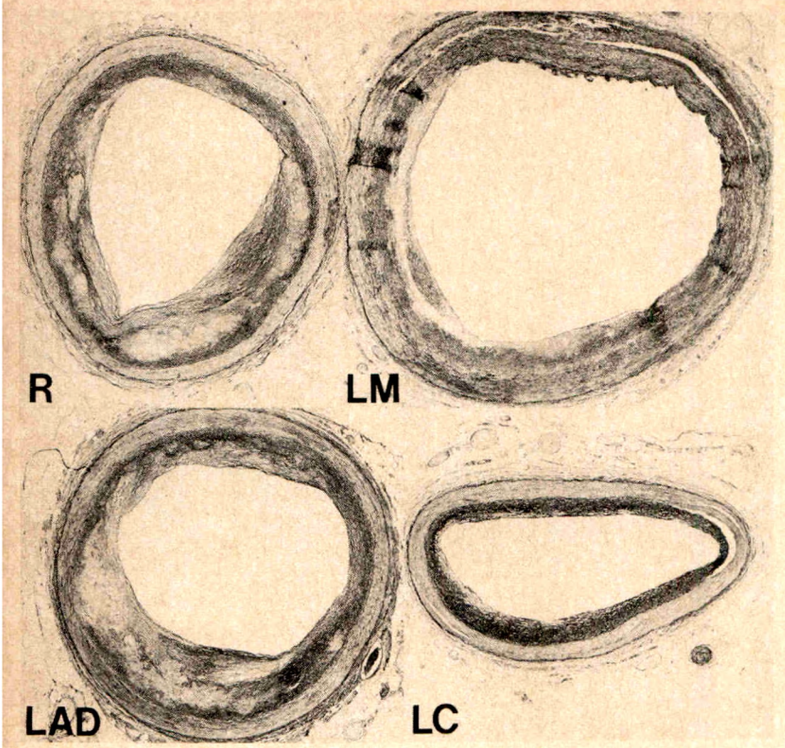

**FIGURE 8.** Patient 40 (GT #70A301). Right (R), left main (LM), left anterior descending (LAD), and left circumflex (LC) coronary arteries at sites of maximal narrowing in a 103-year-old woman. She never had evidence of cardiac dysfunction and died from complications of a duodenal ulcer. The coronary arteries are devoid of calcium and of significant narrowing. (Elastic van Gieson's stain; magnification ×16, reduced 31%.)

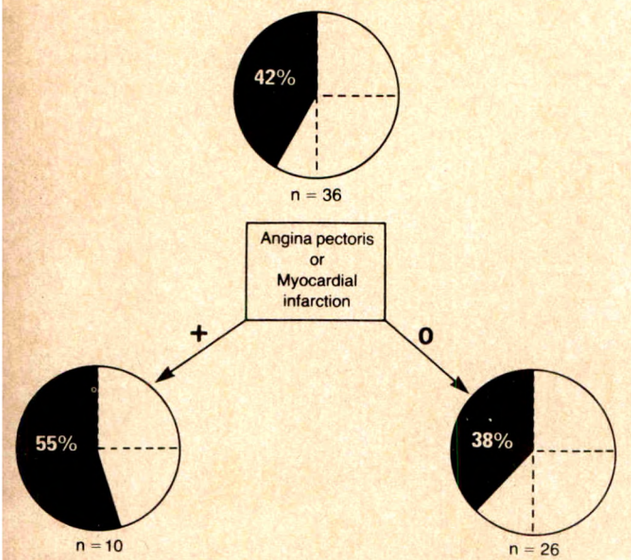

**FIGURE 9.** Mean percent cross-sectional area narrowing by atherosclerotic plaques in 1,789 5 mm segments of the 4 major epicardial coronary arteries in 36 necropsy patients aged 90 years and older, 10 of whom had angina pectoris or acute myocardial infarction or both and 26 of whom did not. The mean percentage of narrowing for each 5 mm segment differs significantly in the group with clinical evidence of myocardial ischemia (55%) and the group without such evidence ($p < 0.05$).

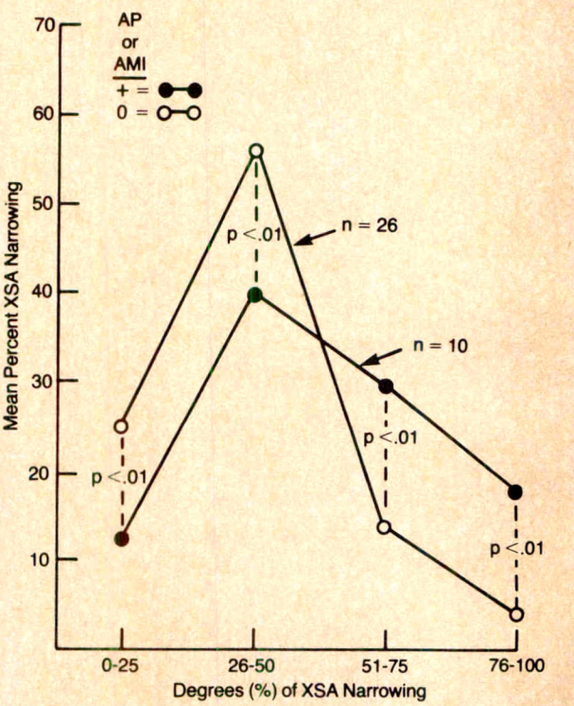

**FIGURE 10.** Mean percent cross-sectional area (XSA) narrowing by atherosclerotic plaques in the 5 mm segments of the right, left main, left anterior descending, and left circumflex coronary arteries in the 36 patients in whom the 4 major coronary arteries in their entirety were available for examination. The 36 patients were classified into 10 with and 26 without clinical evidence of myocardial ischemia. For each of the 4 categories of narrowing, a highly significant ($p < 0.01$) difference in the amount of narrowing was observed.

the 10 patients without significant narrowing, 465 5 mm segments were examined: 23 (5%) were narrowed 51 to 75% in XSA by plaque; 263 (57%), 26 to 50%; and 179 (38%) ≤25%. The total score for each of these 10 patients ranged from 53 to 138 (average 85) and the mean score per 5 mm segment, from 1.28 to 2.07 (average 1.66). Thus, each of the 465 segments was narrowed an average of approximately 29%.

*Left ventricular fibrosis or necrosis or both:* Of the 40 patients, 18 (45%) had ≥1 grossly visible foci of transmural (involvement of all the inner one half and a portion of or all of the outer one half of left ventricular wall) sites of necrosis or fibrosis or both (Fig. 3 and 4). Of the 18 patients, 5 had foci of transmural necrosis only, 8 had transmural scars only, 4 had transmural foci of necrosis and fibrosis, and 1 had transmural fibrosis and subendocardial (involvement of less than the inner one half of the left ventricular wall) necrosis. Of the 23 transmural infarcts in 18 patients, 11 (2 acute, 11 healed [10 patients]) were "small"; 9 (7 acute, 2 healed [8 patients]) were "large"; and 2 (both healed [2 patients]) were "intermediate" in size. All 18 patients had narrowing of 76 to 100% in XSA by atherosclerotic plaque of ≥1 of the 4 major epicardial coronary arteries. None of the 10 patients with fatal acute myocardial infarction had a thrombus in a major coronary artery at necropsy.

*Valvular and anular calcification* (Fig. 11 to 16): Grossly visible calcific deposits were present in ≥1 of the 3 aortic valve cusps (on their aortic surfaces) in 22 patients (55%): in 20 patients, the amount of calcium on the cusps was mild (graded 1+ or 2+/4+) and valvular function was considered normal; in the other 2 patients (Cases 1 and 17) (Fig. 11), the cuspal calcific deposits were extensive (4+/4+) and cuspal mobility was limited, and the orifice in each appeared severely stenotic.[5]

Of the 40 patients, 19 (47%) had grossly visible *mitral anular calcific deposits:* graded 1+ in 5 patients (26%), 2+ in 5 (26%), 3+ in 5 (26%), and 4+ in 4 (22%).[6] In 1 of the 4 patients with 4+ mitral anular calcium (Patient 11), the mitral orifice appeared stenotic (Fig. 13). Of the 40 patients, 26 (65%) had calcific deposits in the aortic valve or mitral anulus or both: in both aortic valve and mitral anulus in 16 (62%), in aortic valve only in 7 (27%), and in mitral anulus only in 3 (11%).

*Cardiac amyloidosis* (Fig. 17): Four patients had extensive amyloid deposits detected grossly in the walls of all 4 cardiac chambers and in many other body organs.[8] The extent of the deposits in each patient produced symptoms and signs of cardiac dysfunction,

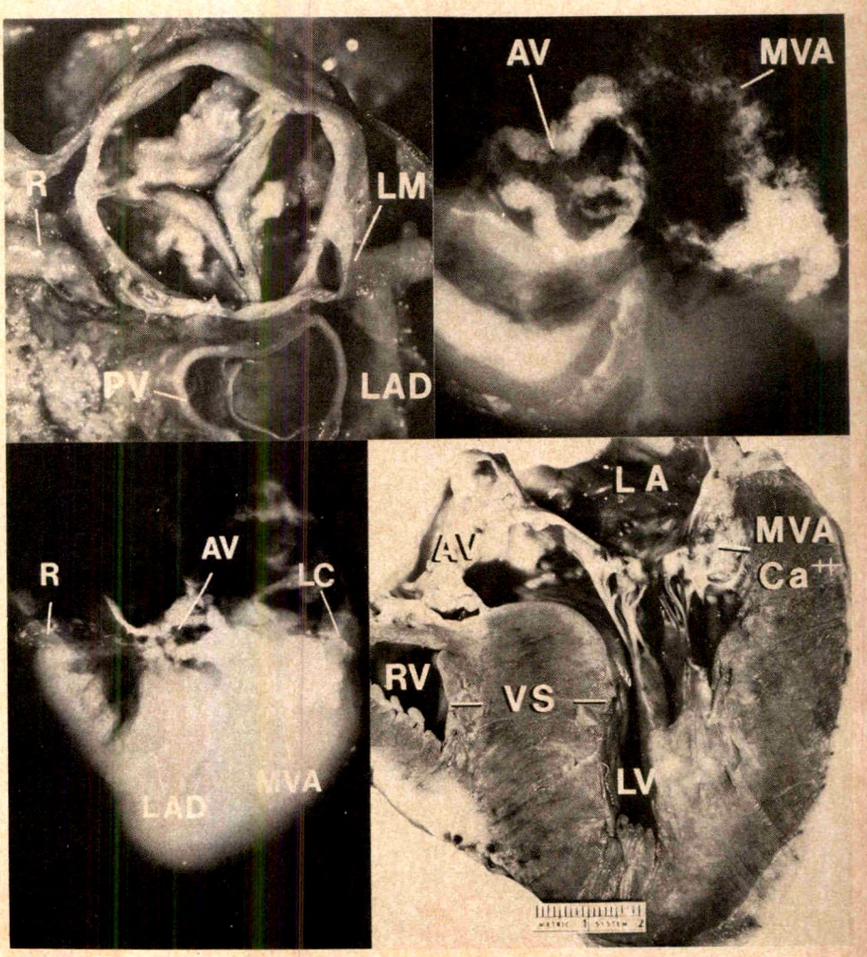

**FIGURE 11.** Patient 17 (GT #78A58). A 92-year-old woman with clinically recognized and eventually fatal aortic valve stenosis. **Top left,** stenotic aortic valve from above. PV = pulmonic valve; R = right; LM = left main; LAD = left anterior descending coronary arteries. **Top right,** postmortem radiogram showing heavy calcific deposits in the aortic valve (AV) and in mitral valve anular (MVA) region. **Bottom left,** radiogram of the heart at necropsy showing calcific deposits in the coronary arteries, in the aortic valve, and in the mitral anular region. **Bottom right,** long-axis view of heart (M-mode or 2-dimensional long-axis view) showing a small left ventricular (LV) cavity, a thickened and "sigmoid-shaped" ventricular septum (VS), and the stenotic aortic valve just above the right ventricular (RV) outflow tract. LA = left atrium.

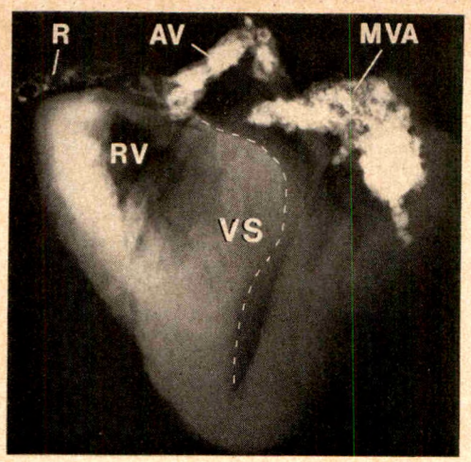

**FIGURE 12.** Patient 31 (GT #68A-367). Radiogram of the heart showing heavy calcific deposits in the aortic valve (AV), mitral valve anulus (MVA), and right (R) coronary artery. The ventricular septum (VS) has a *S* or sigmoid shape (**dashed line**). RV = right ventricle.

manifested primarily by chronic congestive cardiac failure. The presence of extensive amyloidosis was confirmed by histologic examination. At least 5 other patients also had amyloid deposits. The extent of the cardiac amyloid deposits in these 5 patients, however, was minimal and detectable only by histologic examination. Among the 40 patients, histologic sections (1 to 8 per patient [mean 3]) of left ventricular myocardium extending from endocardium to epicardium were examined in 37: 9 of the 37 patients (24%) had amyloid deposits, which were "massive" in 4 and minimal in 5.

*Idiopathic dilated cardiomyopathy:* One patient (Case 30) had a large heart (700 g), dilated ventricular cavities without foci of myocardial fibrosis or necrosis, normal valves and pericardia, epicardial coronary arteries virtually free of atherosclerotic plaques, and chronic congestive heart failure. Although a history of systemic hypertension was absent, the blood pressure in the last month of life was recorded as 140/90 mm Hg. The kidneys, however, were near normal. This patient, therefore, fulfills criteria for diagnosis of idiopathic dilated cardiomyopathy. The patient apparently had habitually consumed excessive quantities of alcohol.

*Obliterative "pericarditis":* Two patients (Cases 14 and 34) had obliterated space between visceral and parietal pericardia by adhesions, some calcified. One (Patient 14) had had talcum powder sprinkled on the epicardium 29 years before death at operation (Beck procedure) for relief of angina pectoris.[9] This patient was the only 1 of the 40 who had undergone a cardiovascular operation. The cause of the obliterative pericardial disease in the other patient was not determined.

*Disease of aorta:* In 34 of the 40 patients, the status of the aorta was known. In all 34, the aorta was dilated in both its transverse and longitudinal dimensions. The latter produced varying degrees of tortuosity. Some degree of atherosclerotic plaquing was present in the aorta in all 34 patients. The most extensive plaquing involved the abdominal portion. Three patients (Cases 8, 13, and 34) had atherosclerotic fusiform abdominal aortic aneurysms with intraaneurysmal thrombus; death in 1 (Patient 8) was secondary to aneurysmal rupture. One patient (Case 25) had an atherosclerotic fusiform aneurysm of the descending thoracic aorta which ruptured, and 1 patient (Case 11) had a dissection limited to descending thoracic aorta; death was due to rupture of the aneurysm into the esophagus.[10]

*Cerebrovascular disease:* Extensive cerebral arterial atherosclerosis was described in the necropsy reports in each of the 4 patients (Cases 30, 31, 33, and 38) with clinical strokes.

*Pulmonary embolism:* Massive pulmonary embolism, that is, thromboembolic material in 1 or both major right and left main pulmonary arteries, was observed at necropsy in 2 patients (Cases 10 and 26). Both had underlying chronic obstructive pulmonary disease.

**Clinical observations:** *Evidence of coronary heart disease:* Of the 40 patients, 12 (30%) had definite or probable clinical evidence of coronary heart disease as manifested by angina pectoris or acute myocardial infarction or both: 1 patient (Case 14) had angina only, 1

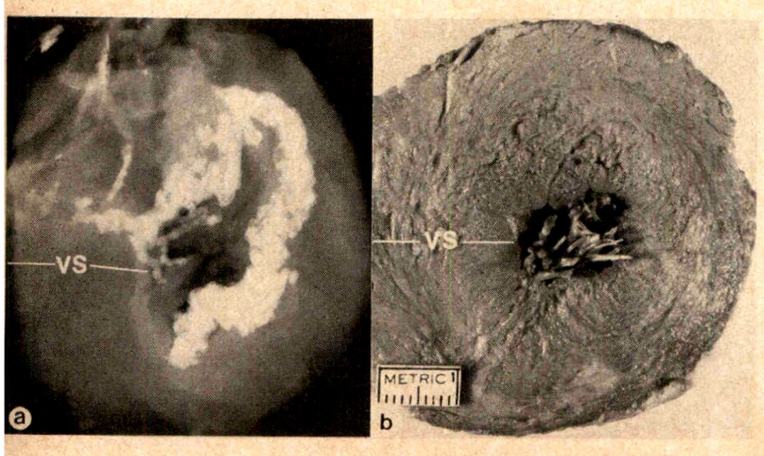

**FIGURE 13.** Patient 11 (GT #80-A-126). A 90-year-old woman with heavy mitral valve anular calcific deposits which reduced the mitral valve orifice to <1 cm in diameter (**a**). The unusual feature of the mitral calcium in this patient was that it not only was located behind the posterior mitral leaflet (mitral anular region) but it also extended across the anterior mitral leaflet nearly producing a letter *O*, as has been described previously.[7] She died from rupture of a descending thoracic aortic aneurysm. VS = ventricular septum. **b,** view of the left ventricle at the level of the tips of the mitral leaflets showing a very small cavity.

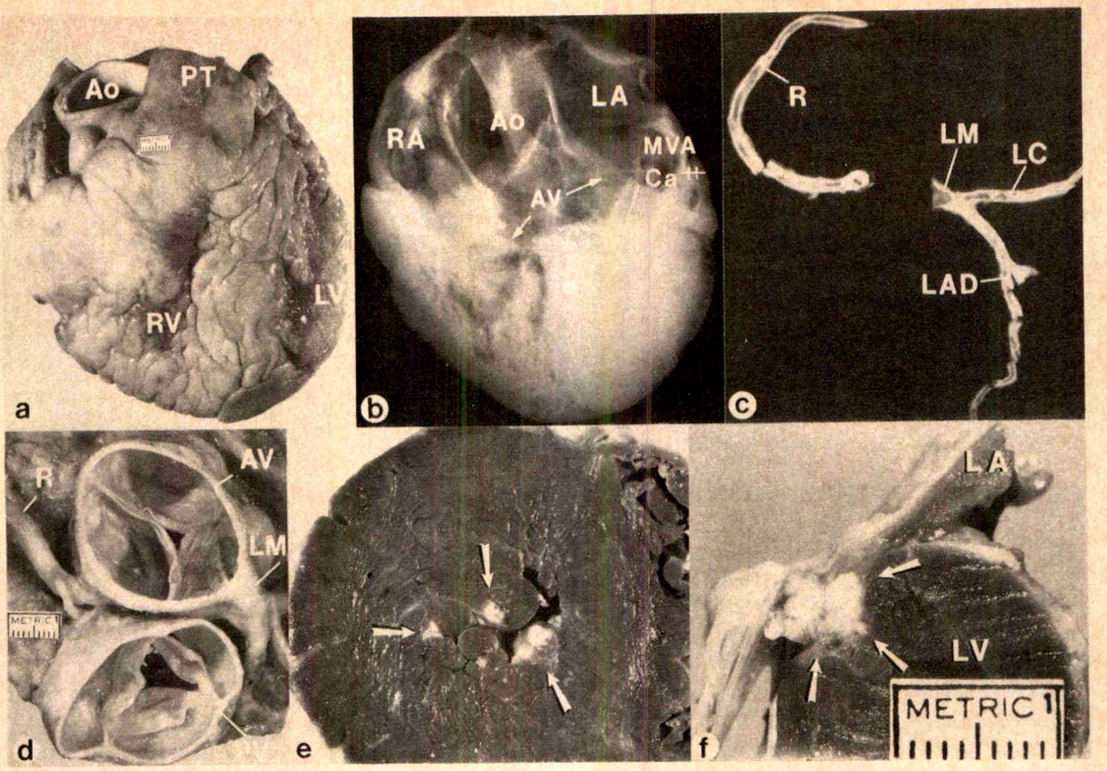

**FIGURE 14.** Patient 32 (SH #A81-62). A 97-year-old woman who never had clinical evidence of cardiac dysfunction and who died from cancer. **a,** external view of anterior surface of the heart showing an increased amount of subepicardial fat. Ao = aorta; LV = left ventricle; PT = pulmonary trunk; RV = right ventricle. **b,** postmortem radiogram showing calcific deposits in the mitral valve anulus (MVA) and aortic valve (AV). LA = left atrium; RA = right atrium. **c,** radiogram of the excised coronary arteries showing a few calcific deposits. LAD = left anterior descending; LC = left circumflex; LM = left main; R = right. **d,** view of aortic valve (AV) and pulmonic valve (PV) from above. **e,** view of left ventricle showing calcific deposits (**arrows**) in the papillary muscles. **f,** calcific deposits in mitral anular region.

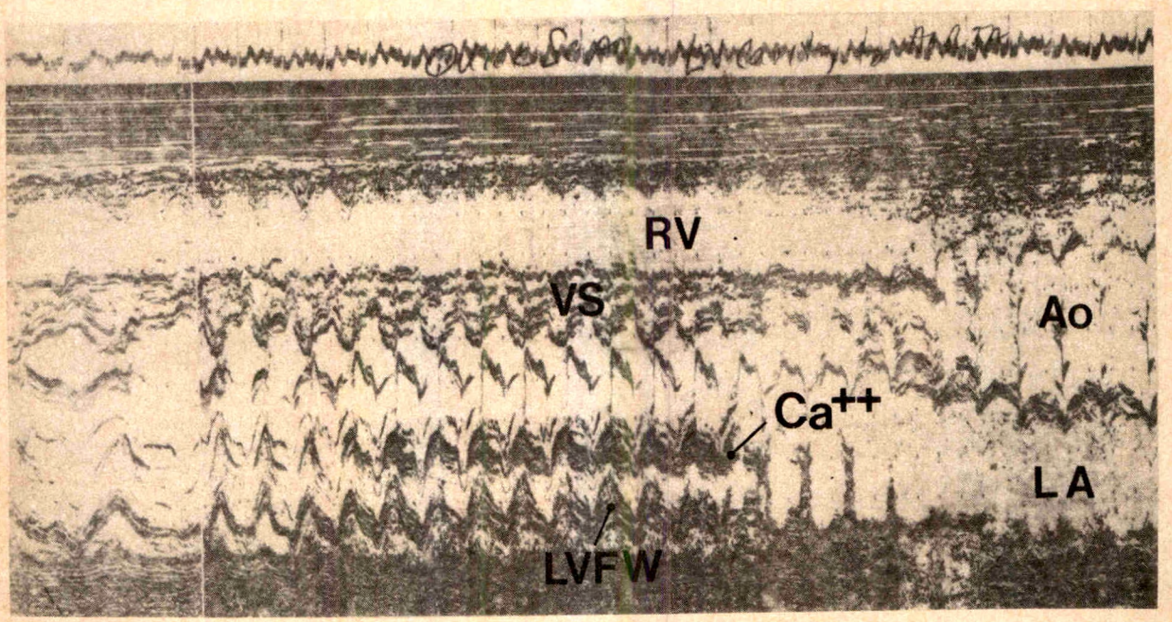

**FIGURE 15.** Patient 32 (SH #80-18). M-mode echocardiogram obtained 10 months before death from the patient whose heart is shown in Figure 14. The ascending aorta (Ao) has a larger diameter than does the left atrium (LA). The left ventricular (LV) cavity is small. Calcium is present in the mitral anular region. (We thank Dr. Robert Montgomery, Bethesda, Maryland, for allowing us to show this echocardiogram from his patient.)

(Case 37) had angina and a nonfatal acute myocardial infarct 2 years before death. (This patient died 24 hours after onset of increased dyspnea and vague chest pain but at necropsy no myocardial necrosis was visible histologically.) One patient (Case 2) had angina and a fatal acute myocardial infarct, and 9 patients had fatal acute myocardial infarcts which in each was the first one seen clinically. The clinical records regarding anginal attacks in the 3 patients are deficient in details: 2 patients (Cases 2 and 37) were stated to have had angina for "many years" and the third patient (Case 14) had angina for 29 years (since age 63). In none of the 3 patients was there information regarding the frequency of the anginal attacks and only 1 (Patient 37) was known to have taken nitroglycerin tablets.

Ten patients had deaths compatible with acute myocardial infarction. Of these 10 patients, however, only 3 (Cases 13, 16, and 23) had typical "crushing" substernal chest pain associated with typical electrocardiographic changes and enzyme elevations. The remaining 7 patients all were hospitalized because of some acute change in their status; however, acute myocardial infarction was never clearly established in these patients until necropsy. Only 5 of the 7 had chest pain, and it was atypical and not severe. Four had acute worsening of dyspnea. None had typical electrocardiographic features of acute myocardial infarction, but 5 had complete left bundle branch block at admission to the hospital. In 5 of these 7 patients in whom serum enzymes (creatine phosphokinase, lactic dehydrogenase, serum glutamic-oxaloacetic transaminase) were determined, the values were elevated in 4. Of the 14 patients with transmural left ventricular scars, only 1 had a clinical event diagnosed as acute myocardial infarction.

Chronic congestive heart failure was described in 8 patients (20%). In 4 patients (Cases 4, 21, 27, and 34) its cause, as determined initially by necropsy, was diffuse cardiac amyloidosis: in 1 patient (Case 17), its cause was aortic valve stenosis, which was diagnosed clinically; 1 patient (Case 14) had obliterative pericardial disease from the Beck procedure 25 years earlier[9]; 1 patient (Case 30) had cardiomegaly (660 g heart) of uncertain cause clinically (at necropsy the condition was considered idiopathic dilated cardiomyopathy); 1 patient (Case 22) also had congestive heart failure of uncertain cause clinically but at necropsy had a transmural left ventricular scar and severe narrowing of all 3 major epicardial coronary arteries. Of the 8 patients with chronic congestive heart failure, all had cardiomegaly at necropsy and 6 had histories of systemic hypertension during life.

*Systemic hypertension:* Information regarding "a history of hypertension" or an actual indirect systemic arterial blood pressure recording in the last year of life was available in 39 of the 40 patients: 19 (51%) had "a history" of systemic hypertension; of the 34 patients with actual blood pressure recordings, only 7 had systolic pressures >140 mm Hg or diastolic pressures >90 mm Hg. Of the 39 patients on whom information was available, 27 (69%) had either "a history of hypertension" or a recorded elevated blood pressure in the last year of life. Of the other 12 patients, only 1 (Case 23) had unequivocal cardiomegaly without explanation.

*Diabetes mellitus:* Five patients, all women, had diabetes mellitus. In 2, its duration was known: 20 years (Patient 5) and 40 years (Patient 20). One patient (Case 5) was treated with insulin; 1 (Case 9) with diet alone; 1 (Case 2) with diet plus tolbutamide; in 2 patients the type therapy received was unknown. Although 3 patients (Cases 2, 5, and 20) had transmural left ventricular scars, none had clinical events compatible with acute myocardial infarction.

*Precordial murmurs:* Of the 40 patients, 25 (62%) had had precordial murmurs. In all 25, the murmur was

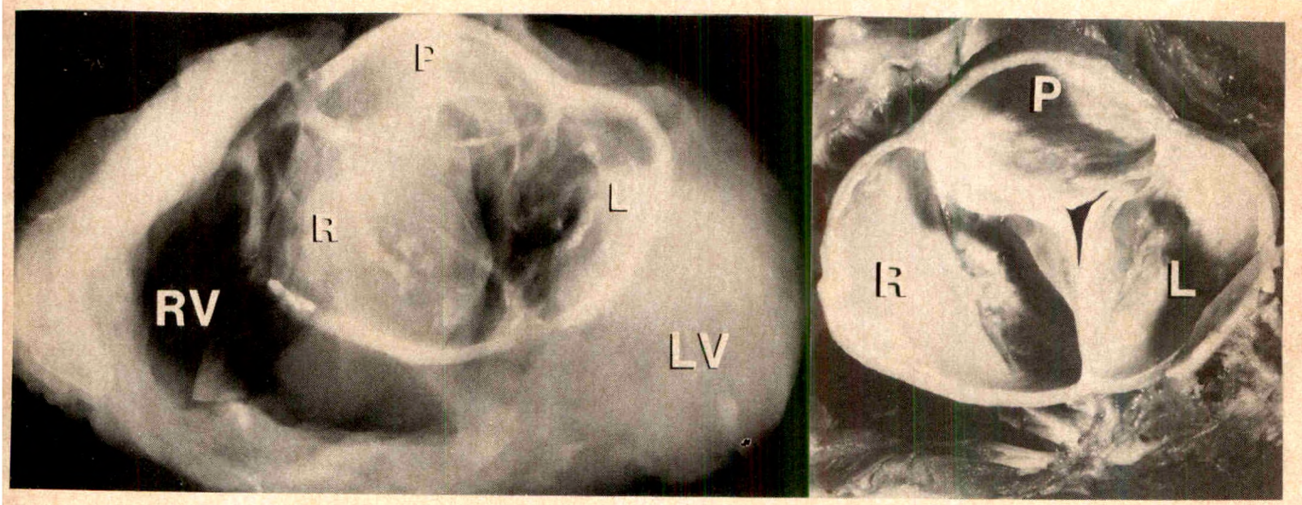

**FIGURE 16.** Patient 28 (SH #79-77). A 95-year-old man who never had symptoms of cardiac dysfunction and died from sarcoma. The coronary arteries are shown in Figure 2. **Left,** radiogram of heart at necropsy showing considerable enlargement of the aorta in comparison to the ventricles. LV = left ventricle; RV = right ventricle; R = right, L = left, and P = posterior sinuses of Valsalva. **Right,** aortic valve from above. The coronary arteries had been excised before the radiogram and photographs were taken.

described as systolic: apical only in 6; left sternal border only in 8; basal only in 2; all 3 locations in 3; and unspecified in 6. Only 1 (Case 9) of the 25 patients had both diastolic and systolic precordial murmurs. The diastolic murmur appeared to represent mild aortic regurgitation from systemic hypertension. The intensity of the murmur in the 24 patients with purely systolic murmurs was grade 1/6 in 2 patients, grade 2/6 in 5, grade 3/6 in 8, grade 4/6 in 4, and unspecified in 5. The cause of the precordial systolic murmurs was variable and often unclear. Of the 24 patients, 17 (71%) had calcific deposits in either the mitral valve anulus or aortic valve cusps or both: in mitral anulus only in none, in aortic valve only in 4, and in both mitral anulus and aortic valve in 13. In only 4 of the 17 patients, however, was the extent of calcium grade 3 to 4/6. In contrast, of the 15 patients without precordial murmurs recorded, 8 (53%) had calcific deposits in either mitral anulus or aortic valve cusps or both: in 3, the extent of the calcific deposits was either grade 3 or 4/6, but 4 of these 8 patients underwent precordial examination while in severe respiratory distress (3 patients) or in coma (1 patient). The blood hematocrit level ranged from 29 to 46% (mean 39) in the 18 patients with precordial murmurs and known hematocrit values, and from 30 to 57% (mean 38) in the 10 without precordial murmurs but known hematocrit values.

*Noncardiac vascular disease:* Five patients had strokes, which were fatal in 4 (Cases 12, 31, 33, and 38) and nonfatal in 1 (Case 30). Of the 3 patients with fusiform abdominal aortic aneurysms, only the 1 (Case 8) which ruptured was diagnosed during life. Neither the patient (Case 25) with a ruptured fusiform aneurysm of thoracic aorta nor the patient (Case 11) with rupture of the descending thoracic aorta into the esophagus had the condition diagnosed during life.[10] Five patients (Cases 1, 3, 9, 20, and 25) had leg claudication, requiring amputations in 2 (Cases 3 and 9) for gangrene. In the 2 patients with massive pulmonary embolism, this condition was suspected clinically.

*Electrocardiographic data* (Fig. 18 and 19) (Tables III and IV): Information on electrocardiograms recorded at age 90 years or later was available in 30 of the 40 patients. In 24 patients, the electrocardiograms were available for reexamination but in the other 6 patients, only the electrocardiographic reports were available. Of the 30 patients, 3 (Cases 1, 3, and 5) had electrocardiograms recorded during the acute illness (recordings 4, 9, and 7 days, respectively, before death). The illnesses, although not diagnosed clinically, were seen at necropsy

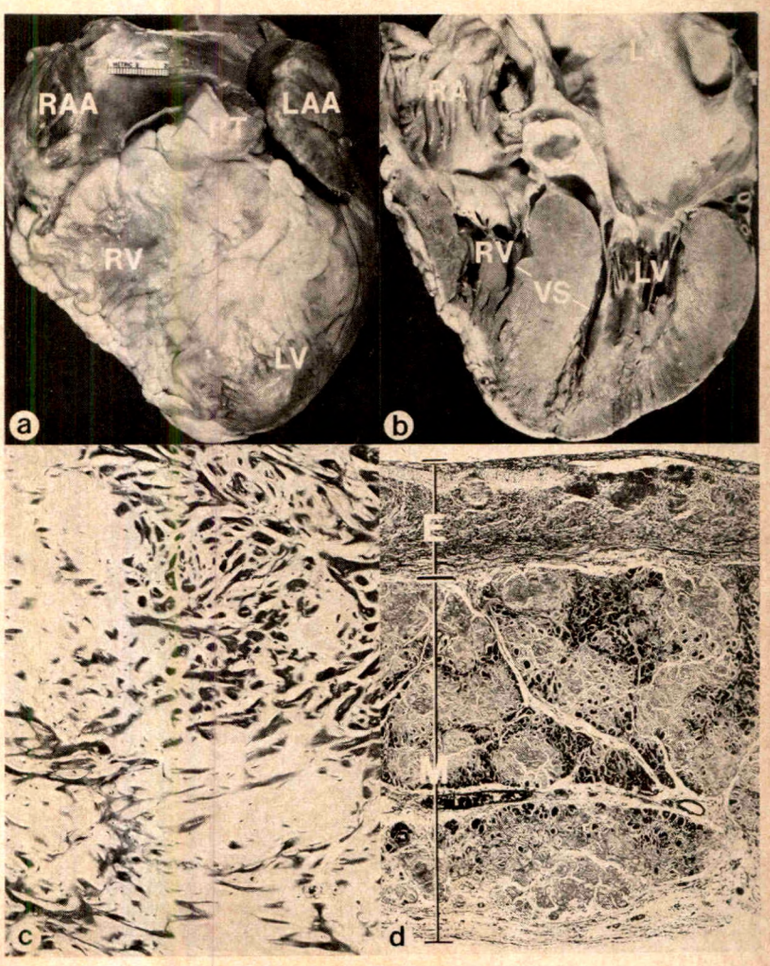

**FIGURE 17.** Patient 4 (DCGH #69A391), a 90-year-old man with chronic, eventually fatal congestive heart failure from clinically unrecognized cardiac amyloidosis. **a,** external view of the heart showing a prominent left ventricle (LV) and left atrial appendage (LAA). PT = pulmonary trunk; RAA = right atrial appendage; RV = right ventricle. **b,** right-to-left longitudinal cut of the heart (4-chamber, 2-dimensional echocardiographic view) showing thickened ventricular walls and dilated right (RA) and left (LA) atria. VS = ventricular septum. **c,** photomicrograph of a portion of the left ventricle showing extensive amyloid deposits. **d,** photomicrograph of LA wall showing amyloid deposits in endocardium (E) and in myocardium (M). (Hematoxylin-eosin stains; magnification ×100 (**c**) and ×25 (**d**), both reduced 35%.)

to clearly result from acute myocardial infarction. The electrocardiograms in all 3, however, disclosed only atrial fibrillation and complete left bundle branch block and these findings in all 3 patients were known to be present before the fatal acute myocardial infarction. The electrocardiograms in the other 27 patients were not recorded during periods of acute myocardial ischemia. Of the 30 patients on whom electrocardiographic information was available, 8 had clinical evidence of heart disease and 22 did not; the findings are summarized in Table III.

The QRS voltage in all 12 leads in each of 24 patients is summarized in Table IV (Fig. 19). The total 12-lead QRS voltage ranged from 82 to 251 mm (mean 151) (10 mm = 1 mV). In the 19 women, the total voltage ranged from 82 to 251 mm (mean 158), and in the 5 men, from 105 to 154 mm (mean 101) ($p < 0.05$). The total 12-lead QRS voltage did not correlate with either heart ($r = -0.01$) or body weight ($r = -0.2$). The 24 patients in whom the total 12-lead QRS voltage was measured were separated into 2 groups: 8 patients in whom clinical evidence of cardiac dysfunction was present (coronary heart disease in 5, massive cardiac amyloid in 2, aortic valve stenosis in 1) and 16 patients without such evidence. Comparison of the total QRS voltage in the 8 patients with and in the 16 patients without clinical evidence of heart disease disclosed no significant difference (mean 147 mm versus mean 152 mm). Breakdown on the 8 patients with cardiac dysfunction did show some differences: the total 12-lead QRS voltage in the 5 patients with angina pectoris or acute myocardial infarction (Patients 1, 3, 5, 14, and 37) ranged from 123 to 163 mm (mean 143); in the 2 patients with massive cardiac amyloidosis (Patients 21 and 27) it was 102 and 117 mm (mean 109); and in the 1 patient with aortic valve stenosis (Patient 17) it was 238 mm.

Of 29 patients on whom information was available, 18 (62%) received *digitalis* and only 2 appeared to have evidence of digitalis toxicity.

*Blood hematocrit levels* in the last month of life, known in 29 patients, ranged from 29 to 57% (mean 38).

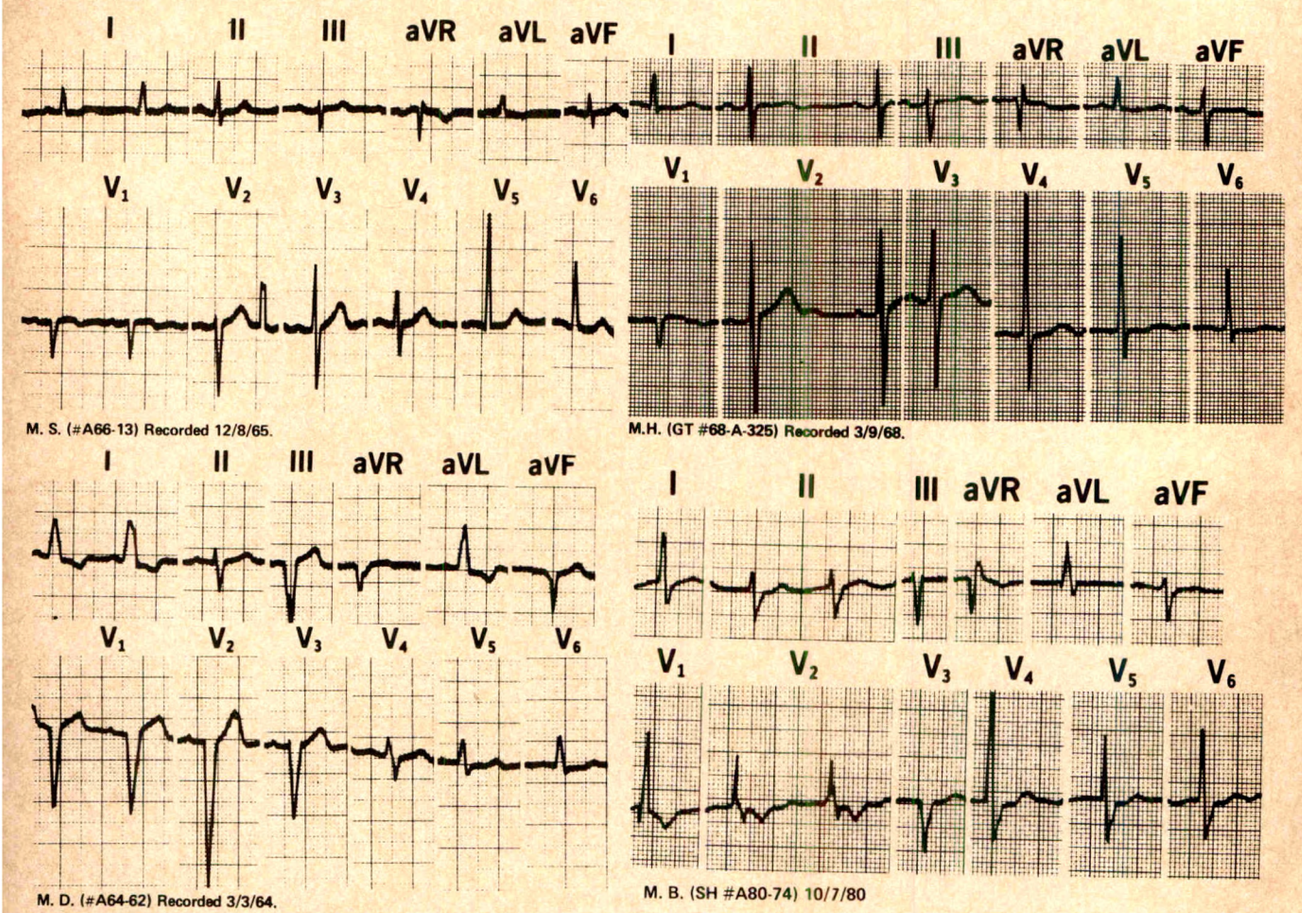

**FIGURE 18.** Electrocardiograms in 4 patients, each recorded at age 90 years or older. None ever had symptoms of cardiac dysfunction and each died from noncardiac conditions. **Top left,** Patient 7 (A66-13). The electrocardiogram was recorded 43 days before death and it is normal (heart weight 270 g). **Top right,** Patient 15 (GT #68A325). The electrocardiogram was recorded 11 days before death and it shows left QRS axis deviation and a slightly prolonged P-R interval (heart weight 400 g). **Bottom left,** Patient 36 (A64-62). This electrocardiogram was recorded 28 days before death and it shows left-axis deviation and complete left bundle branch block (heart weight 320 g). **Bottom right,** Patient 29 (SH #A80-74). This electrocardiogram was recorded 128 days before death and it shows atrial fibrillation, left-axis deviation, and complete right bundle branch block (heart weight 440 g).

*Total serum cholesterol levels* recorded at age 90 years or older, available in 10 patients, ranged from 108 to 283 mg/100 ml (mean 220).

*Total serum protein values*, available in 18 patients, ranged from 5.2 to 8.1 g/100 ml (mean 6.8). Serum albumin values, available in 19 patients, ranged from 2.0 to 4.5 g/100 ml (mean 3.3).

*Blood urea nitrogen values*, available in 27 patients, ranged from 7 to 70 g/100 ml (mean 33). Most values were obtained during the last month of life and some patients were clearly dehydrated at the time.

*Modes of death:* Of the 40 patients, 18 (45%) appeared to have died from consequences of cardiac disease, 7 (17%) from noncardiac but vascular problems, and 15 (38%) from noncardiac and nonvascular problems.

Of the 18 patients with cardiac causes of death, 10 had acute transmural myocardial infarcts, 1 (Case 14) had chronic congestive cardiac failure after healing of acute transmural myocardial infarcts, and 1 (Case 37) died in ventricular fibrillation after 24 hours of chest pain and at necropsy was shown to have severe coronary atherosclerosis without myocardial necrosis. Fatal congestive heart failure was due to aortic valve stenosis in 1 (Patient 17), to cardiac amyloidosis in 4 (Patients 4, 21, 27, and 34), and to idiopathic dilated cardiomyopathy in 1 (Patient 30). Of the 7 patients with noncardiac and nonvascular causes of death, 4 (Patients 12, 31, 33, and 38) died from complications of strokes, and the other 3, from rupture of aortic aneurysms (Patients 8, 11, and 25). Of the 15 patients with noncardiac and nonvascular causes of death, 7 (Cases 6, 7, 9, 28, 32, 35, and 36) died from various malignant neoplasms; 3 from nonneoplastic gastrointestional problems (bowel obstruction from adhesions in 1 [Patient 15], perforated gastric ulcer in 1 [Patient 29], and active duodenal ulcer in 1 [Patient 40]); 2 (Patients 24 and 39) from complications of bone fractures after falls; 2 (Patients 10 and 26) from massive pulmonary emboli superimposed on chronic obstructive pulmonary disease; and 1 (Patient 18) from uncertain cause. Of the 7 patients with fatal malignant neoplasms, 3 (Cases 6, 7 and 28) had 2 neoplasms and 4 (Cases 9, 32, 35, and 36) had 1 neoplasm.

## Discussion

As in any body organ or tissue, certain changes take place in the cardiovascular system as life progresses. Some of these changes allow easy identification of the very elderly heart when examining cardiac specimens as unknowns. The "normal" elderly heart has relatively small ventricular cavities and relatively large atria and great arteries (Fig. 20). The ascending aorta and left atrium, in comparison with the relatively small left ventricular cavity, appear particularly large. The cor-

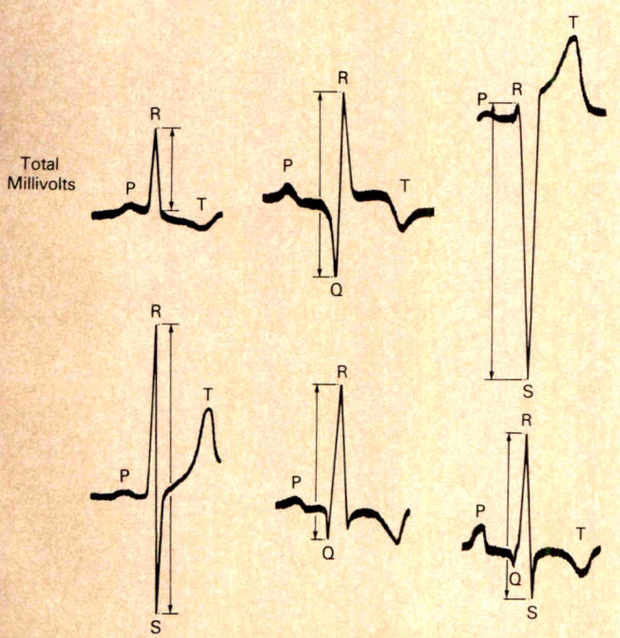

**FIGURE 19.** Various QRS complexes, and how each was measured. (Reproduced with permission from Siegel RJ, Roberts WC: Electrocardiographic observations in severe aortic valve stenosis: correlative necropsy study to clinical, hemodynamic, and ECG variables demonstrating relation of 12-lead QRS amplitude to peak systolic transaortic pressure gradient. Am Heart J 1982;103:210–221.)

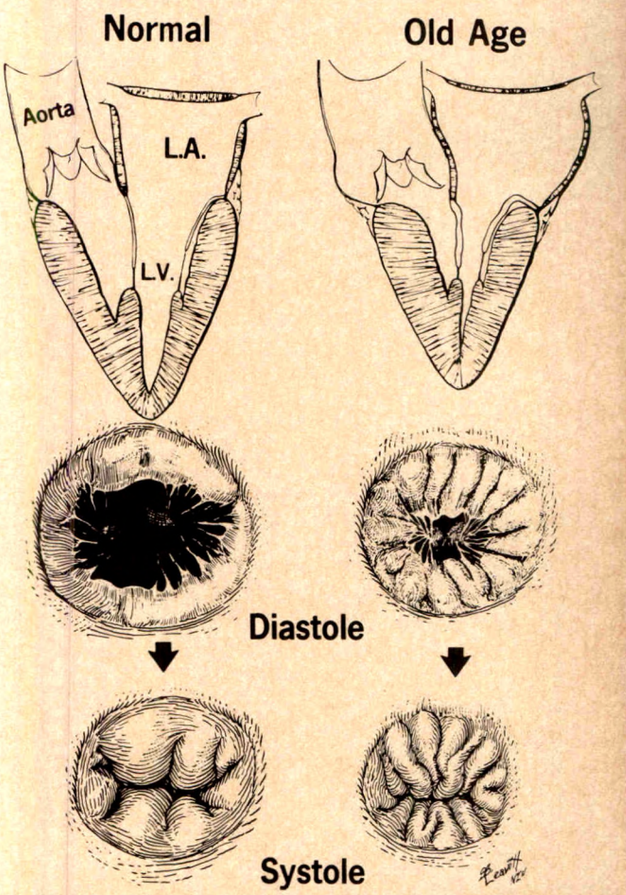

**FIGURE 20.** Diagram summarizing cardiac changes in the very elderly. The left atrial (LA) cavity enlarges and the left ventricular (LV) cavity becomes smaller. The amount of space available for the mitral leaflets decreases with aging, and consequently the number of scallops in the leaflets appears to increase.

onary arteries increase in both length and width and the former, particularly in association with the decreasing sizes of the cardiac ventricles, results in tortuosity. (The young river is straight and the old one, winding.) The subepicardial adipose tissue increases in amount with aging. The leaflets of each of the 4 cardiac valves thicken with age, particularly the atrioventricular valves, which have a smaller area to occupy in the ventricles because of the diminishing size of the latter. Histologic examination discloses large quantities of lipofuscin pigment in myocardial cells; some contain mucoid deposits ("mucoid degeneration"). These changes appear to affect all population groups of elderly individuals irrespective of where they reside on this earth and irrespective of their level of serum lipids. An elevated systemic arterial pressure appears to both accelerate and amplify these "normal" expected aging cardiac changes.

Both the aorta and its branches and the major pulmonary arteries and their branches enlarge with age. Because the enlargement is in both longitudinal and transverse dimensions, the aorta, like the coronary arteries, tends to become tortuous. This process also is amplified as the vertebral bodies become smaller and the height, somewhat shorter. The major pulmonary arteries appear to be too short and to have too low a pressure to dilate longitudinally.

Although several reports have described cardiovascular finding at necropsy in aged persons, old age was defined as >55,[11] >65,[12] or >75[13] years, and consequently findings in those aged 90 years and over could not be separated from those occurring in the "younger" older persons. The present study appears to be the first to focus entirely on a group of necropsy patients aged 90 years or older. A major finding in our study is the high frequency of calcific deposits in the heart. Of the 40 patients, 37 (92%) had calcific deposits in the epicardial coronary arteries. In most, the deposits were extensive. Although the calcific deposits were located entirely in atherosclerotic plaques, which are located in the intima, the presence of calcific deposits in the coronary arteries in this very elderly population did not necessarily indicate the presence of significant (>75% XSA) luminal narrowing. In contrast, the presence of calcific deposits in epicardial coronary arteries in persons aged <65 years generally indicates the presence of significant luminal narrowing.[14] The calcific deposits tended to occur in each of the 4 major (right, left main, left anterior descending, and left circumflex) epicardial arteries and were always larger in the proximal than in the distal halves of the right, left anterior descending, and left circumflex arteries or, if small, limited to their proximal halves.

Calcific deposits occurred with near equal frequency (55% and 47%) in the aortic valve cusps and in the mitral anular region. The deposits in the aortic valve were located on the aortic aspects of 1 or more of the 3 cusps and usually were unassociated with commissural fusion. The presence or absence of aortic valve stenosis was determined by the quantity of calcium deposited. In 2 patients, the extent of the calcific deposits imparted an immobility to the cusps resulting in aortic valve stenosis. The mitral "anular" calcific deposits, of course, were not limited to the anulus but included the space between the ventricular aspect of the posterior mitral leaflet and the mural endocardium of left ventricular free wall behind posterior mitral leaflet. Often this "anular" calcium extended into the adjacent left ventricular myocardium. Most patients with aortic valve calcium had mitral "anular" calcium and vice versa and all with aortic valvular or mitral "anular" calcium had coronary arterial calcific deposits.

The presence of calcium in the 3 locations in the heart, namely the coronary artery, the aortic valve, and

Pt = patient; Wt = weight.

the mitral "anulus," might be termed *the senile cardiac calcification syndrome* and strongly suggests that the etiology of the calcific deposits in each of the 3 locations is similar. It is well appreciated, as already mentioned, that the calcific deposits in the coronary arteries are located in atherosclerotic plaques and, therefore, that the calcific deposits in both aortic valve and mitral anular regions might be viewed as anatomic expressions of the atherosclerotic process. All 3 appear to occur only in populations where the total serum cholesterol level is >150 mg/700 ml. Of our 40 patients, total serum cholesterol levels were available in 10: in only 1 (Patient 30) was the level <150, and in 2 the level was 150 to 200 mg/100 ml. In Patient 30, whose value was 108 mg/100 ml, no calcific deposits were present in any of the 3 sites; in Patient 36 whose level was 165 mg/100 ml, minimal calcific deposits were present only in the coronary arteries; and in Patient 28, whose level was 181 mg/100 ml, small calcific deposits were present in the aortic valve (Fig. 16) and coronary arteries. In contrast, of the 7 patients in whom the total serum cholesterol level was >200 mg/100 ml, calcific deposits were present in either aortic valve or mitral anulus or both in 5 patients and in the coronary arteries in all 7 patients; in each the deposits were larger. Calcific deposits in the coronary artery, aortic valve cusp, and mitral anulus are extremely rare in populations where total serum cholesterol levels are <150 mg/100 ml and, of course, clinical evidence of coronary heart disease in these population groups is extremely rare[15] despite a high prevalence of systemic hypertension.

Of the 40 patients, 28 had narrowing of >75% in XSA of ≥1 of the 4 major epicardial coronary arteries. Of the 28 patients, 17 had transmural foci of left ventricular fibrosis or necrosis (myocardial infarction) and of the 12 with insignificant coronary narrowing, none had grossly visible acute or healed myocardial infarcts. Of the 14 patients with healed myocardial infarcts, only 1 had a clinical event compatible with acute myocardial infarction which healed. Of the 10 patients with acute myocardial infarcts at necropsy, only 3 had typical clinical features of acute myocardial infarction; the other 7 had acute changes in their clinical course and acute myocardial infarction was either suspected or compatible with the acute illness. Angina pectoris was described in 3 patients, 1 of whom was among the 10 with fatal acute myocardial infarcts, and 1 of whom had had a nonfatal acute infarct. Thus, 12 patients had clinical features compatible with coronary heart disease and each was among the 28 with significant narrowing of ≥1 of the major coronary arteries. Conversely, of the 28 patients with significant coronary narrowing at necropsy, 16 (57%) never had either angina pectoris or acute myocardial infarction. Of the total 40 patients, only 12 (30%) had clinical events compatible with coronary heart disease and only in 6 were the clinical events really typical.

In 36 of the 40 patients, each of the 4 major coronary arteries were divided into 5 mm long segments and the degree of XSA narrowing by atherosclerotic plaque was determined for each segment. Of the 1,789 5 mm segments in the 36 patients, the average amount of XSA narrowing by atherosclerotic plaques/segment was 42% (range 19 to 69). Of the 467 5 mm segments in the 10 patients with clinical evidence of coronary heart disease, the average amount of XSA narrowing/segment was 55% (range 43 to 69), and 1,322 segments in the 26 patients without clinical evidence of coronary heart disease, 38% (range 19 to 40) ($p < 0.01$). Among 129 patients aged 22 to 85 years (mean 56), the amount of XSA narrowing by atherosclerotic plaques/segment averaged 67%; in the control subjects, that is, those without symptomatic coronary heart disease, XSA narrowing averaged 32%. The mean percent of 5 mm coronary segments narrowed 76 to 100% in XSA in the 36 patients was 13% (range 2 to 89); of the 10 patients with symptomatic coronary heart disease, the mean was 19% (range 10 to 34); and of the 26 patients without symptomatic coronary heart disease, the mean was 7% (range 2 to 28) ($p < 0.05$). The mean of 19% in patients with symptomatic coronary heart disease aged ≥90 was half that observed in patients aged ≤85 years (mean 56) with fatal coronary heart disease and the mean of 8% was nearly 3 times that observed in the younger patients without fatal coronary heart disease.[16–21]

These detailed morphologic studies of the coronary arteries in these very elderly persons suggest that the degree of severe coronary narrowing necessary to have a fatal or near-fatal coronary event is considerably less than that necessary to have a coronary event in younger patients. Moreover, these studies indicate that these very elderly patients without symptoms of coronary heart disease have distinctly more coronary luminal narrowing by atherosclerotic plaques that do control subjects who are younger, (mean age 52 years).[16–21] The latter observation suggests that coronary heart disease may be underdiagnosed clinically in the very elderly.

Clinical diagnosis of cardiac and other conditions in patients aged 90 years and over appears more difficult than in younger persons. Historic information may be difficult to obtain because of impaired intellect on the part of the patient and an impaired diagnostic pursuit on the part of the physician. Physicians caring for these very elderly persons may focus primarily on the prevention of suffering and only secondarily on accurate diagnosis or longer-term therapy. Patients aged 90 years and over generally have outlived their spouses and private physicians, and often are "inherited" by nursing-home physicians who may have limited access to earlier medical records.

Angina pectoris appears particularly difficult to diagnose in the very elderly because they may not be able to describe this symptom. Acute myocardial infarction also is difficult to diagnose clinically but it is often fatal in the very elderly. Of 11 clinical acute infarcts at or after age 90 years in our patients, 10 were fatal. Only 4 of the 11 acute infarcts were clearly diagnosed clinically; most others were manifest as more dyspnea. Furthermore, the electrocardiogram is not as useful in diagnosis of acute myocardial infarction in the very elderly because left bundle branch block is frequent and it, of course, prevents the appearance of typical changes. Serial recordings of electrocardiograms also appear to be quite infrequent in the very elderly. Only

2 of our 10 patients with fatal acute myocardial infarction had as many as 2 electrocardiograms recorded during the final illness.

Physical examination in the very elderly may be both difficult and misleading. The lack of mobility may prevent proper positioning of the elderly patient for proper examining. Precordial murmurs, although very common (25 of our 40 patients), infrequently indicate significant functional abnormality. Although 22 of our 40 patients had calcific deposits in the aortic valve, only 2 appeared to have actual aortic valve stenosis. Likewise, although 19 of the 40 patients had mitral anular calcific deposits, in only 1 patient did the calcific deposits appear to actually narrow the mitral orifice.

Electrocardiographic abnormalities are common in elderly persons. Of our 30 patients with electrocardiograms available, all had ≥1 abnormalities recorded, the most frequent ones being abnormal axis, atrial fibrillation, and complete bundle branch block. Although 15 of the 30 patients had cardiomegaly (>350 g in women, >400 g in men) at necropsy, only 1 had voltage criteria for left ventricular hypertrophy shown by electrocardiography. Likewise, only 1 had low voltage. Measurement of the QRS amplitude in each of the 12 leads was performed in 24 patients; these measurements have never been recorded previously in elderly individuals. The total QRS voltage was similar in the 8 patients with and in the 16 patients without clinical evidence of cardiac disease (mean 147 mm versus mean 152 mm [10 mm = 1 mV]). Although normal amplitudes of the QRS complexes in all 12 leads in elderly patients are lacking, Simonson[22] provided data on the upper and lower limits of amplitude of the QRS complexes in each of the 12 leads in normal men and women aged 20 to 59 years (means not available). The upper and lower limits of normal for men aged 50 to 59 years was 277 and 36 mm, and for the women 248 and 27 mm, respectively.

# Hemodynamic Effects of a New Antiarrhythmic Agent, Flecainide (R-818), in Coronary Heart Disease

VICTOR LEGRAND, MD, MICHEL VANDORMAEL, MD, PIERRE COLLIGNON, MD, and HENRI E. KULBERTUS, MD

**The hemodynamic effects of flecainide acetate, a new class I antiarrhythmic agent, were studied in 10 patients with coronary heart disease. The drug was injected intravenously at a dose of 2 mg/kg over 30 minutes. The mean drug plasma level achieved was 394 ng/ml (range 329 to 470). The heart rate did not change, but a significant increase ($p < 0.001$) in P-R (+17%), QRS (+15%), and Q-T (+7%) duration occurred after drug administration. Negative inotropic effects also were observed and consisted of an increase ($p < 0.01$) in pulmonary wedge pressure (+27%) and a decrease ($p < 0.01$) in stroke index (−10%), left ventricular stroke work index (−12%), and left ventricular ejection rate (−11%). No significant change in mean aortic pressure or systemic and pulmonary vascular resistance occurred. Left ventriculography performed after drug infusion revealed a significant increase ($p < 0.01$) in systolic volume (+9%) and a decrease in ejection fraction (−9%) and mean velocity of circumferential fiber shortening (Vcf) (−13%). A progressive and significant decrease of dP/dt was observed during drug infusion, but 15 minutes after the injection, dP/dt had returned to near basal values. Thus, flecainide acetate has slight, but significant negative inotropic effects, particularly conspicuous during drug infusion. The drug should be administered with caution in patients with poorly compensated heart.**

Flecainide acetate is a novel antiarrhythmic drug that has many properties of class I antiarrhythmic agents. It possesses local anesthetic properties and in preliminary clinical trials has markedly or completely suppressed ventricular arrhythmias.[1-8] Despite very promising results, better knowledge of the hemodynamic effects of flecainide is needed before its wide acceptance for clinical use. Previous studies in animals[9,10] showed a slight negative inotropic effect, whereas noninvasive studies in man yielded controversial results.[4,11]

It is particularly important to know whether flecainide has deleterious negative inotropic effects in patients with serious cardiac disorders, especially coronary heart disease. This study was undertaken to examine the hemodynamic effects of flecainide in patients with ischemic heart disease who are theoretically at special risk when this agent is administered intravenously.

From the University of Liège, School of Medicine, Section of Cardiology-Electrocardiology, 66 Boulevard de la Constitution, 4020 Liège, Belgium. Manuscript received May 18, 1982; revised manuscript received and accepted August 20, 1982.

Address for reprints: Henri E. Kulbertus, MD, Department of Medicine, Section of Cardiology, Hôpital de Bavière, 66 Boulevard de la Constitution, B 4020 Liège, Belgium.

## Methods

**Patients:** Ten patients with recent acute myocardial infarction submitted to angiographic and hemodynamic evaluation constituted the study group (Table I). All required antiarrhythmic therapy because of ventricular premature beats or tachycardia. The nature of the procedure was explained to the patient and informed consent was obtained.

**Procedures:** The studies were performed in the afternoon. Four patients (Patients 2, 3, 6, and 10) were currently treated by beta blocking drugs; none received calcium antagonists. All previous therapy was withdrawn for at least 12 hours.

With the patient in the supine position, a Swan-Ganz and a pigtail catheter were introduced using the Seldinger technique and a femoral approach. Pressure was recorded from the left ventricle, aorta, right ventricle, right atrium, pulmonary artery, and pulmonary wedge by means of a Statham P23 db strain gauge on a Philips photographic recorder. The common zero reference level for all pressures was set at the mid-chest. The mean pressure values and determination of dP/dt maximum were determined electronically by an automatic catheterization system (Philips Physio Cardiopan System PC 5000). Cardiac output was determined in triplicate with thermodilution techniques using an Edwards model 9620 thermodilution cardiac output computer.

The systemic (SVR) and pulmonary (PVR) vascular resistance and total pulmonary resistance (TPR) in dynes s $cm^{-5}$ were obtained using the following formulas: SVR =

**TABLE I Patients' Characteristics**

| Case | Age (yr) & Sex | Electrocardiographic Site of Infarction | Peak CK (U/liter) | Delay From MI to Investigation (days) | Diseased Vessels (n) | Total R-818 Injected Intravenously (mg) |
|---|---|---|---|---|---|---|
| 1 | 58M | Inferior | 873 | 21 | 2 | 150 |
| 2 | 62M | Inferior | 1,063 | 43 | 1 | 165 |

| 5 | 50M | Inferior | 970 | 26 | 2 | 160 |
| 6 | 58M | Inferolateral | 2,850 | 35 | 1 | 140 |
| 7 | 43M | Inferior | 296 | 17 | 1 | 140 |
| 8 | 55M | Inferoposterior | 1,380 | 20 | 3 | 150 |
| 9 | 40M | Inferior | 1,143 | 20 | 2 | 165 |
| 10 | 36M | Inferior | 1,503 | 20 | 1 | 180 |

CK = creatine kinase; MI = myocardial infarction.

(MBP − MRA)·1.332/CO, PVR = (MPAP − PCWP)·1.332/CO; TPR = MPAP·1.322/CO, where MBP = mean aortic blood pressure (mm Hg), MRA = mean right atrial pressure (mm Hg), MPAP = mean pulmonary artery pressure (mm Hg), PCWP = pulmonary capillary wedge pressure (mm Hg), and CO = cardiac output (ml/min).

Left ventricular stroke work index (LVSWI) in g·m/m$^2$ and mean systolic ejection rate (MSER) in ml/s·m$^2$ were calculated from the following formulas: LVSWI = SVI [MBP − LVEDP] ×13.6/100 and MSER = SVI/SEP, where SVI = stroke volume index (ml/m$^2$), MBP = mean aortic blood pressure (mm Hg), LVEDP = left ventricular end-diastolic pressure (mm Hg), and SEP = systolic ejection period (s/beat).

Left ventricular volumes were determined using the Simpson's rule by an automated program. End-diastolic volume (EDV), end-systolic volume (ESV), stroke volume (SV = EDV − ESV), and ejection fraction (SV/EDV) were calculated for each patient. The mean velocity of circumferential fiber shortening (Vcf) was obtained as follows: Vcf = (dED − dES)/(dED·ejection time). In this equation, dED and dES are the left minor axes in end-diastole and end-systole obtained after determination of end-diastolic and end-systolic areas planimetered in the right anterior oblique view (D area and S area) and the corresponding left major axes (lED and lES): dED = 4 D area/$\pi$lED, and dES = 4 S area/$\pi$lES. A quantitative analysis of segmental wall motion was applied for each ventriculogram according to the technique described by Ingels et al.[12] A point located at 69% of the distance from the anterolateral edge of the aortic valve to the ventricular apex at end-systole served as a fixed reference. Using polar coordinates, regional shortening for all points along the ventricular outline was calculated and displayed by an automated system, which gives an objective and quantitative evaluation of regional contractility.

**Study protocol:** The hemodynamic variables were first measured in basal conditions. Thereafter, a left ventriculogram was obtained in a 30° right anterior oblique view followed by coronary arteriography. Ten minutes were allowed to elapse before the infusion of flecainide was started. Flecainide, 2 mg/kg, was then injected intravenously at a constant rate over 30 minutes. Fifteen minutes after the end of the infusion, hemodynamic measurements were repeated and a second ventriculogram was performed. In the last 6 patients, dP/dt was also recorded using a Millar micromanometer throughout the infusion of the drug and 15 minutes later. At least 55 minutes separated the first and second angiogram: the pharmacologic effects of contrast medium on myocardial contractility were thus most probably eliminated.[13–15]

Blood samples for determination of plasma flecainide concentration were obtained during the second hemodynamic measurements, 15 minutes after the end of the infusion. The plasma concentration of flecainide was measured by gas-liquid chromatography.[4] Averaged data are presented as mean ± standard deviation. Student's $t$ test for paired observations was used. Statistics are based on the raw data.

## Results

**Heart rate and electrocardiogram (Fig. 1):** No significant change in heart rate was observed after administration of the drug. Significant increases in P-R (+16.6%), QRS (+15.2%), and Q-T (+6.6%) ($p < 0.001$) were noted.

**Pressure and cardiac index (Fig. 2):** The mean pulmonary capillary wedge pressure (PCWP) increased in all but 1 patient ($p < 0.01$) and the stroke index decreased ($p < 0.01$) in all except 1 (in whom PCWP in-

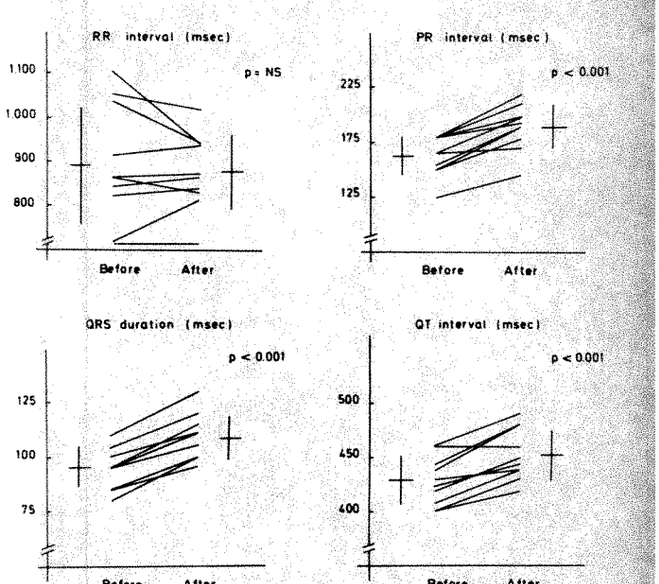

**FIGURE 1.** Diagrams showing the individual variations in R-R, P-R, QRS, and Q-T intervals. Changes induced by flecainide infusion (before = before infusion; after = after infusion). The p value indicated is the level of significance of $t$ test for paired data. NS = not significant.

**TABLE II Plasma Flecainide Concentrations and Relative Changes in Main Electrocardiographic Hemodynamic and Angiographic Variables**

| Patient | Plasma Level (ng/ml) | Change in P-R Duration (%) | Change in QRS Duration (%) | Change in PCWP (%) | Change in SI (%) | Change in LVSWI (%) | Change in LVER (%) | Change in EF (%) | Change in Mean Vcf (%) |
|---|---|---|---|---|---|---|---|---|---|
| 1 | 470 | +9 | +14 | +25 | −10 | −7 | −7 | −11 | −10 |
| 2 | 388 | +22 | +10 | +7 | −13 | −9 | −14 | −3 | −5 |
| 3 | 425 | +27 | +16 | +50 | −15 | −12 | −20 | −10 | −27 |
| 4 | 390 | +16 | +12 | +37 | −12 | −18 | −12 | −16 | −17 |
| 5 | 361 | +20 | +18 | 0 | −12 | −19 | −11 | −9 | −9 |
| 6 | 413 | +21 | +25 | +57 | −14 | −1 | −9 | −5 | −22 |
| 7 | 329 | +22 | +26 | +50 | +4 | −14 | +1 | +4 | −9 |
| 8 | 397 | +11 | +18 | +56 | −6 | −16 | −7 | −7 | 0 |
| 9 | 394 | +8 | +10 | −7 | −13 | −24 | −12 | −23 | −16 |
| 10 | 373 | +17 | +11 | +25 | −2 | 0 | −8 | −8 | −18 |
| Mean | 394 ± 38 | +17 | +15 | +27 | −10 | −12 | −11 | −9 | −13 |

All changes express the variation in percentage after flecainide infusion compared with the basal value. EF = ejection fraction; LVER = left ventricular ejection rate; LVSWI = left ventricular stroke work index; mean Vcf = mean velocity of circumferential fiber shortening; PCWP = pulmonary capillary wedge pressure; SI = systolic index.

creased from 12 to 18 mm Hg). No significant change in mean aortic pressure was noted. A significant increase in mean pulmonary pressure ($p < 0.001$) was also observed, whereas mean right atrial pressure did not change.

**Vascular resistance and cardiac performance index (Fig. 3):** Slight but insignificant increases in systemic and pulmonary vascular resistance were noted. The left ventricular stroke work index was reduced in 9 patients ($p < 0.01$). The left ventricular ejection rate also decreased in all but 1 patient ($p < 0.001$). The dP/dt was measured during flecainide infusion in 6 patients. Although significant changes were not demonstrated by an analysis of variance, individual variations in dP/dt showed a progressive decrease which became significant 15 minutes after the beginning of infusion as compared with basal value (paired $t$ test). Fifteen minutes after the end of the injection, dP/dt had returned to near basal values (Fig. 4).

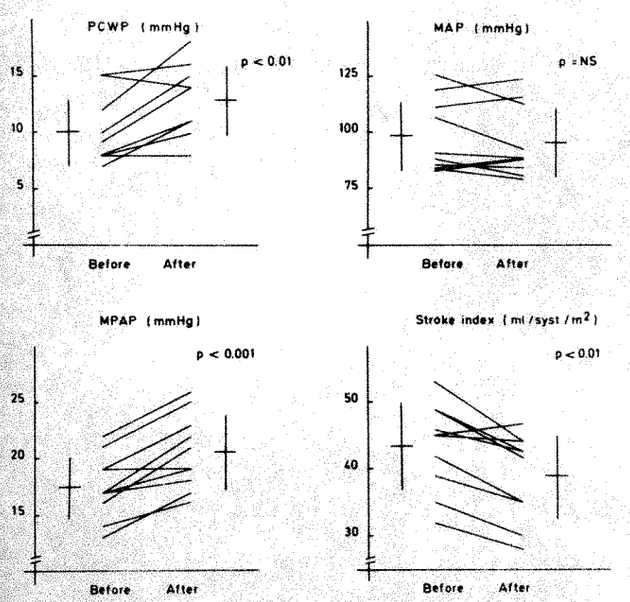

**FIGURE 2.** Diagrams showing the individual variations in pulmonary capillary wedge pressure (PCWP), mean aortic pressure (MAP), mean pulmonary arterial pressure (MPAP), and stroke index induced by flecainide infusion (before = before infusion; after = after infusion). The p value indicated is the level of significance of Student's $t$ test for paired data. NS = not significant.

**Ventricular volumes (Fig. 5):** No significant changes were noted to diastolic volume after flecainide injection. However, systolic volume increased in all patients ($p < 0.01$), causing a significant decrease in stroke volume ($p < 0.01$) and ejection fraction. Mean velocity of circumferential shortening also decreased significantly ($p < 0.001$).

**Regional wall motion:** All patients had regional disorders of left ventricular contractility. In each, the area of asynergy was supplied by a critically narrowed coronary artery and corresponded to the electrocardiographic site of infarction. After flecainide injection, segmental wall motion analysis indicated a slight diffuse decrease in wall movement with no new areas of asynergy.

**Plasma drug concentrations:** Plasma drug levels obtained 15 minutes after the infusion of 2 mg/kg of flecainide over 30 minutes varied from 329 to 470 ng/ml. Within this drug level range, there was no relation between drug concentration and changes in individual electrocardiographic, hemodynamic, and angiographic variables (Table II).

**Side effects:** Apart from the cardiac effects just described, there were no complications or patient's complaints during or after the study.

## Discussion

**Intrinsic myocardial depressant effect:** Intravenous flecainide in doses recommended for the treatment of arrhythmia (2 mg/kg) exerts mild but significant adverse hemodynamic effects in man. In our patients without overt left heart failure, stroke index and index of cardiac contractility (LVSWI and LVER) decreased 10% ($p < 0.01$). The ejection fraction, which is considered one of the most sensitive indexes of global ventricular performance, decreased 9% ($p < 0.01$). No significant

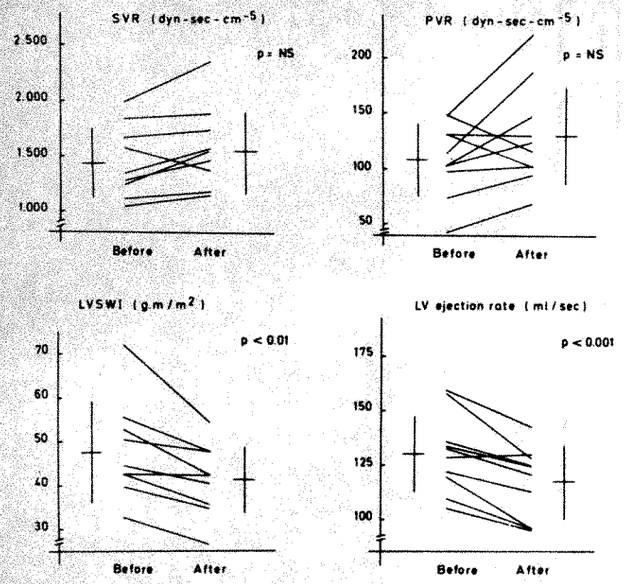

**FIGURE 3.** Diagrams showing the individual variations of systemic vascular resistance (SVR), pulmonary vascular resistance (PVR), left ventricular stroke work index (LVSWI), and left ventricular (LV) ejection rate induced by flecainide infusion (before = before infusion; after = after infusion). The p value indicated is the level of significance of Student's *t* test for paired data. NS = not significant.

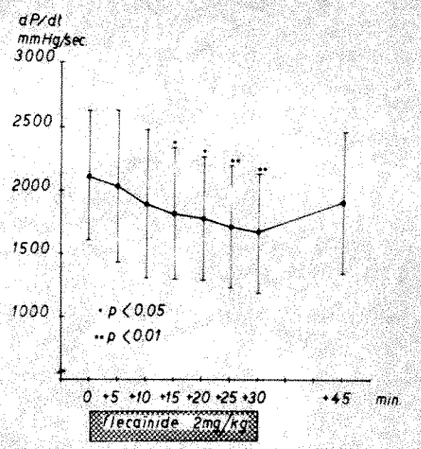

**FIGURE 4.** Mean variations in dP/dt observed during flecainide infusion and 15 minutes after the end of injection. The p value indicated is the level of significance of Student's *t* test for paired data; comparison is made with the basal values before flecainide infusion.

changes in systemic and pulmonary vascular resistance were noted, which suggests the absence of vascular effects. Pulmonary wedge pressure, mean pulmonary arterial pressure, and total pulmonary resistance significantly increased as a consequence of depressed left ventricular function. Thus, flecainide, exerted a direct negative inotropic effect on myocardial fiber but failed to exhibit any significant peripheral vasoconstrictive action.

Although similar hemodynamic side effects were reported with all class I antiarrhythmic drugs,[16] comparative studies are required to evaluate the importance of myocardial depression induced by flecainide as compared with that induced by other class I antiarrhythmic drugs. Previous hemodynamic studies showed that the negative inotropic effect produced by tocainide or encainide is comparable to that observed in our study with flecainide.[17,18]

**Dose-related myocardial depression:** The plasma concentration of flecainide in our patients ranged from 329 to 470 ng/ml, a value similar to that achieved by others after 1 to 2 mg/kg administered intravenously or orally and recognized to have antiarrhythmic effects.[2,4,19]

Interpatient comparison did not reveal any relation between plasma level and cardiac effects of the drug; however, the range of drug concentration was rather small. This observation suggests that within the therapeutic range achieved, the cardiac response to flecainide is individual and cannot be predicted from the plasma drug level.

Experimental studies in pigs have shown a dose-related negative inotropic effect during infusion of the drug.[10] The individual response of dP/dt during drug infusion in 6 of our patients confirmed those observations. As the drug was infused, the contractility index dP/dt exhibited a progressive decrease; however, improvement in myocardial contractility appeared after the end of infusion and dP/dt returned to near basal values within 15 minutes. Plasma levels were not studied throughout drug infusion; however, one may hypothesize that intravenous administration of flecainide results in high plasma levels of the drug which rapidly

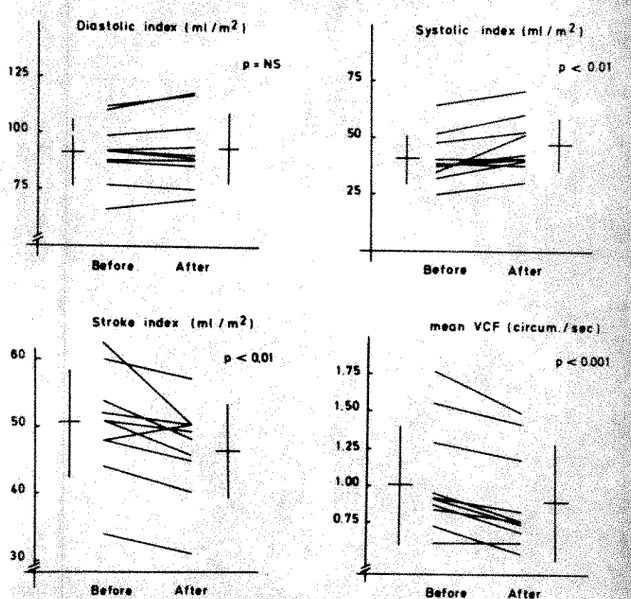

**FIGURE 5.** Diagrams showing the individual variation in diastolic volume index, systolic volume index, stroke volume index, and mean velocity of circumferential fiber shortening (VCF) induced by flecainide infusion (before = before infusion; after = after infusion). The p value indicated is the level of significance of Student's *t* test for paired data.

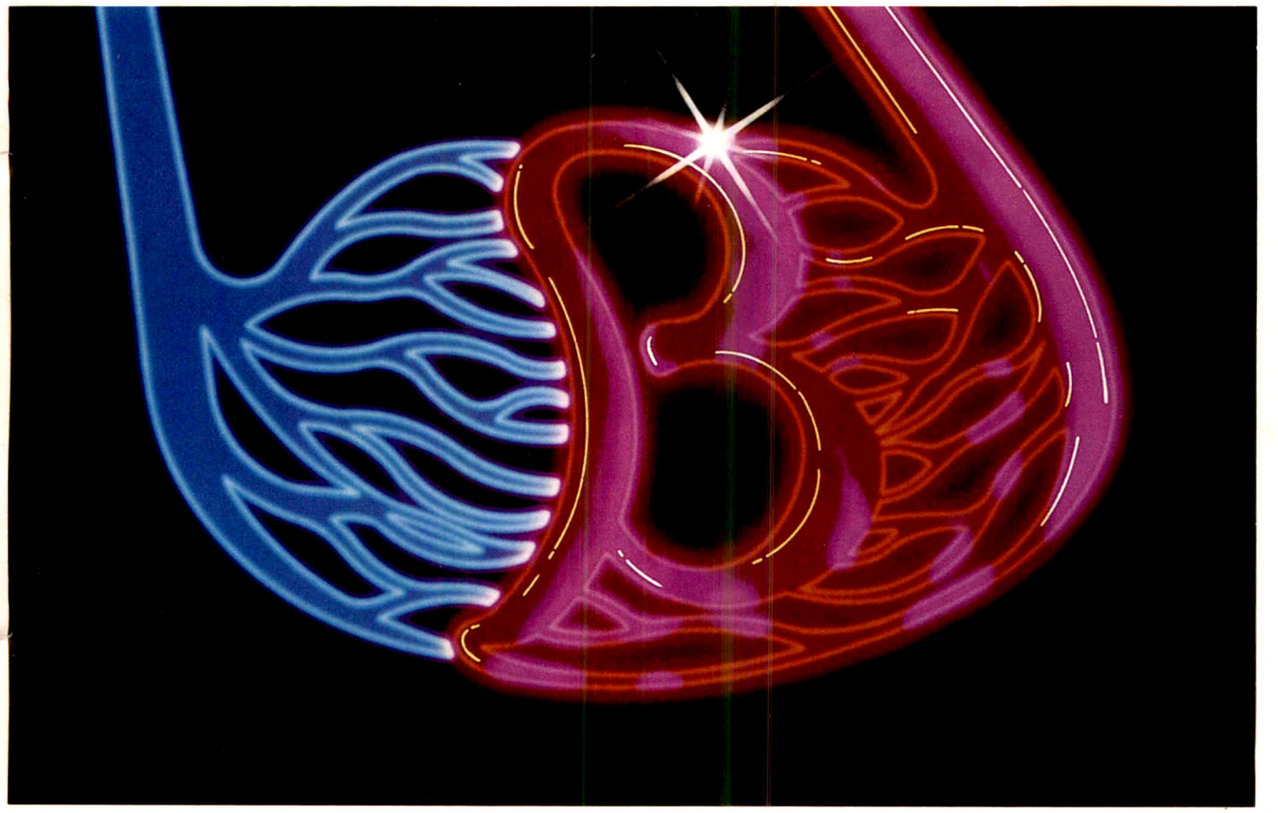
decrease during the first 10 minutes after administration, as shown in animal studies.[10]



**Therapeutic implications:** Flecainide acetate administered intravenously exerts a negative inotropic effect that may be of clinical importance in patients with congestive heart failure. This effect is particularly marked during infusion. Therefore, in patients with an uncompensated or poorly compensated heart, the drug should be administered with caution and the infusion interrupted if any deterioration of cardiac function occurs. In such cases, an initial primary dose of only 1 mg/kg or slower administration over 60 minutes may be preferred.

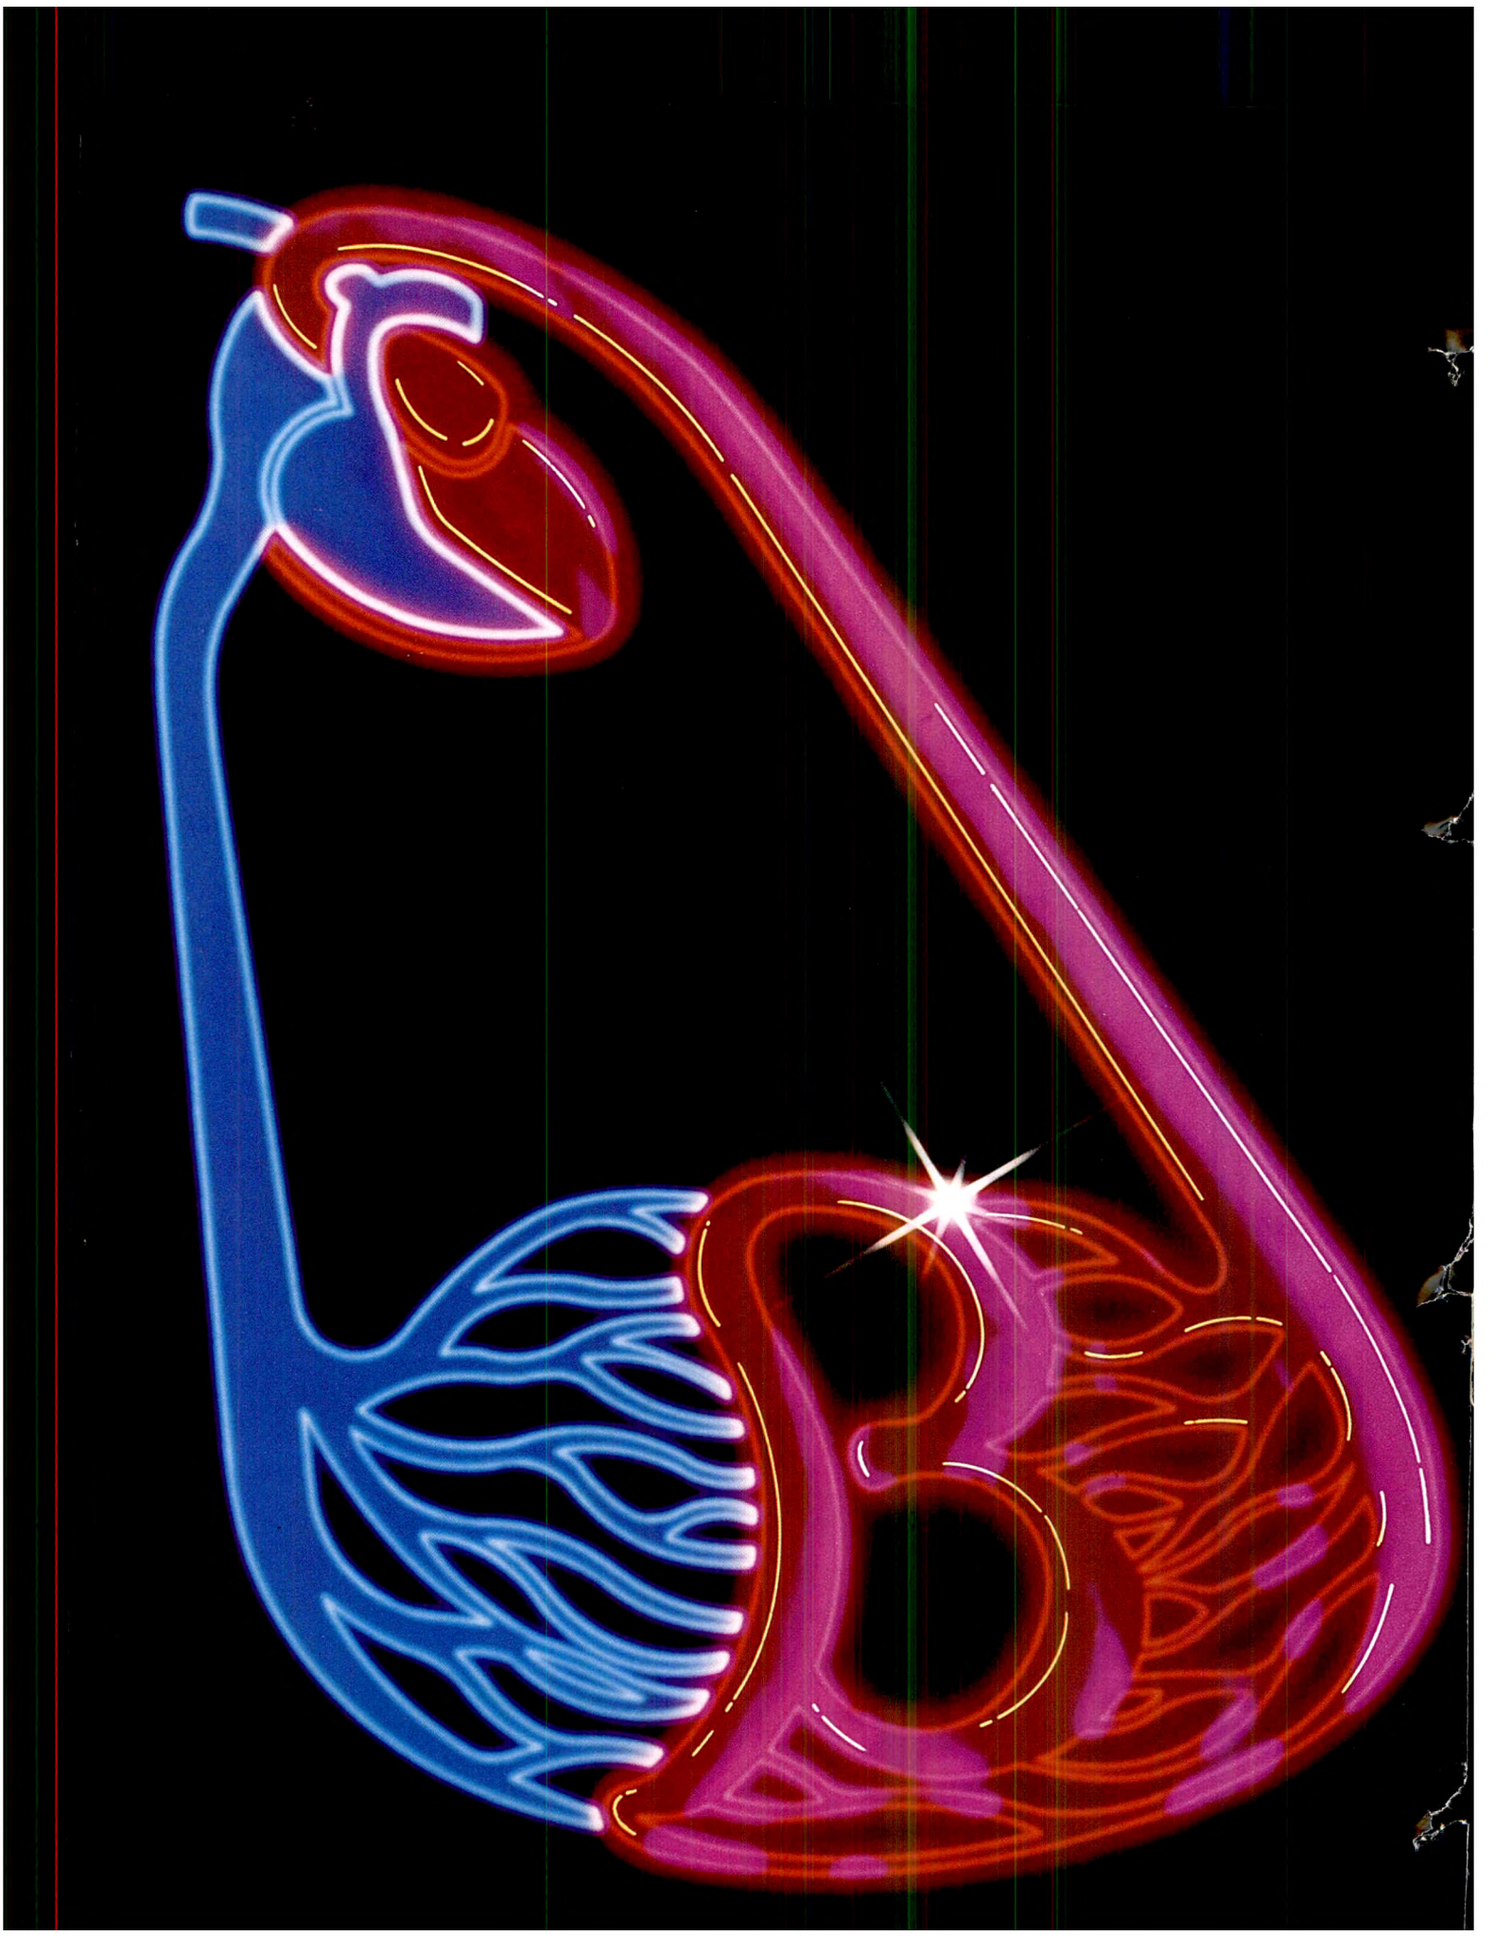
Life is not easy for any of us. But what of that? We must have perseverance and above all confidence in ourselves. We must believe that we are gifted for something, and that this thing, at whatever cost, must be attained.

Marie Curie

**Pick the only beta blocker that reduces total peripheral resistance:**



**1. Inderal®** (propranolol)

**2. Lopressor®** (metoprolol)

**3. Tenormin®** (atenolol)

**4. None of the above**

**(If you picked #4, you're right.)**

## Introducing:

# Visken® (pindolol)

## the only beta blocker that reduces blood pressure and total peripheral resistance*

# Here's the difference:

### Blood pressure

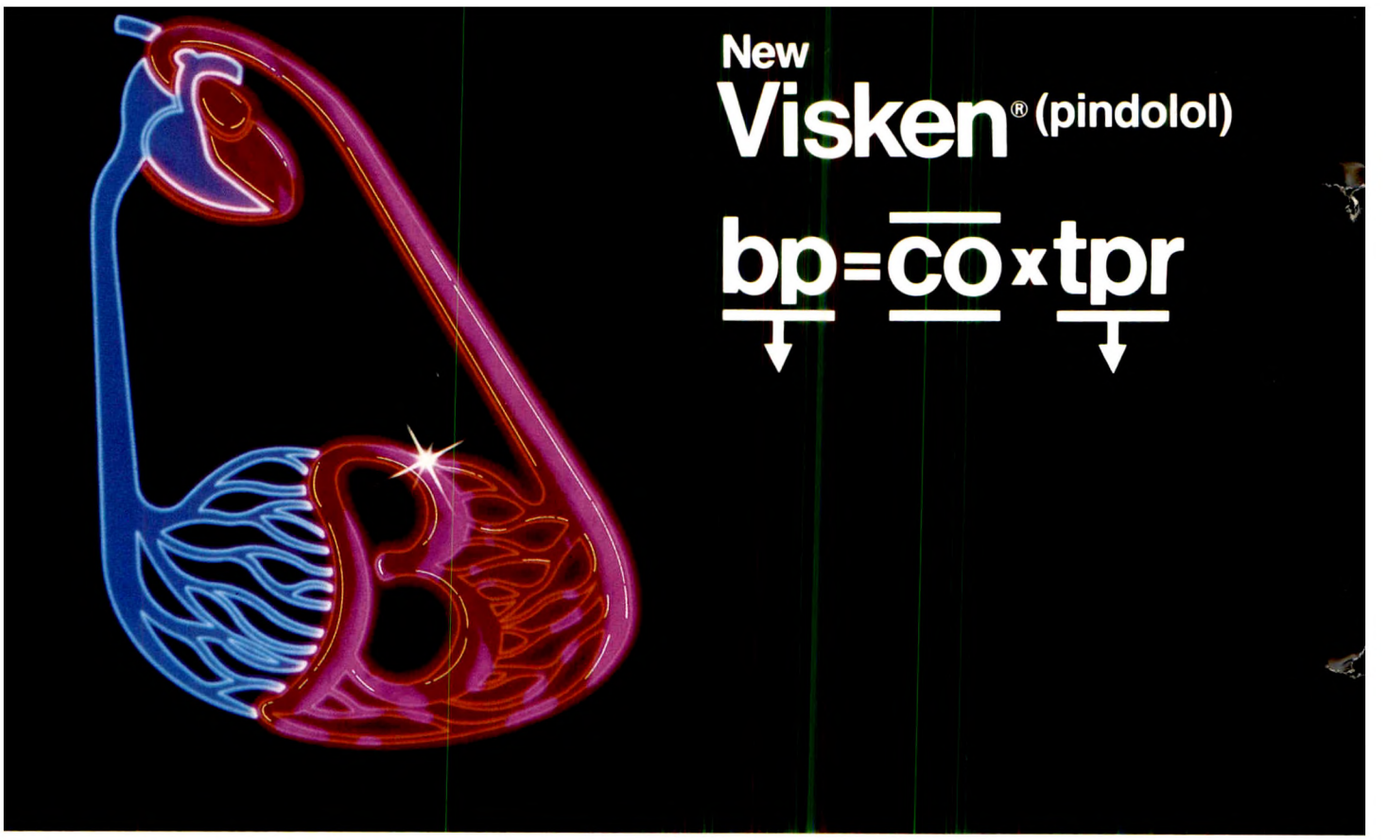
Blood pressure equals cardiac output times total peripheral resistance.

**bp=co×tpr**

### Visken (pindolol)

Visken (pindolol) is the only beta blocker that reduces blood pressure while maintaining resting cardiac output and reducing total peripheral resistance* during long-term therapy.

**bp↓=co×tpr↓**



### All other beta blockers

All other beta blockers reduce blood pressure, and reduce cardiac output with an initial reflex rise in total peripheral resistance and a subsequent return to baseline in many cases.

**bp↓=co↓×tpr↑**

*The clinical significance has not been evaluated.
See clinical significance statement on fourth page of this advertisement.

Please see last page of this advertisement for brief summary of prescribing information.

# Here's the result:

## Reduced blood pressure

U.S. studies at 29 major medical centers[1] have shown that Visken (pindolol) is an effective antihypertensive. It is as effective as propranolol in normalizing blood pressure (dbp≤90 mmHg) when used alone. It is also effective when used in combination with a diuretic.

This antihypertensive effectiveness is supported by 13 years of clinical use throughout the world. In fact, Visken (pindolol) is the #2 beta blocker in the rest of the world.

## Reduced peripheral resistance*

Studies of 178 patients treated with Visken (pindolol) for at least two weeks have shown that Visken therapy reduces total peripheral resistance.[1]*

## Reduction of exercise-induced tachycardia

Like other beta blockers, Visken (pindolol) blocks stimulation by catecholamines to reduce exercise-induced increases in systolic blood pressure and heart rate.

## The clinical significance has not been evaluated

The clinical significance of maintaining resting cardiac output, resting heart rate and reduced total peripheral resistance has not been evaluated and there is no evidence or reason to believe that exercise cardiac output is less affected by Visken (pindolol) than other beta blockers.

*See clinical significance statement.

# Here's the importance:

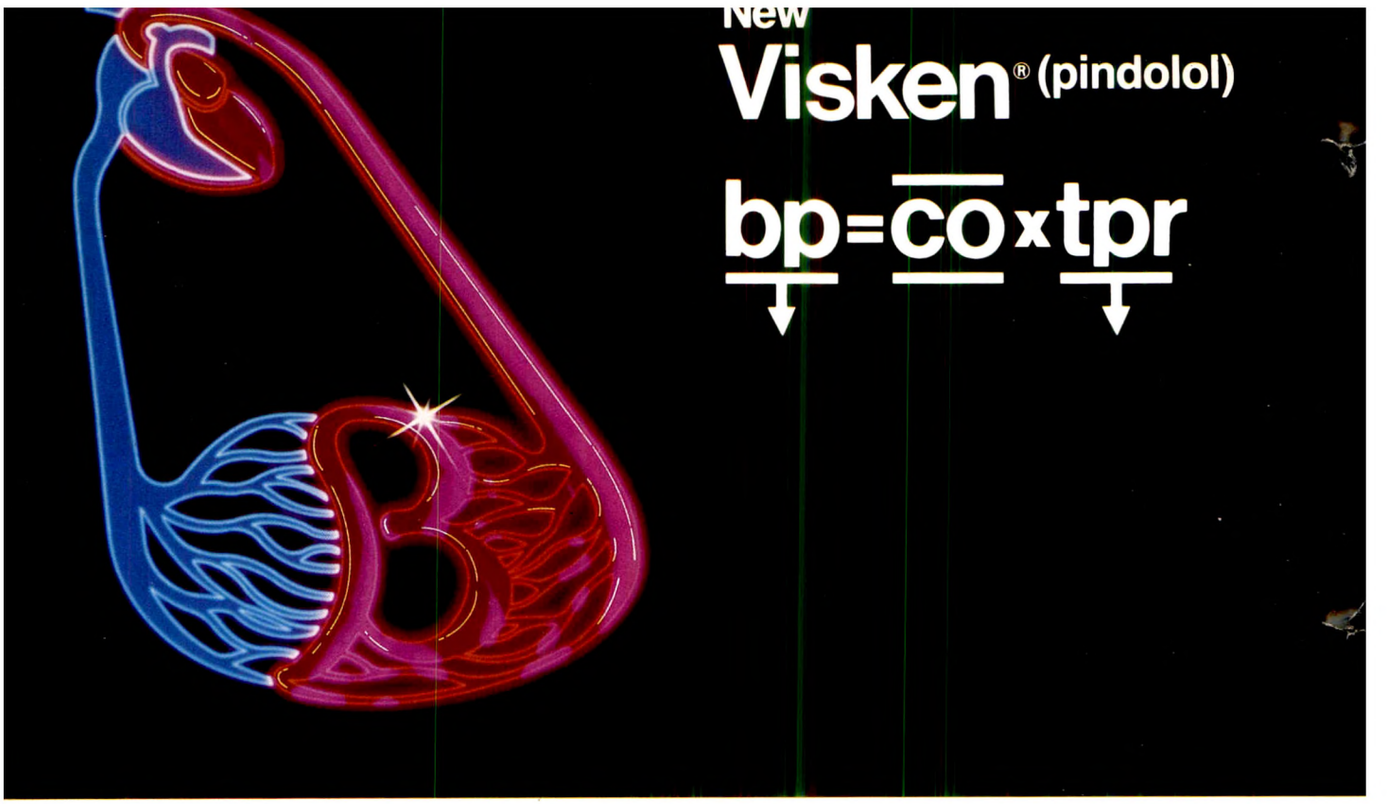
## Visken® (pindolol) reduces blood pressure with little effect on resting cardiac output

Unlike other beta blockers, Visken (pindolol) has little effect on resting cardiac output during long-term therapy.

## Visken (pindolol) makes hemodynamic sense in the treatment of hypertension

Visken (pindolol) reduces one of the recognized components of hypertension: increased peripheral resistance.*

## Visken (pindolol) reduces blood pressure with little effect on resting heart rate



Visken (pindolol) produces minimal changes in resting heart rate. Average reduction: 4-8 beats/minute. Minimal effect on resting heart rate results in low potential for bradycardia.

## Visken (pindolol) maintains renal blood flow

Visken (pindolol) reduces supine and standing blood pressure while maintaining effective renal plasma flow and glomerular filtration rates.[2]

*See clinical significance statement on facing page of this advertisement.

See last page of this advertisement for brief summary of prescribing information.

# Here's what you can expect:

**Reduced total peripheral resistance***

**Minimal effect on resting cardiac output**

**Minimal effect on resting heart rate**

**Minimal effect on renal blood flow**

**Favorable side effect profile†**

**Low incidence of bradycardia**

**Low incidence of cold extremities**

*See clinical significance statement on fourth page of this advertisement.

†Visken (pindolol) is contraindicated in:

1) bronchial asthma
2) overt cardiac failure
3) cardiogenic shock
4) second- and third-degree heart block
5) severe bradycardia

# Prescribing information:

## Available in 5 mg and 10 mg tablets

## Convenient bid dosage

Dosage should be titrated on an individual basis. Many patients respond to 10-30 mg a day in divided doses.

*The clinical significance has not been evaluated. See clinical significance statement on fourth page of this advertisement.

Please see last page of this advertisement for brief summary of prescribing information.

# New Visken® (pindolol)

*Before prescribing or administering, see package circular for full product information. The following is a brief summary.*

## INDICATIONS AND USAGE
Visken (pindolol) is indicated in the management of hypertension. It may be used alone or concomitantly with other antihypertensive agents, particularly with a thiazide type diuretic.

## CONTRAINDICATIONS
Visken (pindolol) is contraindicated in: 1) bronchial asthma; 2) overt cardiac failure; 3) cardiogenic shock; 4) second and third degree heart block; 5) severe bradycardia; (see Warnings).

## WARNINGS
**Cardiac Failure:** Sympathetic stimulation may be a vital component supporting circulatory function in patients with congestive heart failure, and its inhibition by beta-blockade may precipitate more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, Visken (pindolol) can be used with caution in patients with a history of failure who are well-compensated, usually with digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle.

**In Patients Without A History of Cardiac Failure:** In patients with latent cardiac insufficiency, continued depression of the myocardium with beta-blocking agents over a period of time can in some cases lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Visken (pindolol) therapy should be withdrawn (gradually if possible).

**Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal:** Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronically administered Visken (pindolol), particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of one to two weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, Visken (pindolol) administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue Visken (pindolol) therapy abruptly even in patients treated only for hypertension.

**Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema)—Patients with Bronchospastic Diseases Should in General Not Receive Beta-Blockers:** Visken (pindolol) should be administered with caution since it may block bronchodilation produced by endogenous or exogenous catecholamine stimulation of $beta_2$ receptors.

**Major Surgery:** Because beta blockade impairs the ability of the heart to respond to reflex stimuli and may increase the risks of general anesthesia and surgical procedures, resulting in protracted hypotension or low cardiac output, it has generally been suggested that such therapy should be withdrawn several days prior to surgery. Recognition of the increased sensitivity to catecholamines of patients recently withdrawn from beta-blocker therapy, however, has made this recommendation controversial. If possible, beta-blockers should be withdrawn well before surgery takes place. In the event of emergency surgery, the anesthesiologist should be informed that the patient is on beta-blocker therapy. The effects of Visken® (pindolol) can be reversed by administration of beta-receptor agonists such as isoproterenol, dopamine, dobutamine, or levarterenol. Difficulty in restarting and maintaining the heart beat has also been reported with beta-adrenergic receptor blocking agents.

**Diabetes and Hypoglycemia:** Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (e.g., tachycardia and blood pressure changes) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces the release of insulin in response to hyperglycemia; therefore, it may be necessary to adjust the dose of antidiabetic drugs.

**Thyrotoxicosis:** Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta-blockade which might precipitate a thyroid crisis.

## PRECAUTIONS
**Impaired Renal or Hepatic Function:** Beta-blocking agents should be used with caution in patients with impaired hepatic or renal function. Poor renal function has only minor effects on Visken (pindolol) clearance, but poor hepatic function may cause blood levels of Visken (pindolol) to increase substantially.

**Information for Patients:** Patients, especially those with evidence of coronary artery insufficiency, should be warned against interruption or discontinuation of Visken (pindolol) therapy without the physician's advice. Although cardiac failure rarely occurs in properly selected patients, patients being treated with beta-adrenergic blocking agents should be advised to consult the physician at the first sign or symptom of impending failure.

**Drug Interactions:** Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients receiving Visken (pindolol) plus a catecholamine depleting agent should, therefore, be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Visken (pindolol) has been used with a variety of antihypertensive agents, including hydrochlorothiazide, hydralazine, and guanethidine without unexpected adverse interactions.

**Carcinogenesis, Mutagenesis, Impairment of Fertility:** In chronic oral toxicologic studies (one to two years) in mice, rats, and dogs, Visken (pindolol) did not produce any significant toxic effects. In two-year oral carcinogenicity studies in rats and mice in doses as high as 59 mg/kg/day and 124 mg/kg/day (50 and 100 times the maximum recommended human dose), respectively, Visken (pindolol) did not produce any neoplastic, preneoplastic, or nonneoplastic pathologic lesions. In fertility and general reproductive performance studies in rats, Visken (pindolol) caused no adverse effects at a dose of 10 mg/kg.

In the male fertility and general reproductive performance test in rats, definite toxicity characterized by mortality and decreased weight gain was observed in the group given 100 mg/kg/day. At 30 mg/kg/day, decreased mating was associated with testicular atrophy and/or decreased spermatogenesis. This response is not clearly drug related, however, as there was no dose response relationship within this experiment and no similar effect on testes of rats administered Visken (pindolol) as a dietary admixture for 104 weeks. There appeared to be an increase in prenatal mortality in males given 100 mg/kg but development of offspring was not impaired.

In females administered Visken (pindolol) prior to mating through day 21 of lactation, mating behavior was decreased at 100 mg/kg and 30 mg/kg. At these dosages there also was increased mortality of offspring. Prenatal mortality was increased at 10 mg/kg but there was not a clear dose response relationship in this experiment. There was an increased resorption rate at 100 mg/kg observed in females necropsied on the 15th day of gestation.

**Pregnancy—Category B:** Studies in rats and rabbits exceeding 100 times the maximum recommended human doses, revealed no embryotoxicity or teratogenicity. Since there are no adequate and well-controlled studies in pregnant women, and since animal reproduction studies are not always predictive of human response, Visken (pindolol), as with any drug, should be employed during pregnancy only if the potential benefit justifies the potential risk to the fetus.

**Nursing Mothers:** Since Visken (pindolol) is secreted in human milk, nursing should not be undertaken by mothers receiving the drug.

**Pediatric Use:** Safety and effectiveness in children have not been established.

## CLINICAL LABORATORY
Minor persistent elevations in serum transaminases (SGOT, SGPT) have been noted in 7% of patients during Visken (pindolol) administration, but progressive elevations were not observed and liver injury has not been reported in the medical literature over a ten (10) year period of marketing. Alkaline phosphatase, lactic acid dehydrogenase (LDH) and uric acid are also elevated on rare occasions. The significance of these findings is unknown.

## ADVERSE REACTIONS
Most adverse reactions have been mild. The incidences listed in the following table are derived from 12 week comparative double-blind, parallel design trials in hypertensive patients given Visken (pindolol) as monotherapy, given various active control drugs as monotherapy, or given placebo. Data for Visken (pindolol) and the positive controls were pooled from several trials because no striking differences were seen in the individual studies, with one exception. The frequency of edema was noticeably higher in positive control trials (16% Visken (pindolol) vs 9% positive control) than in placebo controlled trials (6% Visken (pindolol) vs 3% placebo). The table includes adverse reactions reported in greater than 2% of Visken (pindolol) patients and other selected important reactions.

| Body System/ Adverse Reaction | Total (Volunteered and Elicited) Visken (pindolol) (N = 322) % | Active Controls* (N = 188) % | Placebo (N = 78) % |

| Rash | 2 | 3 | 3 |

*Active Controls: Patients received either propranolol, α-methyldopa or a diuretic (hydrochlorothiazide or chlorthalidone).

The following selected (potentially important) adverse reactions were seen in 2% or fewer patients and their relationship to Visken (pindolol) is uncertain. AUTONOMIC NERVOUS SYSTEM: hyperhidrosis; CARDIOVASCULAR: bradycardia, claudication, cold extremities, heart block, hypotension, syncope, tachycardia; GASTROINTESTINAL: diarrhea, vomiting; RESPIRATORY: wheezing; UROGENITAL: impotence, pollakiuria; MISCELLANEOUS: eye discomfort or burning eyes.

## POTENTIAL ADVERSE EFFECTS
In addition, other adverse effects not listed above have been reported with other beta-adrenergic blocking agents and should be considered potential adverse effects of Visken (pindolol).

**Central Nervous System:** Reversible mental depression progressing to catatonia; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

**Cardiovascular:** Intensification of AV block. See CONTRAINDICATIONS.

**Allergic:** Erythematous rash; fever combined with aching and sore throat; laryngospasm; respiratory distress.

**Hematologic:** Agranulocytosis; thrombocytopenic and nonthrombocytopenic purpura.

**Gastrointestinal:** Mesenteric arterial thrombosis; ischemic colitis.

**Miscellaneous:** Reversible alopecia; Peyronie's disease.

The oculomucocutaneous syndrome associated with the beta-blocker practolol has not been reported with Visken (pindolol) during investigational use and extensive foreign experience amounting to over 4 million patient-years.

## OVERDOSAGE
No specific information on emergency treatment of overdosage is available. Therefore, on the basis of the pharmacologic actions of Visken (pindolol), the following general measures should be employed as appropriate in addition to gastric lavage:

**Excessive Bradycardia:** administer atropine; if there is no response to vagal blockade, administer isoproterenol cautiously.

**Cardiac Failure:** digitalize the patient and/or administer diuretic. It has been reported that glucagon may be useful in this situation.

**Hypotension:** administer vasopressors, e.g., epinephrine or levarterenol, with serial monitoring of blood pressure. (There is evidence that epinephrine may be the drug of choice.)

**Bronchospasm:** administer a $beta_2$ stimulating agent such as isoproterenol and/or a theophylline derivative.

A case of an acute overdosage has been reported with an intake of 500 mg of Visken (pindolol) by a hypertensive patient. Blood pressure increased and heart rate was ≥80 beat/min. Recovery was uneventful. In another case 250 mg of Visken (pindolol) was taken with 150 mg diazepam and 50 mg nitrazepam, producing coma and hypotension. The patient recovered in 24 hours.

## DOSAGE AND ADMINISTRATION
The dosage of Visken (pindolol) should be individualized. The recommended initial dose of Visken (pindolol) is 10 mg b.i.d. alone or in combination with other antihypertensive agents. Many patients will respond to 15 mg per day (5 mg t.i.d.). The antihypertensive response usually occurs within the first week of treatment. If a satisfactory reduction in blood pressure does not occur within 2-3 weeks, the dose may be adjusted in increments of 10 mg per day at 2-3 week intervals up to a maximum of 60 mg per day.

## HOW SUPPLIED
White, round, scored tablets: 5 mg and 10 mg, packages of 100. 5 mg tablets embossed "VISKEN 5" on one side, and "78-111" and scored on other side (NDC 0078-0111-05). 10 mg tablets embossed "VISKEN 10" on one side, and "78-73" and scored on other side (NDC 0078-0073-05). [VIS-Z2 9/1/82]

# Pindolol and Propranolol in Patients With Angina Pectoris And Normal or Near-Normal Ventricular Function

## Lack of Influence of Intrinsic Sympathomimetic Activity on Global and Segmental Left Ventricular Function Assessed by Radionuclide Ventriculography

DANTE E. MANYARI, MD, WILLIAM J. KOSTUK, MD, S. GEORGE CARRUTHERS, MD, DONALD J. JOHNSTON, MD, and PAUL PURVES, RT

**To investigate the role of intrinsic sympathomimetic activity on left ventricular (LV) function during antianginal therapy with beta-adrenoreceptor antagonists, 23 patients with chronic, exercise-induced angina pectoris and normal or near normal LV function underwent radionuclide ventriculography at rest and during exercise, during 3 randomly allocated periods: (1) treatment with oral propranolol, a drug without intrinsic sympathomimetic activity, 40 to 80 mg 4 times a day; (2) treatment with pindolol, a drug with marked intrinsic sympathomimetic activity, 5 to 10 mg 2 times a day; and (3) a control period. During the control period, the LV ejection fraction decreased from rest (58.9 ± 8.2%) to exercise (54.3 ± 10.7%), and the wall motion score decreased from 0.57 ± 1.08 at rest to 2.39 ± 2.10 during exercise, p <0.001. After propranolol, the ejection fraction did not change significantly at rest (57.2 ± 8.1%) but improved during exercise (56.8 ± 11.8%), compared with control values. After pindolol, the ejection fraction did not change at rest (57.9 ± 8.6%) but improved during exercise (56.9 ± 8.1%), compared with control values. Similarly, the wall motion score after administration of both agents did not change significantly at rest, but improved during exercise (p <0.001). The number of anginal episodes, nitroglycerin tablets consumed, and magnitude of S-T segment depression decreased significantly with both pindolol and propranolol. With both drugs, a similar improvement in exercise tolerance and a similar decrease in exercise heart rate and blood pressure were obtained. It is concluded that pindolol and propranolol, beta-adrenoreceptor antagonists with and without intrinsic sympathomimetic activity, respectively, have similar effects on global and regional LV function in patients with angina pectoris, at doses producing equal suppression of exercise heart rate and similar antianginal effect.**

Comprehensive, carefully designed studies have failed to show any significant antianginal differences between various beta-adrenoreceptor antagonists with different ancillary pharmacologic properties, when administered on a short- or long-term basis to patients with stable, exertional angina pectoris.[1,2] The influence of intrinsic sympathomimetic activity on global or regional LV function in patients with angina is not known. This investigation compared the effects of pindolol and propranolol, drugs with and without intrinsic sympathomimetic activity, respectively, on LV performance at rest and during exercise in patients with exercise-induced angina. LV function was assessed using electrocardiogram-multigated blood pool cardiac scintigraphy, a noninvasive technique which has been shown to reliably assess global and segmental LV function.[3-5]

From the Cardiac Investigation Unit, University Hospital, and the Department of Medicine, University of Western Ontario, London, Ontario, Canada. This study was supported by the Ontario Heart Foundation and Sandoz (Canada) Limited, Dorval, Quebec, Canada. ### Methods

**Patient group:** Twenty-six men, aged 39 to 68 years (mean 52), with exercise-induced angina pectoris were studied. The duration of angina ranged from 3 months to 6 years (average 17 months). No patient had systemic hypertension, valvular

heart disease, intermittent claudication, or any condition that could limit exercise performance. None had diabetes mellitus, obstructive airway disease, or any history of previous adverse reaction to beta-blocking agents. The cardiothoracic ratio was normal in each. There was no clinical or roengtenographic evidence of heart failure. All had sinus rhythm. Ischemic electrocardiographic changes developed during treadmill exercise in all 26. Patients seen consecutively at the outpatient clinic, who met the foregoing criteria, were selected for this study solely on the basis of their willingness to participate.

Coronary cineangiography performed within 1 year of study in 16 of the 26 patients showed evidence of 3-vessel disease in 10, 2-vessel disease in 4, and 1-vessel disease in 2. Two patients had a history of myocardial infarction with abnormal Q waves (>40 ms duration) on the electrocardiogram. Six patients were taking long-acting oral nitrates, which were kept constant during the study period.

**Study design:** This investigation assessed objective measures of LV function; thus an open crossover design was used. Each patient underwent 3 consecutive study periods: (1) a control period in which no beta-adrenoreceptor antagonists were administered; (2) treatment with oral propranolol 4 times a day; and (3) treatment with oral pindolol 2 times a day. The order of the 3 treatment periods was allocated randomly for each patient. The duration of the control period varied between 1 and 4 weeks; the duration of treatment periods with propranolol and pindolol varied from 4 to 6 weeks. The dose of propranolol was 40 mg 4 times a day and the dose of pindolol was 5 mg 2 times a day, a 16:1 ratio shown to exert similar beta-adrenergic blockade.[6] These doses were increased to 80 mg 4 times a day and 10 mg 2 times a day, respectively, in patients in whom clinical improvement did not occur (compared with the control period) or whose exercise heart rate was >120 beats/min with the initial dose, indicating that beta-adrenoreceptor blockade was inadequate. The initial doses were not increased in patients in whom clinical improvement was achieved or in whom the heart rate at peak exercise was lower than 120 beats/min. Improvement was defined by a reduction in the number of anginal attacks of at least 40% compared with that in the control stage. Patients requiring dosage increases underwent more than 3 study periods, but only data during drug treatment with the larger doses are reported. Patients kept a daily record of the number of anginal episodes and the number of therapeutic glyceryl trinitrate tablets consumed.

Change in therapy when switching from one beta-adrenoreceptor antagonist to another was made abruptly from 1 day to the next. When treatment with 1 of the 2 drugs was followed by the control period, the drug was discontinued gradually over 1 week.

At the end of each of the 3 treatment periods, all patients underwent, successively, radionuclide ventriculography at rest and during bicycle exercise 120 to 150 minutes after the morning dose of either drug or at a similar hour of the day after the control period, a treadmill exercise test 45 minutes after termination of bicycle exercise, and clinical assessment.

In the 6 patients taking long-acting nitrates, doses were kept constant throughout the entire investigation, but were withheld for 24 hours before exercise studies; the same dose was given again after clinical assessment.

The clinical assessment was made by 2 participating cardiologists. The number of anginal episodes experienced, glyceryl trinitrate tablets consumed, and adverse effects were recorded. The number of remaining tablets were counted to assess compliance. New drugs, instructions, or both were given.

The treadmill exercise test was performed using a modified Bruce protocol, with elevation of the speed and incline at 3-minute intervals.[7] All patients were exercised to angina during the control stage, and to angina or fatigue after drug treatment. An ischemic electrocardiographic response was a flat or downward sloping depression of the S-T segment of at least 0.1 mV (1 mm) in any lead, persisting for ≥0.08 second and present in 3 consecutive beats with stable isoelectric baseline. Cuff blood pressure measured over the right brachial artery and a 12-lead electrocardiogram were obtained at rest, at each exercise stage, and immediately and at 2, 4, 6, and 8 minutes after exercise. The treadmill walking time was recorded to the nearest 5-second period. Exercise heart rate was measured continuously on a cardiotachometer and the maximal heart rate was measured from 10 consecutive beats on the electrocardiogram recorded during the last 15 seconds of peak exercise. S-T segment depression was measured as the linear depression of the J point from the isoelectric line joining 2 consecutive P-R segments. Measurements were made in the lead that showed maximal S-T segment depression and were averaged over 4 consecutive complexes in which the isoelectric line was stable. The symptoms limiting exercise tolerance were recorded.

**Assessment of LV function:** Radionuclide ventriculography, to assess global and regional LV function, was performed using the electrocardiographic-multigated method described previously.[3-5] After in vivo labelling of the red blood cells with technetium-99m, blood pool cardiac scintigraphy was performed in the modified left anterior oblique projection that best separated both ventricles and atria, at rest and during graded supine bicycle ergometer exercise. Details of the exercise protocol and the instrumentation used in our laboratory have previously been described.[4] Analysis of the radionuclide studies was carried out blindly by an experienced observer. Global LV ejection fraction and semiquantitative measurements of segmental LV function (wall motion score) were obtained at rest and during peak exercise.

In our laboratory, radionuclide LV ejection fraction and wall motion analysis correlated closely with contrast studies, $r = 0.87$.[5] Inter- and intraobserver variability of ejection fraction measurements showed correlation coefficients of 0.97 and 0.92, respectively.[4,5] A radionuclide ventriculogram at rest was considered normal if ejection fraction was ≥55% and the wall motion score was equal to zero. Failure of ejection fraction to increase by at least 7% (absolute value), or any increase in wall motion score from resting values, or both was considered an abnormal LV function response to peak exercise.[4]

**Statistical methods:** Analysis of variance was used to determine the significance of changes during treatment periods. If this analysis indicated a significant difference in the mean values for a variable, then Tukey's multiple comparison procedure was performed. In addition, changes in exercise duration, electrocardiographic S-T segment depression, and wall motion score were also analyzed by a nonparametric method using Wilcoxon's rank sum test. Probability of ≤5% was considered significant.

**TABLE I Order of the Therapy Periods in 23 Patients With Angina Pectoris in This Study**

| Patients (n) | First Therapy | Second Therapy | Third Therapy |
|---|---|---|---|
| 6 | C | Pr | Pi |
| 4 | C | Pi | Pr |
| 3 | Pr | C | Pi |
| 2 | Pr | Pi | C |
| 2 | Pi | Pr | C |
| 6 | Pi | C | Pr |

C = control; Pi = pindolol; Pr = propranolol.

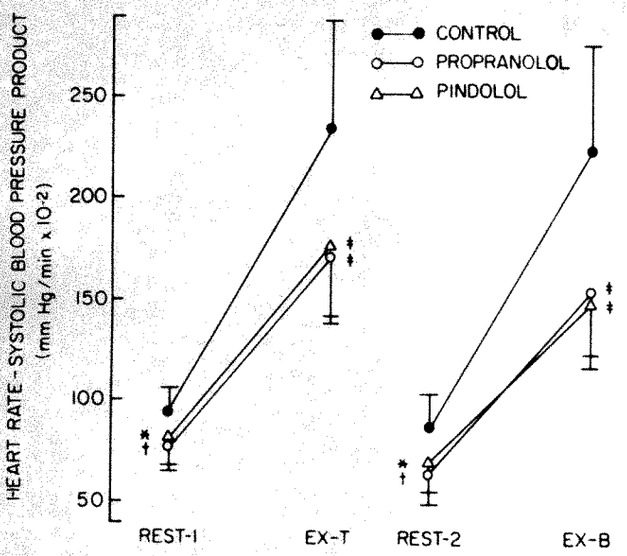

**FIGURE 1.** Comparison of the effects of propranolol and pindolol during sustained therapy in 23 patients with angina pectoris. Data represent mean ± standard deviation. REST-1 = data standing, immediately before treadmill exercise. REST-2 = data supine, just before bicycle exercise. EX-T and EX-B = data at peak exercise on the treadmill and the bicycle, respectively. * $p < 0.05$; † $p < 0.01$; ‡ $p < 0.001$, versus control values.

## Results

Three of the initial 26 patients did not complete the entire investigation: 1 had hypothyroidism during the initial treatment period; 2 became asymptomatic while on treatment with the first beta-adrenoreceptor antagonist and insisted on receiving the same medication thereafter. Thus, these 3 patients were excluded, leaving a total of 23 patients who completed all phases of this study and form the basis of this report.

Random allocation of the order of treatment periods resulted in fairly even distribution of patients among the 6 possible combinations (Table I). Compliance was good because <3% (average value) of the tablets were returned.

No patient experienced adverse effects serious enough to warrant discontinuation of medications during the study period. Complaints such as fatigue, drowsiness, vivid dreams, and cold extremities were reported with similar frequency during therapy with propranolol and pindolol. Clinical improvement of similar degree was observed during propranolol therapy in 17 patients taking 40 mg 4 times a day, in 5 patients taking 80 mg 4 times a day, and during pindolol therapy in 14 patients taking 5 mg twice each day, and in 7 patients taking 10 mg twice a day. In the remaining patient taking propranolol 80 mg 4 times a day and 2 patients taking pindolol 10 mg twice a day, the frequency of angina also was reduced but by <40% despite a significant reduction in the exercise heart rate (to <120 beats/min).

**Effect of treatment on the frequency of angina, number of glyceryl trinitrate tablets consumed, and exercise duration:** During the control period, the mean number of anginal episodes reported was higher ($p < 0.001$) than those during therapy with propranolol or pindolol (19.4 ± 10.4, 7.0 ± 5.7, and 8.6 ± 6.4 anginal episodes/month, respectively). The average number of glyceryl trinitrate tablets consumed was lower ($p < 0.001$) during propranolol and pindolol therapy than during the control period (4.0 ± 3.0, 5.2 ± 5.4, and 11.0 ± 8.3 tablets of glyceryl trinitrate/month, respectively), in keeping with the number of anginal episodes reported.

Exercise duration on the treadmill (Table II) was significantly higher during therapy with both drugs than during the control period. Patients exercised for shorter periods of time on the bicycle, but the mean exercise duration showed trends similar to those of exercise on the treadmill (duration of bicycle exercise: 5.61 ± 2.08 minutes during control, 6.52 ± 1.73 minutes after propranolol, and 6.00 ± 1.81 minutes after pindolol). The treadmill walking time, frequency of angina, and number of glyceryl trinitrate tablets consumed after propranolol were similar ($p = 0.20$) to those after pindolol administration.

**Circulatory changes:** No significant differences were observed between supine and standing resting heart rates. The heart rate increased significantly ($p < 0.001$) from resting values with treadmill and bicycle exercise during the 3 study periods. Resting and exercise heart rates (Table II) were lower during treatment with both beta-adrenoreceptor antagonists when compared

**TABLE II Effects of Propranolol and Pindolol on Exercise Tolerance, S-T Segment Depression, Heart Rate, Systolic Blood Pressure, and LV Function During Sustained Therapy in Patients With Angina Pectoris**

Data expressed as mean ± standard deviation.
EF = LV ejection fraction; SBP = systolic blood pressure; TWT = treadmill walking time; WMS = left ventricular wall motion score. Data for S-T segment depression, exercise heart rate, and systolic blood pressure represent values during peak treadmill exercise. * $p < 0.001$; † $p < 0.01$; ‡ $p < 0.05$ versus control values.

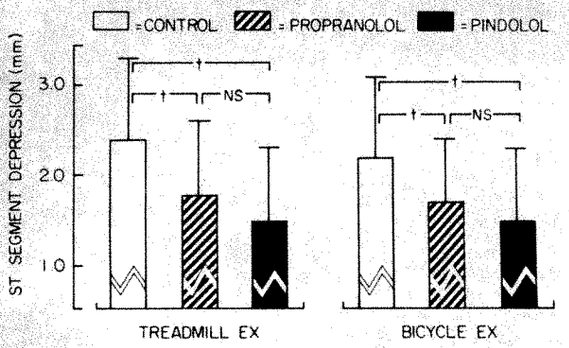

**FIGURE 2.** Comparison of the effects of propranolol and pindolol during sustained therapy in 23 patients with angina pectoris. Data represent mean ± standard deviation at peak exercise (EX) on the treadmill and the bicycle. No significant difference in S-T segment depression was observed between the 2 modes of exercise. † $p < 0.01$; NS = $p > 0.05$.

with heart rates during the control period. Both supine and standing heart rates at rest were somewhat lower during propranolol than during pindolol administration but the difference between means did not reach statistical significance. Heart rates during peak exercise were similar with the 2 drugs. Systolic blood pressure increased ($p < 0.001$) from rest to exercise during control and during administration of propranolol and pindolol (Table II). At rest, supine and standing systolic blood pressure after both beta-adrenoreceptor antagonists were similar to those during the control period. After administration of both drugs, systolic blood pressures at peak exercise, on the treadmill and the bicycle, were significantly lower ($p < 0.001$) than those during control. The differences in systolic blood pressure, at rest or during exercise, after administration of the 2 drugs were not significant.

Compared with the control period, the product of heart rate and systolic blood pressure (Fig. 1), with the patients at rest in both supine and standing positions and during peak treadmill and bicycle exercise, were lower during treatment with both drugs. The products of heart rate and systolic blood pressure were similar after administration of both propranolol and pindolol.

**Electrocardiographic changes:** An ischemic electrocardiographic response to exercise was present in all patients during the control stage, in 14 patients after propranolol, and in 10 patients after pindolol. During the control period, S-T segment depression at peak exercise was significantly greater than after propranolol or pindolol administration (Table II). The difference between mean S-T segment depression after both beta-adrenoreceptor antagonists was not statistically significant (Fig. 2).

**Effects of treatment on global LV function:** During the control stage, the LV ejection fraction at rest was normal (>55%) in 14 patients and abnormal (<55%) in 9 patients, but <50% in only 1 patient. After administration of propranolol, resting ejection fraction was found within the normal range in 14 patients and <50% in 3, whereas after administration of pindolol, the ejection fraction at rest was normal in 18 patients and <50% in the 3 (Fig. 3). There was no significant difference between the means of resting ejection fraction during the 3 study periods (Table II).

An abnormal response of ejection fraction to peak exercise, as defined in the Methods section, was observed in 22 patients during the control period, in 18 patients after propranolol, and in 21 patients after pindolol. During the control period, the mean ejection fraction during peak exercise was significantly lower ($p < 0.05$) than that at rest, whereas it was not significantly different from the resting ejection fraction after administration of both beta-adrenoreceptor antagonists (Fig. 3). The average ejection fraction at peak exercise during therapy with propranolol and pindolol was somewhat greater than during control (Table II), but the differences did not reach statistical significance. No significant differences were observed in rest or exercise mean ejection fraction between patients taking 5 and 10 mg of pindolol twice a day.

**Effects of treatment on regional LV function:** During the control period, 20 patients showed a normal or near-normal segmental LV function (wall motion score values of 0 to 1), the remaining 3 patients had wall motion score values of 2 or higher; in only 1 patient was this higher than 3. After propranolol therapy, the resting wall motion score was normal or near normal in 20 patients, higher than 1 in 3 patients, and higher than 3 in 1 patient. After pindolol, the wall motion score at rest was normal or near-normal in 18 patients, higher than 1 in 5 patients, and higher than 3 in 1 patient (Fig. 4). No significant differences during any of the 3 study periods were found between the means of wall motion score at rest (Table II).

An abnormal response of regional LV function to exercise, as defined previously, was observed in 18 patients during the control stage, in 12 patients after propranolol therapy, and in 10 patients after pindolol administration. The mean wall motion score during exercise was significantly higher ($p < 0.001$) than the respective resting values during the control period, after propranolol, and after pindolol (Fig. 4). However, the mean exercise wall motion score during the control stage was significantly higher than that during therapy with both drugs (Table II). At peak exercise, the mean wall motion score after propranolol was similar ($p = 0.30$) to that after pindolol administration. No significant differences were observed in rest or exercise mean wall motion score among patients taking 5 and 10 mg of pindolol twice a day.

**Effects of treatment in relation to the basal status of LV function:** Resting LV function during the control period was considered normal (ejection fraction >55% and wall motion score, 0) in 13 patients and below in 10 patients. In the former group, the mean ejection fraction was 64 ± 6% and the mean wall motion score was zero; those in the latter group were 52 ± 5% and 1.3 ± 1.3, respectively. In the 2 subgroups, both propranolol and pindolol produced an improvement in global and regional LV function during exercise to an extent similar to that observed in the entire group.

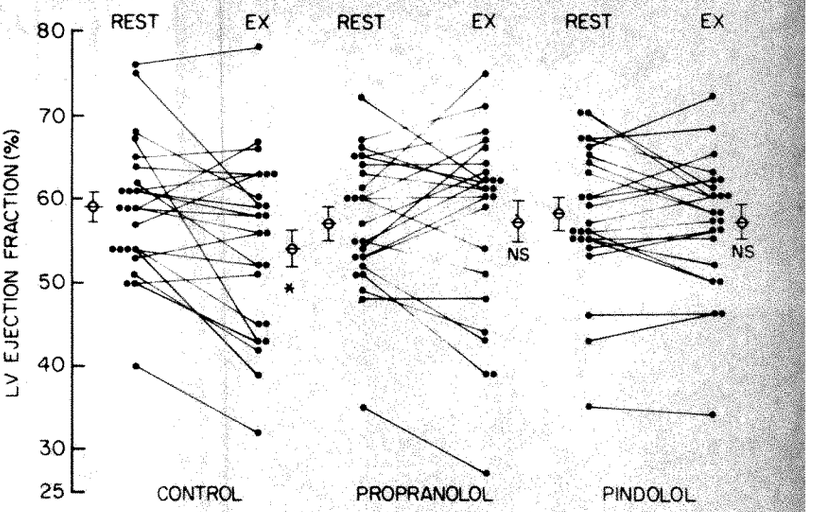

**FIGURE 3.** Effects of propranolol and pindolol on global LV function. Data represent individual and group (mean ± standard error of the mean) values, at rest and during peak exercise (EX). Exercise ejection fraction after both beta-adrenoreceptor antagonist drugs were similar. * $p < 0.05$; NS = $p > 0.05$ versus rest values.

## Discussion

This study shows that pindolol and propranolol, adrenergic beta-receptor antagonist agents with and without intrinsic sympathomimetic activity, respectively, have similar effects on global and regional LV function in patients with angina pectoris. At the doses used, both drugs exerted an equal suppression of the exercise heart rate and had significant and similar antianginal effects.

Differences in the pharmacodynamic and pharmacokinetic properties[8] of the many beta-adrenoreceptor antagonists available have led investigators to postulate the theoretical advantages of some over others when treating patients with angina pectoris.[9–11] One such ancillary property is the intrinsic sympathomimetic activity or partial agonist activity. Drugs with this characteristic cause a measurable agonistic response when they interact with beta-adrenergic receptors in the absence of a primary agonist such as adrenaline or isoprenaline; this can be demonstrated in the adrenalectomized animal treated beforehand with reserpine.[9] Although drugs with and without partial agonist activity have been available for patient treatment for several years, the clinical significance of this property remains uncertain.[10,12] It has been suggested that drugs with partial agonist activity induce less subjective and objective respiratory impairment in patients with bronchospastic disease and lessen exercise cardiac output to a reduced degree in patients with hypertension[13,14] than drugs without partial agonist activity.

Thadani et al[1,2,15] and others[16–18] found that beta-adrenoreceptor antagonist drugs with and without partial agonist activity are equally effective in the treatment of angina pectoris. However, no information is available regarding the role of the partial agonist activity on global and regional LV function. We therefore elected first to compare pindolol and propranolol because pindolol is the drug with the most pronounced partial agonist activity.[19] Second, because myocardial oxygen supply and demand in patients with chronic, stable angina pectoris are at equilibrium at rest and myocardial ischemia develops only during stress, we studied the effects of both drugs on ventricular function at rest as well as during exercise. Third, we used the

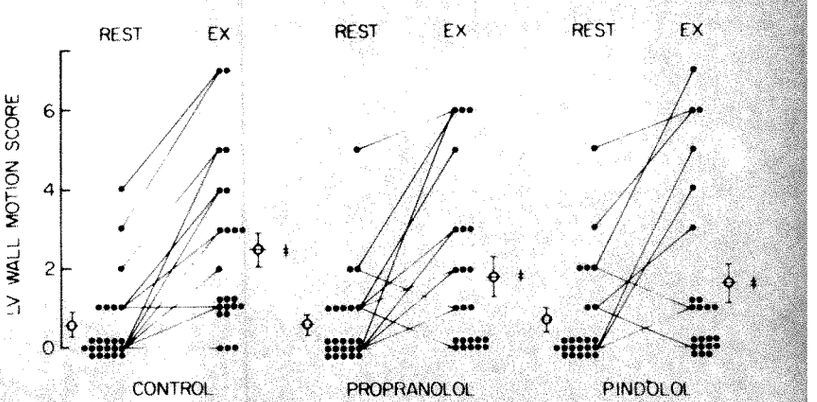

**FIGURE 4.** Effects of propranolol and pindolol on regional LV function. Data represent individual and group (mean ± standard error of the mean) values, at rest and during peak exercise (EX). LV exercise wall motion score improved significantly ($p < 0.01$) after both beta-adrenoreceptor antagonists. There was no significant difference ($p > 0.05$) in exercise LV wall motion score between the 2 drugs. ‡ $p < 0.001$ versus rest values.

electrocardiographic-multigated blood pool cardiac scintigraphy, a reliable, noninvasive technique well-suited for repeated measurements at rest and during exercise.[3-5]

On the basis of previous experience with the drugs tested,[10,16,20] we used 2 dose levels. With use of only 2 dose levels, it is possible that the optimal dosage may not have been reached in a few patients; however, a significant beta-adrenoreceptor blocking effect was obtained at the doses used. Our results are in agreement with more comprehensive dose-response studies in which pindolol, 10 to 20 mg/day, and propranolol, 160 to 320 mg/day, were found to be well within the therapeutic range.[15,21,22]

Several aspects of our study need further comment. Open trials do not constitute worthwhile evidence of treatment efficacy. However, our principal aim was to assess the effects of pindolol and propranolol on objective measurements of LV function. The antianginal efficacy of the drugs used was not in question and a double-blind study was not vital. All radionuclide studies were analyzed blindly at the end of the trial. Although we did not have formal run-in and trial-proper periods, and we were not concerned about possible carry-over effects, we believe that the random distribution of the order of treatment and control sequences (Table I) and the existence of 2 dose levels reconciled these deficiencies in design. In those subjects who received 320 mg/day of propranolol or 20 mg of pindolol/day, an actual run-in period was present. Moreover, rest-exercise studies were carried out after a minimum of 4 weeks of treatment and the carry-over effect by then should have been nonexistent. Lastly, patients were carefully selected and all had uncomplicated, stable angina pectoris and an ischemic electrocardiographic response to exercise. This may impose limitations in applying the results to a broader clinical population, but is necessary for meaningful comparison of the drug effects.

At the doses used, pindolol and propranolol were efficacious antianginal agents. Both drugs reduced clinical and electrocardiographic signs of myocardial ischemia, and improved exercise tolerance to a similar degree. No further comments are needed regarding these effects because many previous well-designed studies[16,23] have shown similar results.

**LV function changes at rest:** In patients with normal or near normal LV function, previous studies have shown that oral administration of propranolol did not significantly influence resting global or segmental systolic LV function as assessed by radionuclide methods.[23-26] In patients with moderate to marked LV dysfunction,[26] or when studies were performed in the upright position,[27] a decreased LV ejection fraction was observed after propranolol administration. The results of the present study, which largely involved patients with normal or near normal LV function studied in the supine position, are in keeping with these observations.

LV ejection fraction and wall motion patterns at rest were also minimal and were not significantly affected by oral pindolol at clinically effective doses. Moreover, with a few exceptions, individual responses to propranolol were closely correlated with those to pindolol.

The comparative angiographic response to propranolol and pindolol, or between beta-adrenergic receptor antagonists with and without partial agonist activity, has not previously been reported. Frishman et al[10] found that the LV ejection fraction improved significantly after pindolol but was significantly reduced compared with control values after propranolol. The differences between the results in that study[10] and ours are unlikely to reflect differences in study design because the clinical, electrocardiographic, and circulatory changes were similar to those in the present study. Two factors may account for the divergent results: (1) The ejection fraction in Frishman's study was derived from the M-mode echocardiogram. This method has recognized limitations, especially in subjects with coronary heart disease in whom localized areas of LV dysfunction may go undetected. The left ventricle was assumed to have the shape of a cube.[10] With the radionuclide method, counts in the entire ventricle are included to calculate ejection fraction, and no assumptions are made to the LV shape. Several investigations using radionuclide methods[23-26] have shown that resting ejection fraction is not significantly altered by oral administration propranolol at the doses used in Frishman's study. (2) We administered pindolol at approximately one third of the dose given by Frishman et al.[10] Future studies should investigate whether larger doses of pindolol may increase resting ejection fraction.

**LV function changes during exercise:** The beneficial effects of oral propranolol on LV function during exercise in patients with stable angina pectoris has previously been documented.[24-26] In our study, both propranolol and pindolol prevented the ejection fraction from decreasing significantly with exercise, and both drugs improved exercise wall motion score to the same extent.

The mechanisms whereby beta-adrenoreceptor antagonists improve global and segmental systolic function during exercise in patients with coronary artery disease are not known. Possible mechanisms include a decrease in myocardial oxygen requirements, an improved total myocardial blood flow, or a favorable redistribution of myocardial blood flow. We conclude that this mechanism is independent of the presence or absence of intrinsic sympathomimetic activity.

A major shortcoming of the present study was failure to measure LV volumes. Possible differences in the effects of propranolol and pindolol on ventricular volumes were not assessed.[28,29]

**Effects of treatment in relation to the basal status of LV function:** If partial agonist activity has any beneficial effect on LV function, this effect would be more important in patients with impaired or borderline LV performance.[9,10,12] The patient group in this investigation included, with 1 exception, subjects with normal or near normal LV function. Thus, we cannot make any valid conclusions regarding the comparative effects of propranolol and pindolol on LV function in patients with poor LV performance.

# Determination of the Angiographic Appearance of Coronary Collateral Vessels: The Importance of Supplying and Recipient Arteries

HARVEY L. GOLDBERG, MD, JONATHAN GOLDSTEIN, MD, JEFFREY S. BORER, MD, MICHAEL B. COLLINS, MD, JEFFREY W. MOSES, MD, GEORGE ELLIS, MD, *With the technical assistance of* RICHARD QUIROZ, BA

**The appearance of coronary collateral vessels at coronary angiography generally is believed to provide additional information regarding coronary flow and myocardial oxygen supply beyond that obtained from angiographic assessment of the large coronary arteries. To evaluate the adequacy of this assumption, to determine the relation between the angiographic appearance of coronary arteries and of coronary collateral vessels, and to gain additional insight into the mechanisms governing collateral flow in man, the coronary arteriograms of 121 patients in whom at least 1 coronary artery manifested ≥75% stenosis (193 arteries demonstrated ≥90% stenosis, and 94 of these were totally occluded) were examined. Collateral vessels were graded absent, "poor," or "good" based on the size and intensity of filling. Stenosis of the recipient artery significantly affected the angiographic appearance of collaterals vessels. No artery with <90% stenosis received angiographically detectable collateral vessels; 118 of the 193 vessels with ≥90% stenosis received collateral vessels: 79 of 94 (84%) totally occluded arteries versus 39 of 99 (39%) with ≥90% but <100% stenosis ($p < 0.001$). Good collateral vessels went to 70 of the 79 (89%) totally occluded arteries, but only 17 of 39 (49%) subtotally occluded arteries ($p < 0.001$). Of the 87 good collateral vessels, only 16 (18%) were supplied by single arteries manifesting ≥75% stenosis; of 31 poor collateral vessels, 20 (65%) were supplied by arteries with ≥75% stenosis ($p < 0.001$). When the patency of all the arteries that could supply collateral vessels to the 94 totally occluded was semiquantitated, the extent of obstruction of the potential suppliers was significantly greater in those arteries with none or poor collateral vessels ($p < 0.001$ for both groups of arteries with good collateral vessels).**

**It is concluded that the angiographic appearance of the recipient and supplying coronary arteries is a major predictive factor in the angiographic appearance of coronary collateral vessels.**

Coronary collateral vessels, described anatomically in 1907,[1] were first observed angiographically by Molnar[2] in 1960. However, the factors which determine coronary collateral flow in man, and therefore the determinants of the angiographic appearance of collateral vessels, are poorly understood. In addition, the precise relation between the angiographic appearance of the large coronary arteries and the appearance of collateral vessels has not been well defined. While it is generally accepted that collateral vessels can be visualized only when they supply a stenotic artery, the degree of stenosis required for visualization has varied widely among reported investigations.[2–11] Moreover, the relation between the extent of recipient artery stenosis and the angiographically demonstrable characteristics of the collateral vessel is uncertain.[5,10–13] Finally, little direct attention has been focused on the effect of stenosis in the artery supplying the collateral vessel on the angiographic appearance of the collateral vessel, although the preponderance of data suggest, surprisingly, that stenosis of the supplying arteries is not an important factor in the appearance of the collateral vessel.[13–17]

Clarification of the relation between the angiographic appearance of large coronary arteries and of collateral vessels is of potential value. To the extent that the appearance of collateral vessels can be predicted from the severity of stenosis of large arteries, current concepts regarding the functional, clinical, and surgical importance of angiographically demonstrable collateral vessels may require revision.

Therefore, to clarify the relation between the angiographic appearance of coronary arteries and coronary collateral vessels, we assessed the coronary angiograms obtained in 121 patients with ischemic heart disease.

## Methods

**Patients:** Coronary angiography was performed in 121 patients (85 men and 36 women) ranging in age from 33 to 75 years (average 54). All patients had clinically apparent ischemic heart disease. Angiograms were selected for inclusion in this study on a random basis from among patients who underwent coronary arteriography at the New York Hospital in 1979 to 1980. Angiograms then were excluded from assessment unless at least 1 coronary artery manifested ≥75% reduction in luminal diameter in at least 1 angiographic view. Twenty-six patients manifested such stenoses in 1 major artery; in 42 patients, 2 major arteries were affected; and in 53 patients, all 3 major arteries were affected. Angiograms demonstrating ≥50% stenosis of the left main coronary artery were excluded. Patients with valvular, congenital, or primary myocardial heart disease detectable at catheterization or echocardiography were excluded from study. Patients were included irrespective of the presence or absence of clinical evidence of previous myocardial infarction.

**Angiography:** Catheterization was carried out with the patients under mild sedation (sodium pentobarbital), with local anesthesia, and in the fasting stage. No nitrate vasodilators were administered within 4 hours of catheterization, and no other vasodilator agents were employed in the treatment of these patients.

Selective coronary arteriography was performed by the Judkins technique, using Renografin®-76 contrast medium. All angiograms were recorded at 60 frames/s on 35 mm Kodak CFS film using a General Electric Fluoricon 300 system. Radiographic parameters were automatically adjusted to attain consistent and optimal film quality. A standard injection routine was utilized in an attempt to deliver contrast at a uniform rate during each injection. Film was processed in a Jameson 54 processor and densitometric quality control measures were employed regularly to ensure optimal and consistent film quality. The left coronary artery was routinely visualized in at least 4 views. Each segment of all arteries was visualized in at least 2 orthogonal (or nearly orthogonal) views. Caudad and cephalad angulation was used routinely in at least 2 views in each patient. Thus, every attempt was made to minimize variation in coronary artery and collateral appearance due to technical factors.

**Assessment of anatomy:** To assess stenosis of coronary arteries receiving or supplying collateral vessels, the severity of obstruction of each atherosclerotic lesion was defined as the greatest percent reduction in luminal diameter that was seen in any view compared to the nearest proximal section that was judged free of disease. Lesions were stratified into 4 levels of obstruction (<75%, ≥75 to 89%, ≥90 to 99%, 100%),[18] with caliper measurements employed to quantify luminal diameter reduction. The most severe of serial stenoses was used in stratifying those arteries with multiple lesions.

In this study, extent of collateral flow to a distal segment of an obstructed artery was assessed only if obstruction was present in the proximal or mid-portions of 1 of the 3 major coronary arteries (left anterior descending, circumflex, and right) or in the proximal or mid-portion of 1 of the major branches of a major artery. (If the only ≥90% stenosis, or the most severe stenosis, was in the distal portion of an artery, that vessel was not included in the analysis of collateral flow. There were 5 such arteries among the diseased arteries.) Collateral vessels were considered present (1) if a totally obstructed artery was visualized on homolateral injection; (2) if a subtotally obstructed artery was seen to fill in a retrograde fashion on homolateral injection; or (3) if an artery filled on contralateral injection. Collateral vessels were graded as good, poor, or absent based on a modification of the criteria of Levin[5]: good collateral vessels caused complete opacification of the portion of the recipient coronary artery distal to the obstruction lesion. Poor collateral vessels caused faint or incomplete visualization of the recipient artery distal to its obstructing lesion (with concomitant clear visualization of the region proximal to any obstruction in the injected artery, indicating technically adequate contrast administration). If there were multiple collateral vessels, only the vessel with the best grade was used in analysis. Multiple poor collateral vessels were treated as a single poor vessel.

Assessment of both coronary stenosis and collateral grade was performed independently by 2 observers; in cases of disagreement, a final decision was reached by consensus after joint review of the angiogram. To establish the reliability of our observations, a subgroup of 27 angiograms was reassessed by 1 observer several months after initial reading. There was complete agreement (24 of 24) between initial and follow-up readings of those stenoses graded as 100%; 91% (29 of 32) concordance of those lesions initially read as ≥90% to 99%; and 76% (16 of 21) concordance of those lesions initially read as ≥75 and <90%, with 2 of the 5 disagreements resulting in downgrading the severity of stenosis. There was 93% (27 of 29) concordance of those collaterals initially graded good, and 90% (9 of 10) concordance of those collaterals initially graded poor. Therefore, we believe our method of analysis is sufficiently reproducible to permit firm conclusions from data based on the large number of observations involved in this study.

To evaluate arteries with clearly supplied collateral vessels, the extent of stenoses was defined by the most severe reduction in luminal diameter proximal to the origin of the collateral vessel. If the stenosis was ≥75% of luminal diameter, the supplying artery was termed *obstructed*, and if stenosis was <75%, the artery was termed *nonobstructed*.

Finally, to determine the importance of obstructive disease in all arteries with potential for supplying collateral vessels, each totally occluded artery was considered to be potentially supplied by branches of either of the 2 other major arteries, and by the proximal portion of the occluded artery itself. Stenosis of each potential supplier was assessed by caliper measurement, as above; a stenosis causing a ≥75% reduction in luminal diameter was considered to indicate that a potential supplier was obstructed. As Levin has demonstrated, potential suppliers differ in probability of supplying collateral vessels to specific totally occluded arteries. Therefore, to each potential supplying artery, we assigned a relative weight (Table I) according to the probability that the artery would supply a collateral vessel (after Levin[5]). The system was designed such that when the relative weights assigned to branches of any major artery were summed, the result was equal to the relative weight assigned to the major trunk artery. The number of obstructed suppliers, each multiplied by its weight, was summed. The resulting quantity was termed the *supplier obstructive index*. The supplier obstructive index ranged from 0 (all potential suppliers having <75% stenosis) to 11 (all potential suppliers manifesting ≥75% stenosis).

**Statistics:** The chi-square test was used to compare frequency of observation between groups. The Kruskal-Wallis one-way analysis for K groups[19] was used to establish the existence of a difference in supplier obstructive index among our patient subgroups; the Kruskal-Wallis test as modified by Dunn[19] was used to compare supplier obstructive indexes among specific subgroups.

## Results

The 121 patients had a total of 269 arteries with ≥75% reduction in luminal diameter: 76 of the 269 arteries manifested ≥75% but <90% stenosis; 99 of 269 arteries manifested ≥90% but less than total occlusion; and 94 of 269 arteries were totally occluded. Thus, 193 arteries manifested ≥90% stenosis.

**TABLE 1 Potential Supplier Scoring System***

| Totally Occluded Artery | Potential Supplier | Relative Weight |
|---|---|---|

* Based on relative quantitative importance (weight) of potential collateral supply (see text).
The maximal possible supplier obstructive index is 11.
Cx = circumflex coronary artery; LAD = left anterior descending coronary artery; OM = obtuse marginal branch of the left circumflex artery; Prox = proximal (in LAD, proximal to first septal perforating artery; in Cx, proximal to first obtuse marginal; in RCA, proximal to acute marginal; RCA = right coronary artery. Parentheses indicate portions of a major artery.

**Effect of recipient stenosis on collateral frequency and grade:** The presence or absence of angiographically apparent collateral vessels was significantly affected by the severity of stenosis of the potential recipient artery. Of the 193 vessels with ≥90% stenosis, 118 (61%) received collateral vessels. In contrast, none of the 76 arteries with ≥75% but <90% stenosis received collateral vessels ($p < 0.001$). Of the 99 vessels with ≥90% stenosis that were not totally occluded, 39 (39%) received collateral vessels, while 79 of the 94 (84%) totally occluded vessels received collateral vessels ($p < 0.0001$) (Fig. 1).

Similarly, the grade of angiographically apparent collateral vessels was significantly affected by the severity of recipient artery stenosis. Of the 118 arteries receiving collateral vessels of either grade, collaterals supplying 87 arteries were graded good. Good collateral vessels supplied 70 of 94 (74%) of totally occluded arteries, but only 17 of 99 (17%) of subtotally occluded arteries ($p < 0.001$) (Fig. 2). Conversely, of the 79 collateral vessels to totally occluded arteries, 70 (86%) were good. In contrast, of the 39 collateral vessels to subtotally occluded arteries, 17 (44%) were good ($p < 0.001$).

**Effect of supplier stenosis:** Stenosis of the single artery most clearly supplying angiographically apparent collateral vessels significantly affected the grade of the collateral vessel. Thus, only 16 (18%) of the 87 good collateral vessels were supplied by obstructed (that is, with ≥75% stenosis proximal to the origin of the collateral) arteries; in contrast, 20 (65%) of the 31 poor collateral vessels had obstructed sources of supply ($p < 0.001$) (Fig. 3).

If a collateral vessel arose from an obstructed supplier, it invariably went to an artery whose stenosis was greater than that of the supplier. Sixteen collateral vessels clearly arose from single obstructed suppliers. Five collateral vessels arose from an artery with ≥75%

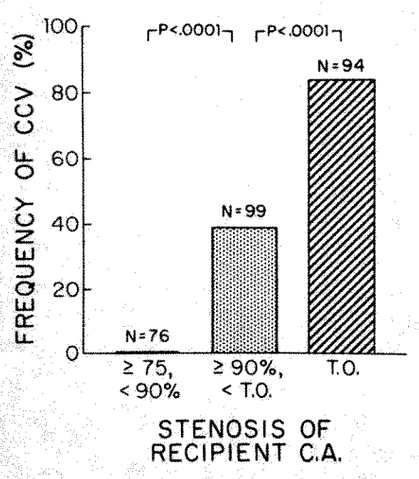

**FIGURE 1.** The frequency of angiographically demonstrable coronary collateral vessels (CCV) in arteries with ≥75% but <90% stenosis, with ≥90% stenosis but less than total occlusion (T.O.), and with total occlusion.

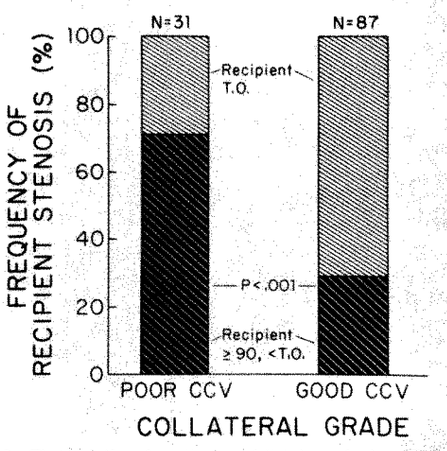

**FIGURE 2.** The relative frequency of total occlusion (T.O.), and of ≥90% stenosis but less than total occlusion, in arteries receiving poor and good coronary collateral vessels. Most arteries receiving good coronary collateral vessels (CCV) manifested total occlusion, while most arteries receiving poor coronary collateral vessels had less severe stenosis.

stenosis and each supplied a totally occluded artery; the 11 collateral vessels from ≥90% stenotic arteries also invariably supplied totally occluded arteries.

The importance of patency of supplying arteries in collateral appearance was confirmed by assessment of all *potential* sources of collateral supply. To eliminate the effect of variations in recipient artery obstructions, the analysis was limited to assessment of collateral vessels to the 94 totally occluded arteries. As shown in Figure 4, the extent of obstruction of potential suppliers (supplier obstructive index) was significantly higher in those arteries with no or poor collateral vessels ($p < 0.001$ for both groups of arteries versus arteries with good collateral vessels).

## Discussion

Our data indicate that the angiographic appearance of collateral vessels in patients with coronary artery occlusive disease is determined in large part by the presence and severity of stenosis of the large coronary arteries *supplying* and *receiving* the collateral flow.

We found that collateral vessels arose more frequently from nonobstructed than from obstructed arteries. The intensity of collateral filling at angiography was also influenced by supplier obstruction. Finally, the integrity of *potential* suppliers, as determined by our supplier obstructive index, affected the frequency and quality of collateral vessels to totally occluded arteries. While most totally occluded arteries received good collateral vessels, the absence of collateral vessels, or the presence of only poor ones, generally was seen only if most or all of the potential suppliers were obstructed.

The preferential origin of collaterals from nonobstructed arteries has not been previously appreciated. Similarly, the influence of supplier stenosis on collateral grade has not been reported. Analyses of the influence of potential suppliers on the likelihood of collateral development have yielded conflicting results. Most have suggested that stenotic lesions in potential suppliers have no effect on collateral appearance.[15–17] Although the issue of "potential suppliers" was not directly considered, evidence suggesting the lack of importance of potential suppliers can be inferred from the findings of Hamby et al,[17] who assessed the frequency of collateral supply to totally occluded left anterior descending or right coronary arteries. These investigators found that the presence or absence of collateral supply to either artery was unaffected by the presence of hemodynamically important obstructions of other arteries.[17] However, Hamby et al excluded from assessment those patients with total occlusion of potential suppliers, and defined other potential suppliers as obstructed if these manifested stenoses of ≥50%, a more lenient definition than that employed in the present study. Thus, the study design of Hamby et al differed significantly from ours, precluding direct comparison.

The relative unimportance of potential supplier stenosis also is implied by reports suggesting that the extent of visualization of collateral vessels is proportional to the overall severity of obstructive disease of the large coronary arteries.[15,16] If this were true, increasing collateralization might be expected to occur as potential suppliers develop increased disease, a conclusion which is directly contradicted by our findings. However, analyses leading to such conclusions generally have not considered the severity or location of the obstructive lesions in recipient arteries and potential suppliers, perhaps explaining in part the discrepancy between previous findings and those of the present study.

In contrast, in a study of the effects of collateral vessels on left ventricular function at rest and during exercise, Schwarz et al[14] concluded that collaterals are seen more frequently in patients with a single occlusion

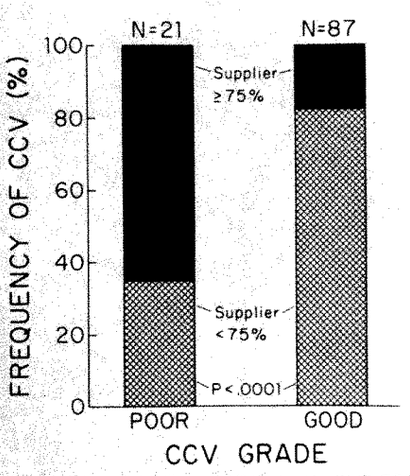

**FIGURE 3.** The relative frequency of "obstructed" (≥75% stenosis, **solid bar**) nonobstructed (<75% stenosis, **hatched bar**) suppliers to poor and good coronary collateral vessels (CCV). Good coronary collateral vessels usually have nonobstructed suppliers; poor coronary collateral vessels usually have obstructed suppliers.

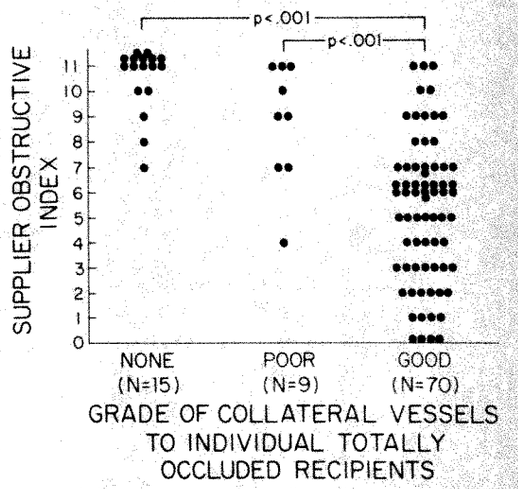

**FIGURE 4.** The supplier obstructive index, a measure of the patency of all arteries potentially supplying collateral vessels to totally occluded recipients, is higher when collateral vessels are absent or poor than when collateral vessels are graded good at angiography. The Supplier Obstructive Index was significantly ($p < 0.001$, by Dunn modification of Kruskal-Wallis test[19]) higher for the groups with no or poor collateral vessels than for the group with good collateral vessels.

than in patients with multiple occlusions.[14] However, their published data actually indicate that the proportion of well-collateralized totally occluded arteries was similar in patients with 1 or 2 totally occluded arteries. Accurate interpretation of the data of Schwarz et al is difficult, however, because the characteristics of the stenotic but not totally occluded arteries were not described.

Although our findings regarding the importance of the characteristics of supplying arteries are at variance with previous reports, our data are consistent with those of other investigators in demonstrating the importance of the severity of obstruction of recipient arteries in determining collateral vessel appearance. Nonetheless, differences exist between our findings and those of some previous studies. We were unable to demonstrate collateral vessels to arteries with <90% reduction in luminal diameter. Other investigators have noted angiographically apparent collateral vessels supplying arteries variously reported to manifest ≥50%,[11] ≥75%,[8,10] and ≥90%[2-4,6] stenoses. The source of this discrepancy is not entirely clear. However, several of the earlier studies did not separate patients with ≥90% stenosis from those with ≥50% and ≥75% obstructive lesions, thus potentially masking a relation between frequency of collateral vessels and severity of recipient artery obstruction. In addition, criteria employed in defining the severity of stenosis often have not been described, providing a potential source of inter-study variation. Finally, it is possible that interobserver variation in angiographic interpretation of coronary artery stenosis may be in part responsible for differences in results, though interobserver variability has been shown to be of relatively little importance when stenosis is ≥90%,[20] the lesion of greatest interest in our assessment.

Among patients with ≥90% stenosis, we found that the frequency and semiquantitative grade of collateral appearance was directly related to the presence of total occlusion. Thus, 84% of totally occluded arteries received collateral supply, while 39% of subtotally occluded arteries were so supplied. Though exceptions exist,[10] most investigators have found a similar relation between collateral frequency and total coronary artery occlusion.[11-13]

It is clear from our data that the relation we have observed, while highly statistically significant, do not describe the characteristics of all supplier-collateral recipient systems, that is, some good collateral vessels arise from obstructed suppliers and not all totally occluded arteries receive good collateral vessels. There are several potential explanations for the limitations of our observations. Of course, it is not possible to exclude the effects of factors unrelated to the extent of large coronary artery stenosis in modifying our results. Such additional influences, described previously by others,[5,11,15,21,22] include genetic predisposition of collateral formation, extent of regional ischemia, extent of physical activity, rate of progression of stenosis in the recipient artery, and concomitant hypoxia and/or anemia. In addition, the transcollateral pressure gradient, probably the major determinant of collateral vessel appearance at angiography, is dependent on the precise degree of luminal obstruction in supplying and recipient vessels. Clearly, although our grading system is highly reproducible and permitted stratification of patients into groups according to angiographic descriptors, no visually based angiographic grading system can precisely quantify anatomic obstruction,[23] or account for tubular stenoses, multiple stenoses, or concentric versus eccentric stenoses. Therefore, we would expect that although our angiographic assessment should generally reflect anatomic findings, an exact correlation would be unlikely, and precise estimate of pressure gradients across obstructive lesions should not be possible in every case.

Our data support the concept, well-substantiated in experimental animals,[24,28] that the specific transcollateral pressure gradient is of primary importance in determining the angiographic appearance of collateral vessels in man, and hence in determining the appearance of the distal portion of obstructed recipient arteries. Further, these results suggest that in the absence of an increase in systemic arterial (perfusion) pressure, collateral flow might be expected to increase only if (1) an increase occurs in the severity of obstruction of the recipient artery, or (2) if a decrease occurs in the severity of obstruction of supplying or potentially supplying arteries. Thus, our data may explain the inability of interventions such as diet and exercise to increase collateral development,[26,27] since neither of these interventions has been shown to decrease the severity of stenotic lesions in man. Similarly, our results are consistent with the finding of a longitudinal angiographic study which indicated that collateral vessels appear only with progression of the severity of a stenotic lesion in a recipient artery.[28]

Our findings have potential practical importance. Appropriate criteria for selection of patients for coronary bypass grafting, based both on myocardium at risk of ischemic damage and on subsequent risk to life, now are the subject of intense concern. As Levin[5] noted, autorevascularization by collateral flow may be sufficient in some cases to obviate the need for surgical intervention. Therefore, proper interpretation of the potential clinical importance of angiographically demonstrable collateral vessels may be essential. Our data suggest the possibility that, even if the angiographic appearance of a collateral vessel is good, decisions regarding the adequacy of collateral flow should perhaps take into account the characteristics of the supplying and recipient arteries. Moreover, of interest in patients in whom bypass grafting is to be undertaken, our data suggest the possibility that the absence of angiographic evidence of widely patent (and, hence, clearly graftable) distal segments of occluded vessels may result from extensive occlusion of potential suppliers, rather than from the intrinsic condition of the distal recipient vessel. If this is so, then planning of bypass grafting procedures must involve some means, perhaps intraoperative, to assure identification of potentially operable, although angiographically inadequate, distal vessels. Thus, our findings indicate that more complete understanding of the functional and clinical implications of angiographically demonstrable collateral vessels is of primary importance if therapeutic decisions are to be properly based on angiographic data.

**Acknowledgment:** We are grateful for the invaluable assistance of Barry Cohen, Salud DeJoya, and Kevin Plancher in the performance of these studies, and of Gail Jackson in the preparation of this manuscript.

# Identification of Septal Ischemia During Exercise By Q-Wave Analysis: Correlation With Coronary Angiography

MICHAEL A. FAMULARO, MD, YOGESH PALIWAL, MD, ROBERT REDD, MD, and MYRVIN H. ELLESTAD, MD

**Septal Q-wave amplitudes were studied in lead $CM_5$ to evaluate its utility in predicting segmental coronary artery pathoanatomy. Q-wave amplitudes were measured in 41 patients with coronary artery disease (CAD) before and immediately after treadmill exercise. All patients studied had either significant single-vessel CAD (>70% diameter reduction) or normal coronary anatomy; 13 had left anterior descending (LAD) CAD, 8 had right coronary occlusions, 8 had left circumflex (LC) CAD, and 12 had angiographically normal coronary arteries.**

**Septal Q-wave amplitude measurements at rest and during peak exercise were recorded in 0.5 mm increments and classified as increasing in 20 patients, decreasing in 8, and no change in 13 with exercise. All 13 patients with isolated LAD narrowing had either no change (5 patients) or a decrease (8 patients) in the septal Q wave with exercise. Statistical analysis revealed 62% sensitivity and 100% specificity for single LAD narrowing if a decreasing Q wave was noted with exercise. Patients with isolated right or LC CAD or normal coronary anatomy had mixed septal Q-wave responses to exercise. Only patients with LAD narrowing had reductions in Q-wave amplitude with treadmill exercise. This finding suggests that low Q-wave voltage and its failure to increase after exercise imply abnormal septal activation, reflecting loss of contraction associated with ischemia from LAD narrowing.**

Exercise testing is a valuable noninvasive tool for diagnosing and monitoring CAD.[1-3] S-T segment depression is considered the hallmark of exercise-induced myocardial ischemia.[4] Unfortunately, the predictive value of the S-T segment response in exercise is subject to the population tested and fails to distinguish with certainty those with or without CAD.[5] As a result of this incidence of false-positive and false-negative results from exercise tests employing analysis of the S-T segment alone, other electrocardiographic indexes have been developed to enhance the diagnostic and prognostic value of exercise testing.[6-8] Additionally, multivariate analysis has been proposed to enhance the accuracy of the exercise test.[9,10]

We recently reported our experience with the septal Q wave in exercise testing.[11] In 100 patients evaluated with exercise tests and coronary angiography, the septal Q wave in bipolar lead $CM_5$ is smaller in patients with CAD than in normal subjects both at rest and in the immediate postexercise recovery period ($p < 0.001$) (Fig. 1 and 2). The average septal Q wave in patients with CAD was 0.5 mm at rest and 0.5 mm in immediate postexercise recovery period. The average septal Q wave in normal patients was 1.0 mm at rest and 2.0 mm in the immediate postexercise recovery period. An increase in the septal Q-wave amplitude with exercise identified a false-positive S-T segment response to stress in 75%

of the cases. Absence of the septal Q wave in bipolar lead $CM_5$ with S-T segment depression identified a true-positive response in 100% of the cases studied. Thus, measurement of the septal Q wave appears to be a useful adjunctive measurement in exercise testing, with its major application in confirming a true-positive response with concomitant S-T segment depression. These data suggest that low septal Q-wave voltage and its failure to increase with exercise imply abnormal septal activation, reflecting loss of contraction associated with ischemia. Unfortunately, specific localization of this electrocardiographic event with coronary artery pathoanatomy was difficult, since 77% of the patients with CAD studied had 2- or 3-vessel disease. This report focuses on the septal Q wave in exercise and corresponding coronary artery segment pathoanatomy (Fig. 1 and 2).

## Methods

**Patients:** The patient were sequentially selected from a computer search of our files to obtain subjects who had both exercise testing and coronary angiograms that fulfilled the criteria necessary for the study; normal coronary anatomy or single-vessel CAD (luminal diameter reduction >70%). No patient was previously studied. Treadmill exercise test records and coronary angiograms of patients referred for evaluation of chest pain were reviewed retrospectively. Patients with an abnormal electrocardiogram at rest were excluded, including left ventricular hypertrophy, right ventricular hypertrophy, left bundle branch block, right bundle branch block, or preexcitation syndromes. Patients with the clinical diagnosis of valvular heart disease or myocardial infarction, and patients taking digitalis or beta-adrenergic blocking drugs were excluded. Of 41 patients studied, 12 had normal coronary anatomy (9 men and 3 women aged 45 to 68 years [mean 62]); 13 had LAD CAD, 8 had right CAD, and 8 had LC CAD. Patients with CAD were aged 36 to 67 years (mean 61); 15 were men and 14 women.

**Treadmill stress test:** The interval between the exercise test and the coronary angiogram ranged from 1 to 60 days. Patients were subjected to a progressive maximal exercise test according to the Ellestad protocol using a 3-lead system consisting of a bipolar lead $CM_5$, a bipolar lead III, and unipolar lead $V_1$. Significant S-T segment depression was upsloping in the immediate postexercise period. The 3 electrocardiographic leads were monitored simultaneously and continuously during and after exercise. All subjects with normal coronary angiogram results were exercised to ≥90% of their normal age-predicted heart rate response to exercise. The septal Q wave was measured only in the bipolar lead $CM_5$ in the period immediately after exercise with the patient standing. This Q wave was compared with that in the standing control period. A 10 mm/mV calibration was used. The septal Q-wave amplitude was measured from the isoelectric line for 5 to 10 beats. The average amplitude was approximated to the nearest 0.5 mm increment. The septal Q waves were measured by either the first or second author and reviewed by the fourth. The treadmill exercise test was examined independently without prior knowledge of the coronary angiogram.

**Cardiac catheterization:** This procedure was performed using either the Sones or Judkins technique. No patient had clinical heart failure at the time of catheterization. Coronary angiography was performed using 35 mm film with multiple views. Single plane left ventricular angiography was performed in the right anterior oblique projection. The criteria for diagnosis of CAD was >70% diameter reduction of the lumen of the artery.

The coronary anatomy and left ventricular angiogram were graded without prior knowledge of the exercise test results by

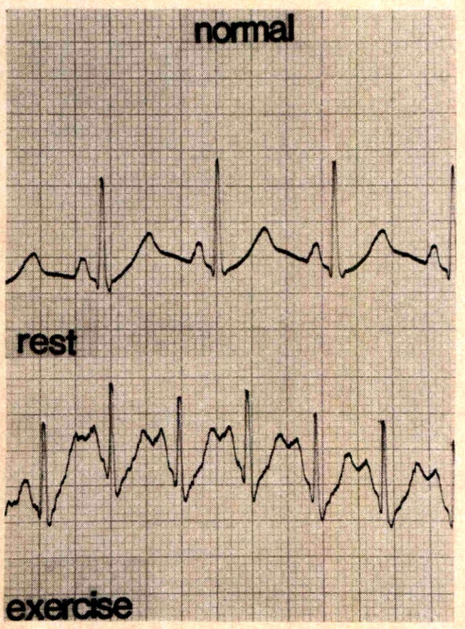

**FIGURE 1.** Q-wave response to exercise in a patient with normal coronary anatomy. The surface electrocardiogram (lead $CM_5$) demonstrates increased Q-wave amplitude with exercise.

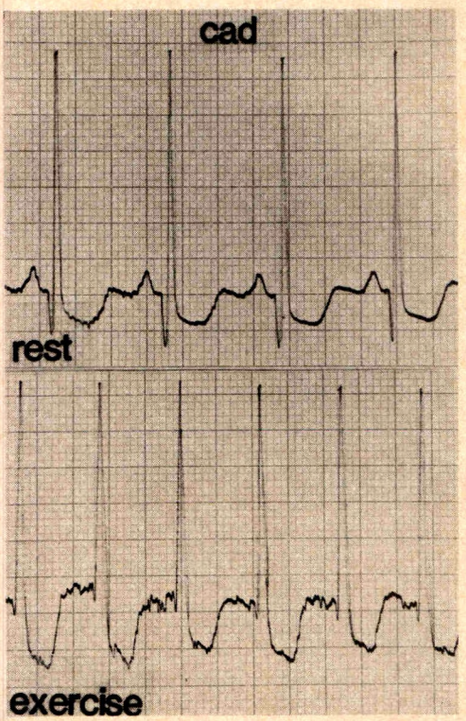

**FIGURE 2.** Q-wave response to exercise in a patient with single-vessel left anterior descending coronary artery disease (cad).

2 independent observers; any discrepancies were resolved by a third observer.

**Statistical evaluation:** Sensitivity was defined as true-positive responses/true-positive + false-negative responses. Specificity was defined as true-negative responses/true-negative + false-positive responses. The sensitivity, specificity, and predictive value for the septal Q-wave change was determined and compared within the multiple patient cohorts.

## Results

**Normal coronary anatomy:** Of the 12 patients with normal coronary angiograms, 9 had an increase in septal Q-wave amplitude with exercise. The increase in septal Q-wave amplitude with exercise was 0.5 mm in 6 patients and 1.0 mm in 3 patients. Three patients had no change in septal Q-wave amplitude with exercise. No patient had a loss of septal Q-wave amplitude with exercise (Fig. 3).

**Single vessel coronary artery disease:** *Left anterior descending:* Of the 13 patients with significant stenosis (>70% cross-sectional area luminal narrowing) isolated to the LAD coronary artery, 8 (62%) had diminution of their septal Q-wave amplitude with exercise. This loss in septal Q-wave amplitude with exercise was 0.5 mm in 4 patients and 1.0 mm in 4 patients. Five patients had no change in septal Q-wave amplitude with exercise. No patient exhibited an increase in septal Q-wave amplitude with exercise (Fig. 3).

*Left circumflex:* Of the 8 patients with isolated significant stenosis to the LC coronary artery, none demonstrated a reduction of septal Q-wave amplitude with exercise. An increase in septal Q-wave amplitude with exercise was present in 5 patients: 0.5 mm in 1 patient, 1.0 mm in 3 patients, and 2.5 mm in 1 patient. Three patients had no change in septal Q-wave amplitude with exercise (Fig. 3).

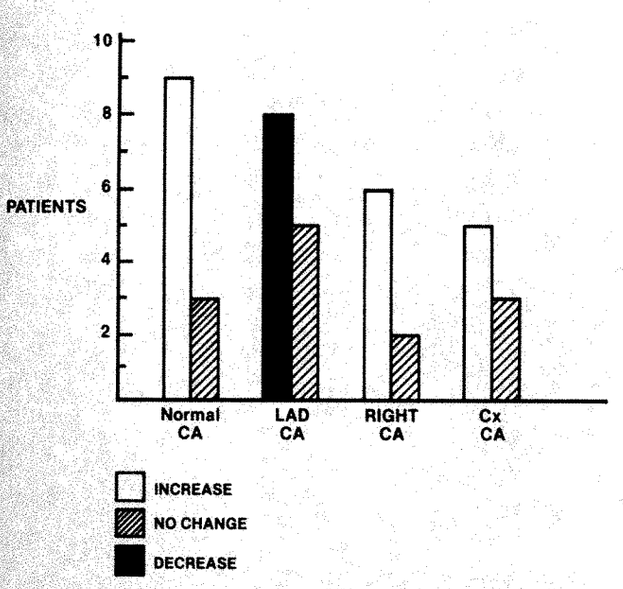

**FIGURE 3.** Septal Q-wave response to exercise in patients with normal or single-vessel coronary artery disease. A decrease in Q-wave amplitude with exercise is seen only in patients with left anterior descending (LAD) coronary artery disease. CA = coronary anatomy; Cx = circumflex.

**TABLE I Statistical Analysis of Septal Q-Wave Response to Exercise and Single Vessel Left Anterior Descending Coronary Artery Disease**

| | Sensitivity | | Specificity | | Predictive Value | |
|---|---|---|---|---|---|---|
| | n | % | n | % | n | % |
| Decreasing Q wave | 62 | 8/13 | 100 | 33/33 | 100 | 8/8 |
| Decreasing or no change in Q wave | 100 | 13/13 | 71 | 20/28 | 62 | 13/21 |

*Right:* Of the 8 patients with significant stenosis isolated to the right coronary artery, none demonstrated a reduction of the septal Q wave with exercise. An increase in septal Q-wave amplitude with exercise was recorded in 6 patients: 0.5 mm in 4 patients, 1.0 mm in 1 patient, and 2.0 mm in 1 patient. Two patients had no change in septal Q-wave amplitude with exercise (Table I).

## Discussion

**Q wave and resting electrocardiography:** Initial ventricular activation originates from the ventricular septum, with Q waves being recorded in both the frontal and precordial planes. Normal Q-wave ranges of amplitude and duration have been previously reported.[12,13] In 1955, Burch[14] described an electrocardiographic syndrome characterized by absence of the Q wave in leads 1, aVL, $V_5$, and $V_6$ due to septal fibrosis. In 1960, Burch and De Pasquale[15] reported cardiac pathologic findings in 142 patients with this electrocardiographic syndrome. Occlusive CAD usually involving the LAD coronary artery or scarring in the septum with little or no scarring in other areas of the myocardium was common. They concluded that the mechanism of the septal fibrosis in patients with prolonged periods of angina pectoris is obscure, but may be due to spasm of the penetrating septal arteries with progressive myocardial injury and eventually septal fibrosis. The changes were confirmed vectorcardiographically by Cabrero.[16]

**Q wave and exercise electrocardiography:** Bruce et al[17] studied 73 volunteers undergoing maximal treadmill exercise testing. Increase in Q-wave amplitude was seen as a normal response to exercise ($p < 0.01$). Recently, Wolthuis et al[18] reported that lead $CM_5$ had the most prominent Q wave and attained the most negative amplitude with exercise.

The current literature is scant with reports of exercise Q-wave responses in patients with abnormal coronary anatomy. Greenspan et al[19] prospectively evaluated and correlated exercise-induced Q waves during treadmill testing with findings at cardiac catheterization. Of 560 patients undergoing treadmill exercise testing, 13 had new Q waves in leads $V_1$ through $V_3$ and 1 had exercise-induced Q waves in leads II, III, and aVF. Of 10 patients who underwent cardiac catheterization, 6 had normal coronary anatomy and 2 had documented previous anterior myocardial infarction. The authors

concluded that exercise-induced Q waves were not diagnostic of underlying coronary disease.

In a recent report, we studied exercise Q-wave responses in bipolar lead $CM_5$. Q-wave amplitude was measured in 50 patients with CAD and 50 normal subjects in the control (pretest) and immediate postexercise period. In 100 patients evaluated by coronary angiography, the septal Q-wave lead $CM_5$ was smaller in patients with CAD than in normal subjects at rest and during the immediate postexercise period. Absence of or embryonic (0.5 mm) Q wave in lead $CM_5$ was significantly more common in patients with CAD at rest and after exercise than in normal subjects. An increase in Q-wave amplitude with exercise identified a false-positive S-T segment response to exercise in 75%, and absence of the Q wave in lead $CM_5$ with S-T segment depression after exercise identified a true-positive response in 100% of the cases. Low Q-wave voltage and failure to increase after exercise suggested a reduction in the septal current of depolarization, reflecting loss of contraction associated with ischemia of the septum. Of our 50 patients with coronary heart disease, 45 had LAD narrowing in addition to narrowings in other coronary arteries.

This report focuses on the correlation of coronary artery pathoanatomy with the exercise septal Q-wave response. All 13 patients with isolated LAD narrowing had either no change (5 patients) or a decrease (8 patients) in the septal Q wave with exercise (Fig. 3). Statistical analysis revealed 62% sensitivity and 100% specificity for single-vessel LAD coronary narrowing if a decreasing Q wave was noted with exercise (Table I). Patients with isolated right or LC narrowing or normal coronary arteries had mixed septal Q-wave responses to exercise; 20 patients had an increase while 13 patients had no change in septal Q wave with exercise. Only patients with LAD narrowing had reduction in Q-wave amplitude with exercise. The 100% sensitivity seen with a decreasing or no change in Q-wave amplitude for LAD narrowing (13 of 13 patients) most likely will decrease as the population studied increases. In a previous longer study,[11] 45 patients with LAD narrowing had a sensitivity of 87% when analyzing a decrease or no change in the exercise Q wave.

This study implies that a decreasing septal Q wave with exercise denotes LAD coronary narrowing and is of benefit in analysis of the S-T segment depression. The exclusions in this study diminish the number of problems related to misinterpretation of the exercise test and the predictive value might be reduced in an expanded population.

# Surgery for Coronary Heart Disease Due to Mucocutaneous Lymph Node Syndrome (Kawasaki Disease)

## Report of 6 Patients

SOICHIRO KITAMURA, MD, KANJI KAWACHI, MD, RYOICHI HARIMA, MD, TETSUO SAKAKIBARA, MD, HAJIME HIROSE, MD, and YASUNARU KAWASHIMA, MD

**Early and late surgical results in 6 patients with coronary heart disease secondary to mucocutaneous lymph node syndrome (MLNS) (Kawasaki disease) are presented. There were 5 male patients and 1 female patient, ranging in age from 2.5 to 26 years at the time of operation. They had severe coronary artery narrowings, obstructions, and aneurysms with or without mitral regurgitation. Previous myocardial infarction was documented in 5 patients. Aortocoronary bypass grafting utilizing the autologous saphenous vein was performed in 5 patients; in the remaining patient, mitral valve replacement was carried out.**

**No operative or late deaths have been encountered. A long-term bypass graft patency was demonstrated in patients aged 26, 17, and 10 years with resulting clinical, angiographic, or scintigraphic improvements, or a combination of these. However, the graft that had been patent in a 4-year-old boy was found completely obstructed 3 years after surgery without any symptomatic changes. The formation of rich collateral channels was found. The risk of saphenous vein graft closure may be high in young growing children. In older children or adolescents, however, coronary vein bypass grafting for this specific inflammatory coronary artery lesion has been effective with long-term graft patency. Severe mitral regurgitation is also an indication for surgery, but poor left ventricular function associated with mitral regurgitation, probably secondary to myocarditis, persists after surgery and may give rise to future problems.**

It is now well known that mucocutaneous lymph node syndrome (MLNS) or Kawasaki disease causes inflammatory coronary arterial and myocardial lesions that may result in coronary artery aneurysms, obstructions, embolism, myocardial infarction, or papillary muscle dysfunction, or a combination of these. Surgery has been attempted for these inflammatory coronary artery lesions and sequelae of myocardial injury such as papillary muscle dysfunction resulting in mitral insufficiency.[1–7] However, the significance and late results of surgical treatment for MLNS have not yet been reported. This report reviews our surgical experiences with 6 patients, and describes late results and problems after surgery.

### Methods

**Patients:** Clinical and angiographic features of 6 patients treated surgically are presented in Table I. There were 5 male patients and 1 female patient; their ages at operation ranged from 2.5 to 26 years. Five patients underwent aortocoronary bypass grafting using autologous saphenous veins; 1 patient aged 2.5 years had mitral valve replacement with use of a porcine xenograft for severe mitral regurgitation secondary to papillary muscle infarction. The patients underwent surgery at least 1 year after the subsidence of acute illness of MLNS. Left main trunk lesions were present in 3 patients; 3-vessel lesions including coronary aneurysms, narrowings, and obstructions were noted in 4 patients. Electrocardiography documented myocardial infarction in 5 patients, inferior wall infarcts in 3, and anteroseptal infarcts in 2. Mitral regurgitation was demonstrated in 2: 1 patient (Case 1) with a 38% regurgitant ratio and the other (Case 4) with 71% severe regurgitation. The left ventricular ejection fraction calculated from cineangiograms ranged from 0.35 to 0.56. Except for Case 4, the ejection fractions were maintained well over 0.4.

Among the 6 patients, no operative or late deaths have been encountered. The postoperative follow-up periods extended

**TABLE I Surgery for Heart Disease Due to Mucocutaneous Lymph Node Syndrome**

| Case | Age (yr) & Sex at Op | MI | MR | Coronary Arteries (N or A) | Preop LVEF | CABG | Grafts Patent | Postop NYHA |
|---|---|---|---|---|---|---|---|---|
| 1 | 26M | + | + | LM, LAD, R | 0.41 | + (LAD, R) | + (3 yr) | II |
| 2 | 4M | + | − | LAD, LC, R | 0.45 | + (LAD, R) | + (1 mo), − (3 yr) | I |
| 3 | 4M | + | − | R | 0.56 | + (R) | No study | I |
| 4 | 2.5M | + | + | LM, R | 0.35 | −, MVR | . . . | I |
| 5 | 17M | + | − | LAD, LC, R | 0.46 | + (LAD, LC) | + (2.5 yr) | I |
| 6 | 10F | − | − | LM, LAD, R | 0.54 | + (LAD, R) | + (LAD, 1 yr), − (R) | I |

A = aneurysm; CABG = coronary artery bypass graft; LAD = left anterior descending artery; LC = left circumflex artery; LM = left main; LVEF = left ventricular ejection fraction; MI = myocardial infarction; MR = mitral regurgitation; MVR = mitral valve replacement; N = narrowing or obstruction; NYHA = New York Heart Association functional class; Op = operation; Postop = postoperative; Preop = preoperative; R = right coronary artery; + = yes; − = no.

from 1 to 8 years. At present, Patient 1 is in the NYHA[8] functional class II and the remaining 5 patients are in class I. Patient 4 has been receiving digitalis and Patient 5 has been taking a small dose of procainamide for arrhythmia. The other patients are medication-free at present.

The operative techniques used for these patients were essentially the same as those used for adult patients with atherosclerotic coronary artery disease. Under cardiopulmonary bypass with moderate hypothermia, aorta-graft anastomosis was performed with 6-0 monofilament sutures and graft-coronary artery anastomosis was carried out with 7-0 monofilament sutures. Both continuous and interrupted sutures were used. The graft material used for the 5 patients were all autologous saphenous veins harvested from the patients' thighs. Brief histories of the patients follow.

## Case Reports

**Patient 1** had a large anteroseptal infarction at age 26 years; study revealed the presence of a large left main trunk aneurysm with stenosis of the left anterior descending artery and total occlusion of the right coronary artery. This patient had a history of high fever associated with skin rash at age 14 years which was diagnosed as probable rheumatic fever at that time. We included this patient in our series because of close similarity to the lesions of MLNS (MLNS has also been reported in young adult patients[9,10]). Two aortocoronary bypass grafts were placed to the left anterior descending and right coronary arteries. The grafts was demonstrated angiographically to be widely patent 3 years after surgery with asymptomatic total occlusion of the left main trunk aneurysm.[1] This patient had had total obstruction of the right coronary artery before operation, and therefore at present, all of his original coronary arteries are obstructed. Postoperative angiograms also showed the irregular coil-shaped posterior descending artery. He has been working daily in the office with some easy fatigability for 8 years after operation.

**Patient 2** was a 4-year-old boy who had temporary circulatory arrest (possibly ventricular fibrillation) with spontaneous recovery after anteroseptal infarction. Total obstructions of the right coronary and left anterior descending coronary arteries, and a small aneurysm of the origin of the circumflex artery were demonstrated by selective coronary arteriography[11] at age 3 years. He underwent double aortocoronary bypass grafting to the right coronary and left anterior descending coronary arteries utilizing the autologous saphenous vein. Two grafts were widely patent 1 month after operation.[2] However, both grafts were found to be totally occluded 3 years after surgery with no symptomatic changes. The restudy was performed in this patient for the purpose of an angiographic follow-up. At present, there are no signs of myocardial ischemia detectable either with exercise electrocardiography or exercise thallium-201 myocardial scintigraphy. It was impossible to identify the time of graft occlusion during the 3-year follow-up. The obstructed right coronary and left anterior descending arteries were perfused by the excellent intra- and intercoronary collateral channels. The distal right coronary artery was connected with the well-developed intracoronary collateral vessels and the left anterior descending artery was perfused through the conus branch of the right coronary artery, proximally and through the apical branch of the circumflex artery, distally.

**Patient 3** was also a 4-year-old boy who sustained an small inferior wall myocardial infarction subsequent to total obstruction of the origin of the right coronary artery. He underwent coronary bypass grafting to the large dominant right coronary artery. He has been followed up for 6 years and is doing well at present, but an angiographic restudy has not yet been performed because of postoperative hepatitis.

**Patient 4** had congestive heart failure and cardiac cachexia at age 2.5 years resulting from severe mitral regurgitation that occurred after inferior wall infarction.[4] The right coronary artery was totally occluded near its origin. The cause of mitral regurgitation was papillary muscle dysfunction, and his left ventricular contraction was markedly depressed with an ejection fraction of 0.35. He underwent mitral valve replacement using a 27 mm porcine xenograft and has been followed up for 3 years. Postoperatively, the left atrial volume has decreased significantly from 220 to 84 ml/m$^2$; however, generalized poor contraction of the left ventricle has not been improved with an actual reduction of the ejection fraction from the preoperative value of 0.35 to 0.26 after operation. The contraction impairment of the left ventricle in this patient is much worse than expected from the electrocardiographic inferior wall infarction, and this fact may suggest the associated myocardial involvement subsequent to MLNS myocarditis. Little pathologic change was identified in the excised mitral leaflets, but extensive myocardial injury with fibrosis was demonstrated in the posterior papillary muscle.[4] The porcine xenograft that has been implanted in this patient has recently shown degenerative changes with resultant stenosis. Reoperation may be required in the future.

**Patient 5** was a 17-year-old boy who had a history of MLNS at age 4. He had been doing well until 1 year before operation, when multiple and repetitive premature ventricular contractions appeared and worsened during exercise, accompanied by a fainting sensation. However, angina pectoris was not apparent. Left ventriculography demonstrated reduced contraction of the anterior and inferior walls with a global ejection fraction of 0.46. Coronary arteriography demonstrated total occlusion of the right coronary artery with intracoronary collateral formation and severe proximal stenoses of the left anterior descending and left circumflex arteries associated with aneurysms (Fig. 1, top). Although he had no obvious angina pectoris, the presence of severe coronary narrowing and refractory ventricular ectopic contractions during exercise prompted surgery. Two aortocoronary saphenous vein bypass grafts were placed to the left anterior descending and circumflex arteries. Ventricular ectopic beats have become controlled with a small dose of procainamide after operation. Two grafts have been patent for 2.5 years after surgery (Fig. 1, bottom). At present, the patient is completely asymptomatic with excellent exercise ability.

**Patient 6** was a 10-year-old girl who had MLNS at age 7. She noted an oppressive feeling in the anterior chest while exercising. A study revealed the presence of a large aneurysm in the left main trunk with a total occlusion of the left anterior descending artery at its origin,

filled retrogradely from the circumflex artery. The right coronary had a small aneurysm at its origin (Fig. 2, top). Hypoperfusion in the anterior wall was clearly demonstrated by exercise thallium-201 myocardial scintigraphy with recovery 2 hours after exercise by the redistribution study. The patient underwent double aortocoronary bypass grafting to the left anterior descending and right coronary arteries using the autologous saphenous vein and is now completely free from angina pectoris.

Angiographic and scintigraphic evaluations were repeated 1 year after operation. The thallium-201 uptake defect during exercise observed in the anterior wall of the left ventricle before surgery improved significantly after revascularization. The left anterior descending coronary graft was patent. Although the right coronary artery graft was closed, the original right coronary artery was patent with no scintigraphic perfusion defects (Fig. 2, bottom).

## Discussion

Studies regarding surgical treatment for coronary heart disease subsequent to Kawasaki disease are still very limited,[1–7] and little is known of the indications for and long-term results of surgical treatment for this inflammatory pediatric coronary artery disease. We are most concerned with the long-term significance of surgical treatment for this disease and the fate of the saphenous vein aortocoronary bypass grafts implanted during childhood. Although our surgical experiences are also limited, we discuss here some of the findings obtained from 6 patients who underwent surgery.

From our experience, we have confirmed that aortocoronary bypass surgery is effective in selected patients with coronary lesions resulting from Kawasaki disease. Clinical, functional,[2,12] and scintigraphic evaluations in early and late postoperative periods have shown that aortocoronary bypass grafts are functioning well long after operation in our older children or adolescents. In younger children, however, long-term patency of aortocoronary autologous saphenous vein bypass grafts cannot be confirmed from our results. In a 4-year-old boy, the graft that had been patent 1 month after op-

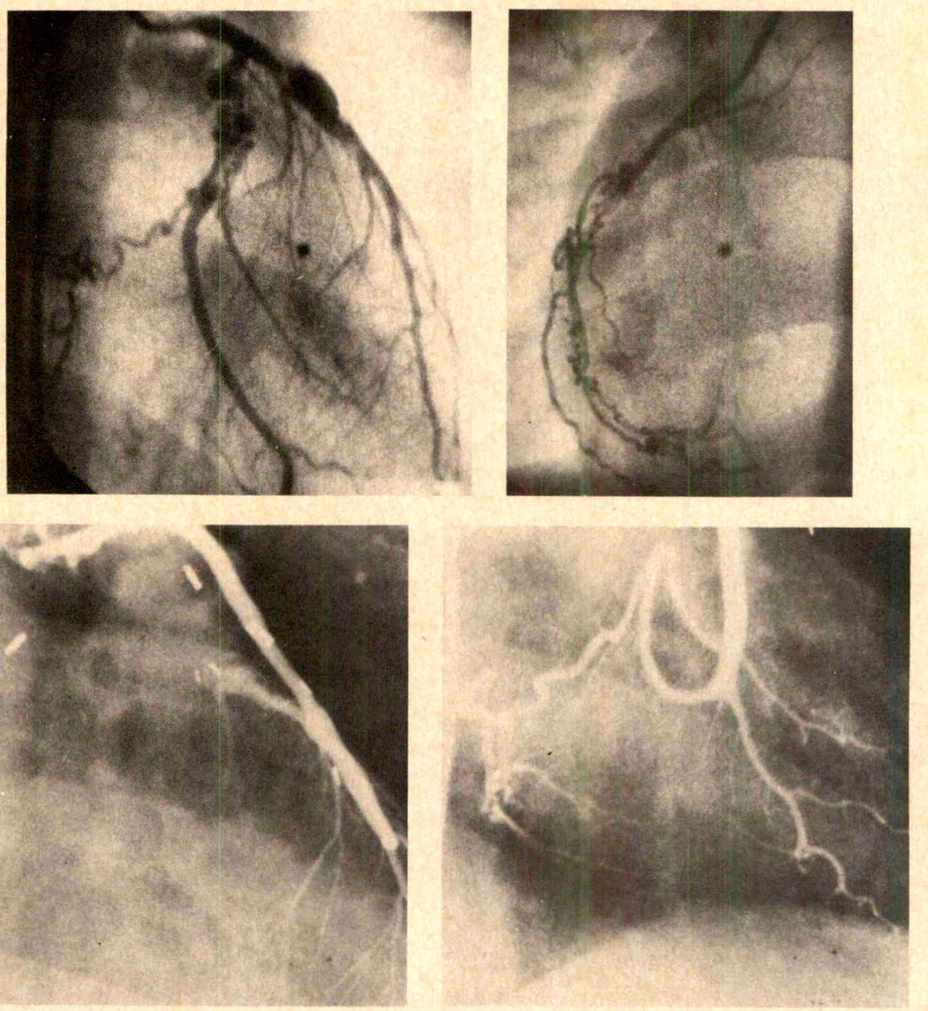

**FIGURE 1.** Patient 5. Pre- and postoperative coronary arteriograms. **Top left,** an aneurysm and a severe stenosis just proximal to the aneurysm were present in the left anterior descending artery. The circumflex arteries had stenosis with coil-shaped collateral connections. **Top right,** the right coronary artery was occluded with intracoronary collateral connections. The autologous saphenous vein bypass grafts to the left anterior descending artery (**bottom left**) and the circumflex artery (**bottom right**) are patent 2.5 years after surgery. The patient is now completely asymptomatic.

eration was found completely occluded 3 years later with no symptomatic changes. Rich collateral channels maintained the adequate myocardial perfusion and, thus, the graft appeared to have occluded slowly. The cause of graft occlusion in this child is not clear. Graft closure might have resulted from simple degenerative mediointimal hyperplasia, but failure of nongrowing conduits in the growing heart of children has been considered[2]; this hypothesis cannot be denied from our present experience. The internal mammary artery graft, although technically more difficult to perform in small children, may be more adequate because it may simultaneously grow, whereas the saphenous vein conduit does not.

**Conclusion:** From our limited experience, in conjunction with that reported by others,[5–7] we believe that aortocoronary bypass grafting utilizing autologous saphenous veins is effective in the treatment of MLNS coronary artery lesions at least in selected older children or adolescents. The adequate age for coronary revascularization in Kawasaki disease has not yet been determined. Judging from our experiences and those of others,[2,6] we consider that an age over rather than under 8 to 10 years would be more appropriate for the use of nongrowing saphenous vein conduits, although more clinical evaluation is required.

Mitral regurgitation due to Kawasaki disease is usually associated with poor left ventricular function

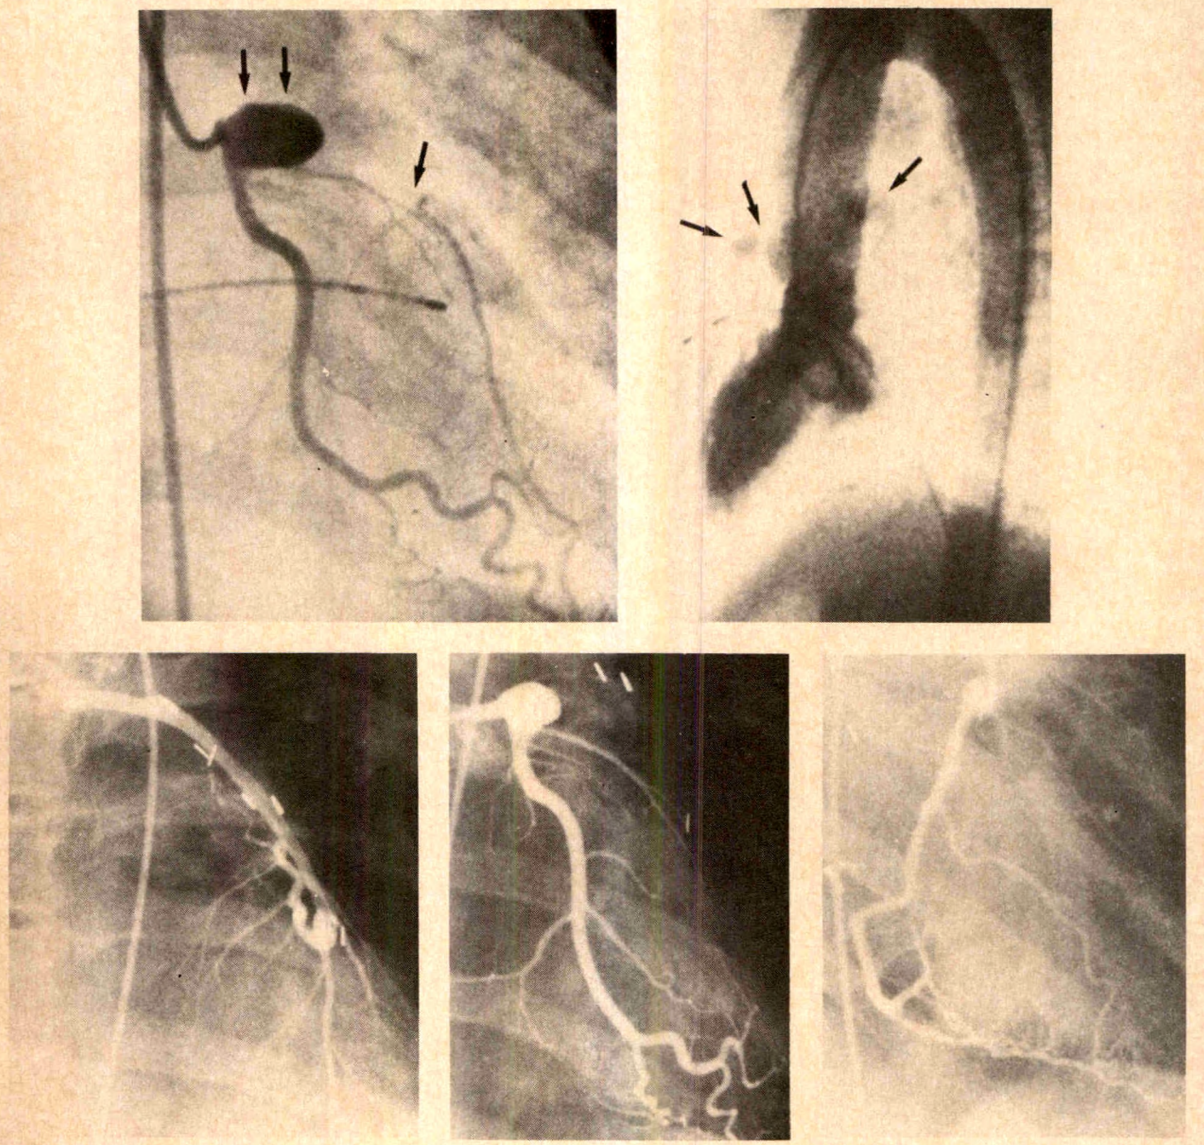

**FIGURE 2.** Patient 6. Pre- and postoperative coronary arteriograms. **Top left,** a large aneurysm was present in the left main artery with the left anterior descending artery totally occluded at its origin and retrogradely filled through the apical connection with the circumflex artery. **Top right,** a small aneurysm was present at the origin of the right coronary artery. **Bottom left,** the graft to the left anterior descending artery is patent 1 year after surgery. **Bottom center,** the circumflex artery is patent, originating from the left main trunk aneurysm which is somewhat reduced in size. **Bottom right,** although the right coronary graft has been occluded, the original right coronary artery is patent with no flow delay.

and complicated coronary artery lesions.[4] Mitral valve replacement[4] or repair[3] has offered good clinical amelioration, but long-term results have not been fully warranted not only because of the unavailability of suitable valve prostheses in children, but also because of associated poor left ventricular function probably secondary to accompanying myocarditis.[4]

# The Changing "Natural History" of Symptomatic Coronary Artery Disease: Basis Versus Bias

LEE GOLDMAN, MD, GILBERT H. MUDGE, Jr., MD, and E. FRANCIS COOK, MS

**In contrast to the 20 to 30% reduction in ischemic heart disease mortality that has been demonstrated by national mortality statistics and by several randomized controlled trials, an uncritical reading of recent "natural history" studies suggests far greater improvements in the survival of symptomatic coronary patients. Although the intrinsic accuracy of such natural history studies is not questioned, attempts to compare patients from different studies and different eras may greatly overestimate the true improvement in natural history because of at least 3 biases in the selection of cases from the spectrum of diseased patients. Because of lead-time bias, patients who are diagnosed earlier live longer regardless of whether interventions are efficacious. Because of referral bias, current patients may have symptoms or anatomy that place them at a different stage of severity than patients who were chosen for earlier studies. Because of incidence-prevalence bias, prevalence studies will be over-represented with survivors of previous incidence cohorts who have slower-progressing disease. We suggest that all natural history studies be carefully scrutinized for such biases before they are compared with each other.**

National statistics indicate that the mortality rate from coronary heart disease (CAD) and acute myocardial infarction declined by about 20% in the United States between 1968 and 1978.[1-5] At the same time that these national mortality rates have been declining, several investigators have reported that the prognosis of their own patients with medically[6] or surgically[7] treated CAD is substantially better than what was reported a decade or so ago. Citing data from several randomized controlled trials,[8-12] some authors have attributed their own uncontrolled observations to improvements in the management of symptomatic patients. However, recent reports of annual mortality rates as low as 1.4%/year[6,7] represent a 76% reduction in annual mortality compared to data from the mid-1960s. This percent reduction is far greater than the change in national mortality statistics or the reductions in mortality that have been reported in any randomized controlled trials of comparable patients. We do not dispute the intrinsic accuracies of any of the uncontrolled studies from the past decade, nor do we dispute the contention that most of the reported patients have done well. We are concerned, however, when "doing well" is equated with "doing better" than patients from different eras or patients from different centers in the same era, because such comparisons are extremely hazardous.

The following discussion demonstrates that attempts to match patients based on 1 or 2 variables such as the number of stenotic vessels or the results of exercise tolerance tests are inadequate for a disease with as broad a spectrum of severity as atherosclerotic CAD. Although epidemiologists have often disagreed about nomenclature, ample methodologic evidence indicates that several distinct types of bias can account for much of the apparent improvement in the prognosis of symptomatic patients with medically treated CAD.[13-18]

## Types of Bias in Patient Selection

To understand the principles of selection bias, it is important first to recognize that many diseases include a wide spectrum of patients[18] who are different in terms

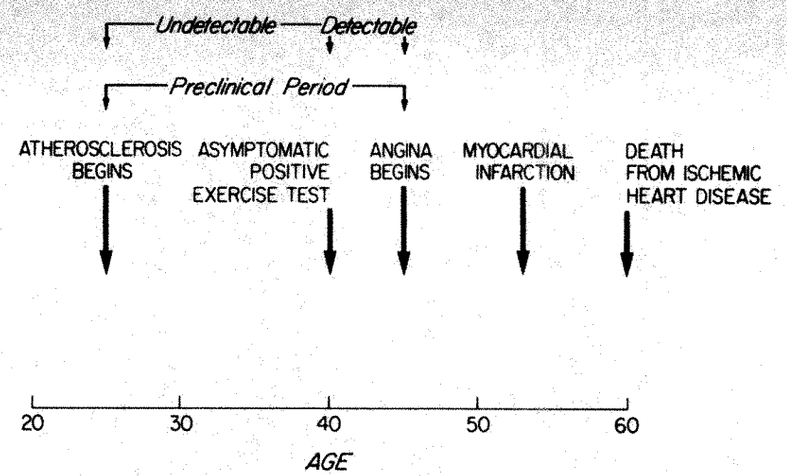

**FIGURE 1.** Natural history of a prototypical patient with CAD. Atherosclerosis begins as an asymptomatic and undetectable pathologic process, proceeds through a detectable preclinical period, and then has a symptomatic period with a duration and expression that vary from patient to patient. If diagnosis is made during the detectable preclinical period, life expectancy is longer than if the disease is diagnosed later, even if there is no difference in the efficacy of the management of the 2 patients (lead-time bias). The reported natural history of a group of symptomatic patients would also depend on their original distribution within the symptomatic phase (referral bias). Even if all patients are at the same phase of the disease when they are originally entered into a study, some will have rapidly progressive and some will have slowly progressive disease. Because the patients with rapidly progressive disease spend less time at any given stage, selecting patients at a particular stage will tend to over-represent the slowly progressive patients and thus to make natural history seem better in a prevalence study than it would in an incidence study (incidence-prevalence bias).

of the severity or the rate of progression of their disease and who thus have different prognoses. The natural history of a particular group of patients with the disease will depend upon the spectrum of patients who are selected for observation.

**Lead-time (starting-time) bias:** Patients whose disease is diagnosed earlier, such as patients whose asymptomatic breast carcinomas are discovered by mammography, may live longer from the time of diagnosis simply because the diagnosis was made earlier and not because any subsequent therapy was efficacious.[13–17] Much like many cancers, atherosclerotic CAD has a long natural history, and it includes several phases (Fig. 1). Autopsy studies from the Korean and Vietnam wars have demonstrated that atherosclerotic lesions in the coronary and systemic arterial circulations may be present in the third decade of life.[19,20] However, most of the affected persons will not become symptomatic or have any signs of CAD detectable by available diagnostic tests for many years. In a prototypical patient (Fig. 1), we speculate that the first diagnosable evidence of CAD may not be present until a person is approximately 40 years old, and an exercise tolerance test, or some other diagnostic test such as an exercise thallium or left ventricular function test, would show abnormalities that are suggestive of CAD. It is assumed that at this time coronary angiography would also document atherosclerosis, even though the anatomical lesions might not be so severe as to warrant surgical or perhaps even medical intervention. At some time after the coronary lesions have been present, the patient will develop symptoms of CAD; the first symptom will usually be angina, but a myocardial infarction will sometimes precede angina.[21] In general, as the patient's anatomic disease progesses, the symptoms will progress as well. A patient who begins with angina that is mild and present only with marked exertion will commonly have the angina gradually worsen, and the course may be punctuated by episodes of unstable angina or myocardial infarction. A patient who presents anew with a first myocardial infarction is likely to have recurrences or to have persistent angina after the infarction. Eventually, the majority of patients with symptomatic CAD will die from their disease and not from some other condition.

The exact time frames displayed in Figure 1 may be prototypical, but they are by no means representative of the course of every patient with CAD. However, issues regarding lead-time bias should be relevant regardless of whether the time spans were contracted or widened. The basic principle is that most patients have an undetectable preclinical phase during which the pathologic process of atherosclerosis is not diagnosable by any available technology.[15] This phase is followed by a detectable preclinical phase during which an exercise test or some other diagnostic test could reveal evidence of atherosclerosis before the patient has any symptoms. It should be obvious that if patients are entered into a study during this preclinical phase, their natural history should be longer than the natural history of patients who are entered in the symptomatic phase, regardless of whether any interventions were actually efficacious for preclinical patients. Similarly, if patients are entered during the early clinical phase, such as when angina is minor or an uncomplicated myocardial infarction has not resulted in serious residual arrhythmias or left ventricular dysfunction, their natural history will be better than the natural history of patients who have had complicated myocardial infarctions or who have unstable angina pectoris. Thus, one would not be surprised

to find that patients who were catheterized for severe angina during the era of internal mammary artery implantation had worse prognoses than current patients who have minimal symptoms and positive exercise tests. This difference in prognosis, based purely on the stage of the disease and not on the efficacy of any intervening therapies, has been called lead-time bias[14,15] or starting-time bias.[16,18]

**Referral (transition) bias:** Another form of bias, which has been termed referral[18] or transition[16] bias, concerns the way in which diseased members of the general population become patients in a particular study at a particular hospital. For example, when a new diagnostic test or a new therapeutic maneuver first becomes available, only the sickest patients are usually studied. If the new technology appears beneficial for these patients, its application will commonly be expanded to include patients who are not as sick. Thus, at first, cardiac catheterizations were performed only on very symptomatic patients who might proceed to internal mammary artery implantations.[22–24] The natural history of such patients would tend to be worse than the natural history of the broader range of patients who had angina. Once a particular therapy or diagnostic procedure is believed to be efficacious, the kinds of patients who are referred for it will tend to be less sick than the original type of patients with whom the therapy or procedure was first tried. These patients will have an inherently better prognosis than the original group of patients, and their better outcome may be due to this inherently better prognosis rather than to improvements in management. Referral bias would also explain how physicians who believe in the efficacy of more conservative therapies may have a large preponderance of patients with better prognoses, simply because primary physicians do not send them their most symptomatic cases.

**Prevalence-incidence (length) bias:** A less obvious type of bias results when one tries to compare natural history based on a study of incident cases to natural history based on a study of prevalent cases[15,17] (Table I). In the former situation, the study population consists entirely of new (incident) cases of the disease that were enrolled into the study at the time of diagnosis. Because of the inherent variability of most diseases, the incident cases will include cases with both short and long survival times. Thus, for example, the Framingham study enrolled healthy people who had no evidence of coronary disease on an entry examination and then reported the natural history of patients who had evidence of the new onset of coronary disease on subsequent yearly examinations.[21]

Conversely, a study based on prevalent cases consists of patients with previously diagnosed disease. Because the prevalence of the disease depends on both the incidence rate of the disease and on the distribution of the survival times, a study based on prevalent cases will likely show a greater proportion of cases with longer survival times (that is, slower progressing disease) than would be seen in a study based on incident cases. This principle is based on the fact that cases with longer survival times, by definition, remain in the pool of prevalent cases for a longer period of time than do their counterparts with shorter survival times. Because of this greater proportion of cases with slower progressing disease, the natural history for prevalent cases may appear to be better than that for incident cases.

**TABLE I Relation Between Incidence and Prevalence**

1. Incidence = newly diagnosed patients in a population previously free of disease/person-years of follow-up
2. Prevalence = proportion of population that has the disease at a given time
3. Therefore, assuming a constant incidence rate and no change in the distribution of life expectancies over time, (prevalence/1 − prevalence) = incidence × average life expectancy of a diseased patient
4. If prevalence is low, prevalence is about equal to incidence × average life expectancy of a diseased patient

This prevalence-incidence bias is closely related to the length bias that has been described in studies of the natural history of cancer.[15] In the cancer screening literature, length bias exists because slow-growing lesions, which are associated with a favorable prognosis, have a longer duration in the detectable preclinical period than do rapidly growing lesions, which are associated with a less favorable prognosis. Therefore, any screening during the detectable preclinical period will yield an over-representation of persons with slow-growing lesions. This length bias described in the cancer literature and the bias we described in the previous paragraphs both result from the selection of prevalent cases either in the detectable preclinical period or in the clinical period.

It should be emphasized that prevalence-incidence (length) bias is distinct from lead-time bias. If the natural history of CAD cases was determined by using the first symptoms of angina as the entry point and if the disease could not be detected earlier, then there would be no possibility of entering patients at an earlier stage, and lead-time bias could not exist. However, prevalence-incidence bias could still occur from the comparison of prevalent cases with incident cases.

These 3 biases (lead-time bias, referral bias, and prevalence-incidence bias), each of which can seemingly improve or worsen the natural history of a disease (Table II), constitute what might be called selection or spectrum bias.[18] If the disease in question has a rather long premorten natural history, different physicians may see patients at different stages. If a new efficacious therapy seems to be available, physicians may respond more vigorously to suggestive signs or symptoms and will use tests to make the diagnosis sooner. This may result in substantial lead-time bias and referral bias when a current series of patients undergoing *any* therapy is compared with a series of patients seen in a previous era.

## Natural History of Medically Treated Coronary Artery Disease: 3 Representative Studies

Although it is not possible for us to present all of the literature regarding the natural history of medically treated patients with symptomatic CAD, 3 prototypical studies that have reported relatively long follow-up periods are adequate to demonstrate the relevance of

**TABLE II Summary of Biases in the Selection of Patients From the Spectrum of Persons With a Disease**

| Types of Bias | Effect on Natural History |
|---|---|
| Lead-time bias | Patients who are diagnosed at an earlier stage of the disease live longer; patients who are diagnosed at a later stage die sooner. |
| Referral bias | Only some diseased persons in a population become part of a particular investigator's natural history study, and these selected persons may have a better or worse prognosis than other people with the same disease. |
| Incidence-prevalence bias | Patients who are at any given stage of disease include some who are progressing rapidly and some who are progressing slowly—the latter will be over-represented in a prevalence study and will make natural history seem better than it would be in an incidence study. |

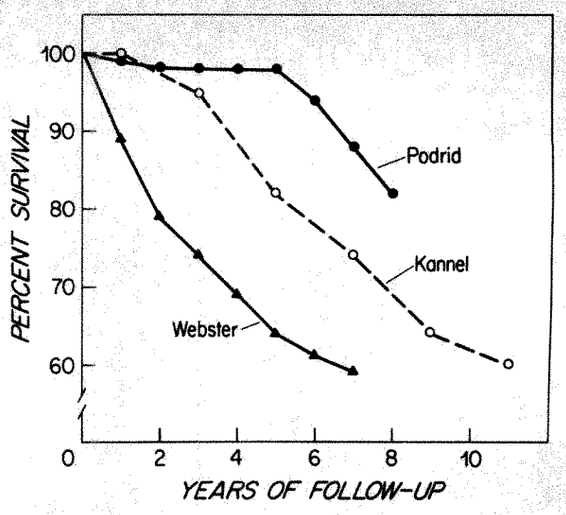

**FIGURE 2.** Survival curves from 3 natural history studies of symptomatic coronary disease. In the Webster study,[21] mortality was very high for the first 3 years, became about 5%/year for years 2 through 5, and then decreased to about 2.5%/year for years 5 through 7. In the true incidence study reported by Kannel,[20] mortality was only about 1.5%/year for the first 3 years but then paralleled the mortality curve of the Webster series. In the more recent study by Podrid et al,[6] mortality was minimal for the first 5 years, but then the mortality curve paralleled the other 2 curves. Although the natural history of symptomatic CAD may in fact be better in 1981 than it was in 1965, much of the difference in these 3 curves can be explained by the biases described in the text.

the biases discussed above. In 1974, Webster et al[22] reported the natural history of 469 patients who had severe proximal lesions in 1, 2, or 3 major coronary vessels at catheterization at the Cleveland Clinic during the years 1960 to 1965.[22] As the investigators indicated, the surgical treatment of CAD was in its infancy during that period, and these patients were treated medically, although they would be considered candidates for coronary bypass surgery in 1981. At 6 year follow-up, the authors reported a total mortality rate of 20% in 1-vessel disease, 40% in 2-vessel disease, and 63% in 3-vessel disease. If all patients were pooled, the overall mortality rate at 6 years was 39%. The survival data from this series (Fig. 2) were similar to the annual mortalities that were reported by 3 other contemporary studies of patients catheterized for symptomatic CAD at other hospitals[23–25] and that were reported by different authors from the same institution in 1978.[26] However, patients from all these series tended to have substantial symptoms, at least partly because surgical therapy for CAD was not well developed in the 1960s. Thus, these studies represented the natural history of a group of patients who were sicker than the average patients with angina of the same era.

In 1971, Kannel and Feinleib[21] reported follow-up data regarding the new cases of angina that were detected by yearly screenings of the Framingham population between about 1949 and 1966.[21] Their men aged >50 years with angina pectoris had about a 4% annual mortality rate after diagnosis (Fig. 2), a mortality rate that was noted to be roughly similar to that associated with survivors of acute myocardial infarction. Although women aged >60 and men aged <50 years had more benign prognoses,[21] the precise data for all such patients were not presented. Thus, the survival curves depicting the natural history of Framingham men aged >50 years provide the best published data regarding the prognosis of an unselected spectrum of incident cases of angina in a defined population.

Most recently, Podrid et al[6] reported on the prognosis of medically treated patients who had ≥2 mm S-T segment depression during exercise testing. Because many patients with such exercise test results will have multivessel disease, their 1.4% annual mortality rate might seem to represent a substantially better natural history than what was reported by Webster[22] or Kannel.[21] Independent of any debates regarding the actual coronary anatomy of Podrid's patients, these patients were substantially less symptomatic than were Webster's patients (Table III). The difference in symptomatic status can be explained by the different criteria by which patients in the 2 studies were referred from the larger population of patients with coronary symptoms. Webster's patients underwent coronary angiography during the early era of the procedure because they were sick enough to be considered for internal mammary

**TABLE III Symptomatic Status of Patients at Entry in 2 Natural History Studies**

| Functional Class* | Webster et al[22] (n = 445†) | Podrid et al[6] (n = 142) |
|---|---|---|
| I | 41 (9%) | 96 (68%) |
| II | 187 (42%) | 46 (32%) |
| III | 139 (31%) | |
| IV | 78 (18%) | 0 |

* In Webster's study,[22] the symptomatic class is as reported by the authors using the New York Heart Association criteria (pooled results for patients with 1-, 2-, and 3-vessel disease). For Podrid's study,[6] the symptomatic class data are estimates made by us based on the investigator's reported duration of exercise using a standard Bruce protocol and on the criteria of the American Heart Association.[27]

† Twenty-four additional patients with atypical angina were not classified by the authors.

artery implantation. Podrid's patients, despite their positive exercise tests, were considered to be tolerating their symptoms to the extent that the investigators did not recommend angiography during an era when the procedure was well established and the surgery that might follow was widely agreed to be efficacious for the amelioration of symptoms.

Our contentions regarding the relevance of lead-time bias and referral bias depend in part on the assumption that patients who have symptoms of angina or congestive heart failure do in fact have poorer prognoses. This assumption has been substantiated by the reports of both Webster[22] and Proudfit[26] from the Cleveland Clinic and by data from Burggraf and Parker,[25] from the Veterans' Administration Cooperative study,[28] and from Duke University Medical Center.[29] Furthermore, a number of studies indicate that the poorer prognosis associated with advanced symptoms is independent of the number of diseased coronary vessels.[22,28,30,31]

The selection of sicker-than-average patients by Webster[22] and less symptomatic-than-average by Podrid[6] would be expected to result in detrimental and favorable lead-time biases, respectively, in comparison with the true incidence study reported by Kannel.[21] In fact, a comparison of the survival rate curves from the 3 studies (Fig. 2) suggests exactly that: after a lag time of about 3 and 5 years, respectively, the annual mortality rate in both the Kannel and Podrid studies becomes about 5 to 6%/year. In the Webster study, the annual mortality rate was very high for the first 2 years, but then became 5%/year for years 3 through 5. By years 6 and 7, the survivors in the Webster series had only a 2.5%/year mortality rate, which may be a reflection of incidence-prevalence bias. Figure 2 also demonstrates the potential confusion inherent in quotations of yearly mortality rate statistics: the yearly mortality rate for a group of patients may vary markedly during different segments of the follow-up period.

Because each of these 3 studies had fewer patients in the later years of follow-up than in the earlier years, the standard deviation of their later mortality rate figures is less certain. Nevertheless, the parallel portion of the mortality rate curves in the various studies suggests that the early favorable natural history statistics of some series of patients with CAD may be misleading because lead-time bias and referral bias may have resulted in the selection of a patient population that has a very favorable short-term (up to perhaps 6 years) prognosis, simply on the basis of their inherent characteristics and not on the basis of any therapeutic intervention.

The pertinence of lead-time bias and incidence-prevalence bias can be further demonstrated by the long-term follow-up data regarding coronary patients from Johns Hopkins.[32] Using a anatomic CAD severity score, Humphries et al showed that the 53% 5-year survival rate of patients with severe disease was significantly worse than the 91% 5-year survival rate of patients with moderate disease. However, during follow-up years 6 through 10, the mortality rate in the group with severe CAD was very low, whereas the mortality rate among patients in the group with moderate disease was substantial; by 10 years after arteriography, the survival rates in the 2 groups were virtually identical. These findings suggest that the differences in early survival rates were related to lead-time bias and that lead-time bias can be overcome if the follow-up is long enough. The flat portion of the curve from years 6 through 10 in the patients with severe CAD was also probably a function of survivor effect: independent of the biases that we have discussed, the survivors of a high death rate period may often have a much lower subsequent mortality rate than the entire cohort had during the high death rate period.

These considerations emphasize that series that have reported a favorable prognosis for selected patients followed for only 5 to 6 years may not have a sufficient duration of follow-up for the lead-time bias to disappear. We do not dispute the contention that some therapies may actually act by delaying rather than preventing mortality, but any such contentions must be shown to be free of lead-time bias.

## Suggested Approach to Interpretation of Studies

There is no doubt that national mortality statistics show about a 20% decrease in CAD mortality rates over the past 10 years. Similarly, randomized controlled trials have shown that some medical[8–10] and surgical[11,12] interventions can reduce mortality rates in selected types of patients by about 30%. Although readers should look carefully for lead-time bias, referral bias, and incidence-prevalence bias in all natural history studies, these data suggest that they must look especially carefully at any study whose patients with medically treated CAD seem to have >30% reduction in mortality rates compared with concurrent or historical control series.

It is important to recognize that the biases that we have discussed cannot be negated by demonstrating that patients are matched with regard to 1 or 2 particular factors. Even sophisticated multivariate matching techniques[33] may not be sufficient if the patients in 2 studies have such inherently different prognoses that the relevant variables in 1 study are not pertinent to the other. Also, most published reports do not provide data in a format that allows subsequent investigators to perform such sophisticated matching techniques. If, however, patients can be suitably matched based on the spectrum of disease and on their prognostic factors,[34,35] concurrent nonrandomized control subjects may sometimes provide enough data for interstudy comparisons. Nevertheless, except when they are contraindicated by logistics or by expense, randomized controlled trials remain the least biased method for comparing the efficacy of various management strategies, and series based on incident cases in a nonreferral population remain the best way to determine natural history.

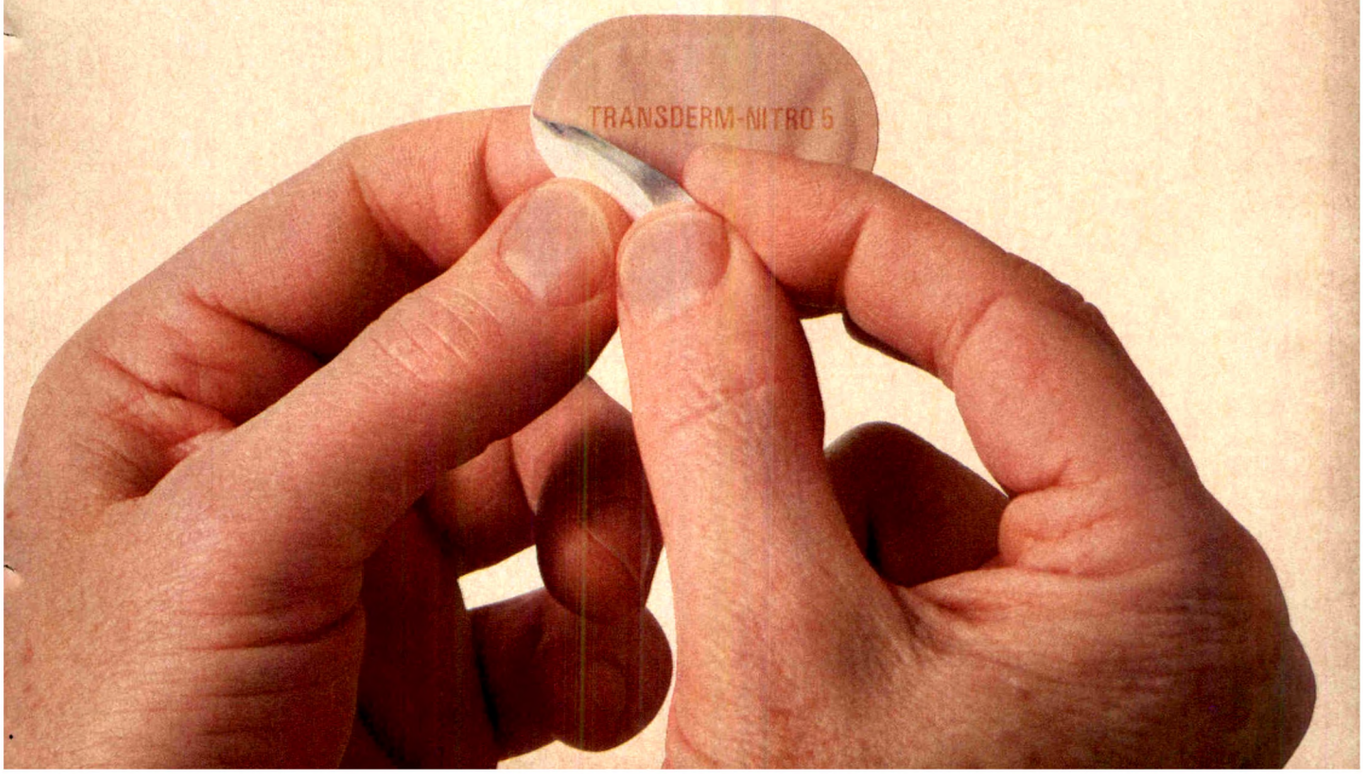
# Baseline anginal therapy simplified

## Approximately 75% of angina patients were successfully controlled on the starting dosage—one Transderm-Nitro 5

*Once-daily application of Transderm-Nitro* was shown to provide effective 24-hour baseline therapy in the step-care approach to angina in a survey* of over 1,000 physicians with more than 10,000 patients under treatment.

Orthostatic hypotension may indicate nitroglycerin overdosage; reduce dosage if symptoms occur. Nitrates are contraindicated in patients with increased intraocular pressure. Withdrawal should be gradual if treatment is terminated. Do not apply to distal parts of the arms and legs.



*For full details, please see the Prescribing Information on the next page.*

## Transderm®-Nitro (nitroglycerin)
**Transdermal Therapeutic System**

### DESCRIPTION
Transderm-Nitro (nitroglycerin) transdermal therapeutic system is a flat unit designed to provide controlled release of nitroglycerin through a semipermeable membrane continuously for 24 hours following application to intact skin. Nitroglycerin (glyceryl trinitrate) is a prompt-acting vasodilator for the relief and prevention of anginal attacks. Systems are rated to release *in vivo* 5 and 10 mg nitroglycerin over 24 hours and are in sizes of 10 and 20 $cm^2$ respectively.

One-fifth of the total nitroglycerin in the system is delivered transdermally to the patient over 24 hours; the remainder serves as the thermodynamic energy source to release the drug and remains in the system. The rated release of drug is dependent upon the area of the system; 0.5 mg nitroglycerin is delivered *in vivo* for every $cm^2$ of system size.

The Transderm-Nitro system comprises four layers as shown below. Proceeding from the visible surface towards the surface attached to the skin, these layers are: 1) a tan-colored backing layer (aluminized plastic) that is impermeable to nitroglycerin; 2) a drug reservoir containing nitroglycerin adsorbed on lactose, colloidal silicon dioxide, and silicone medical fluid; 3) an ethylene/vinyl acetate copolymer membrane that is permeable to nitroglycerin; and 4) a layer of hypoallergenic silicone adhesive. Prior to use, a protective peel strip is removed from the adhesive surface.

Cross section of the system:

### ACTIONS
When the Transderm-Nitro system is applied to the skin, nitroglycerin is absorbed continuously through the skin into the systemic circulation. This results in active drug reaching the target organs (heart, extremities) before being inactivated by the liver. Nitroglycerin is a smooth muscle relaxant with vascular effects manifested predominantly by venous dilatation and pooling. The major beneficial effect of nitroglycerin in angina pectoris is a reduction in myocardial oxygen consumption secondary to vascular smooth muscle relaxation and consequent reduced cardiac preload and afterload. In recent years there has been an increasing recognition of a direct vasodilator effect of nitroglycerin on the coronary vessels.

In clinical studies transdermal absorption of nitroglycerin from a nitroglycerin system occurred in a continuous and well-controlled manner, for a minimum of 24 hours. Therapeutic effect can be anticipated 30 minutes after application of the system and to be maintained for 30 minutes after its removal.

### INDICATIONS AND USAGE
Transderm-Nitro system is indicated for the prevention and treatment of angina pectoris due to coronary artery disease.

### CONTRAINDICATIONS
Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

### WARNINGS
In patients with acute myocardial infarction or congestive heart failure, Transderm-Nitro system should be used under careful clinical and/or hemodynamic monitoring. In terminating treatment of anginal patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

### PRECAUTIONS
Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension may be due to overdosage. When these symptoms occur, the dosage should be reduced or use of the product discontinued.

Transderm-Nitro system is not intended for immediate relief of anginal attacks. For this purpose occasional use of the sublingual preparations may be necessary.

### ADVERSE REACTIONS
Transient headaches are the most common side effect, especially when higher doses of the drug are used. These headaches should be treated with mild analgesics while Transderm-Nitro therapy is continued. When such headaches are unresponsive to treatment, the nitroglycerin dosage should be reduced or use of the product discontinued.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. These symptoms are attributable to the known pharmacologic effects of nitroglycerin, but may be symptoms of overdosage. When they persist, the dose should be reduced or use of the product discontinued.

### DOSAGE AND ADMINISTRATION
Therapy should be initiated with application of one Transderm-Nitro 5 system to the desired area of skin. Many patients prefer the chest; if hair is likely to interfere with system adhesion or removal, it can be clipped prior to placement of the system. Each system is designed to remain in place for 24 hours, and each successive application should be to a different skin area. Transderm-Nitro system should not be applied to the distal parts of the extremities.

The usual dosage is one Transderm-Nitro 5 system every 24 hours. Some patients, however, may require the Transderm-Nitro 10 system. If a single Transderm-Nitro 5 system fails to provide adequate clinical response, the patient should be instructed to remove it and apply either two Transderm-Nitro 5 systems or one Transderm-Nitro 10 system. More systems may be added as indicated by continued careful monitoring of clinical response.

The optimal dosage should be selected based upon the clinical response, side effects, and the effects of therapy upon blood pressure. The greatest attainable decrease in resting blood pressure that is not associated with clinical symptoms of hypotension especially during orthostasis indicates the optimal dosage. To decrease adverse reactions, the size and/or number of systems should be tailored to the individual patient's needs.

Do not store above 86°F (30°C).

### PATIENT INSTRUCTIONS FOR APPLICATIONS
A patient leaflet is supplied with the systems.

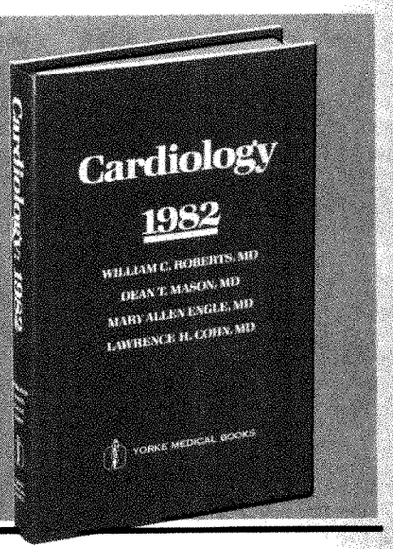
# CARDIOLOGY 1982



## The Second Issue of the New Annual providing a multidisciplinary approach to the latest, most important information on the state-of-the-art of cardiovascular medicine and surgery

*written by:*

- **William C. Roberts, M.D.**
  *Chief, Pathology Branch/National Heart, Lung & Blood Institute/National Institutes of Health/and Clinical Professor of Pathology & Medicine (Cardiology)/Georgetown University School of Medicine, Washington, D.C.*
- **Dean T. Mason, M.D.**
  *Professor of Medicine and Physiology, and Chief of Cardiovascular Medicine, University of California, Davis School of Medicine and University Medical Center, Davis and Sacramento, California*
- **Mary Allen Engle, M.D.**
  *Stavros S. Niarchos Professor of Pediatric Cardiology/Director of Pediatric Cardiology/The New York Hospital-Cornell University Medical College, New York*
- **Lawrence H. Cohn, M.D.**
  *Professor of Surgery/Harvard Medical School/Department of Surgery/Division of Thoracic & Cardiac Surgery/Brigham & Women's Hospital, Boston*

**ISBN 0-914316-27-3 approx. 500 pp., illus., April 1982, $45.00 ISSN 0275-0066**

## What is CARDIOLOGY 1982?

- The second in an annual series to be published in the SPRING each year
- A review of the year's newest and most important developments in cardiology — **665 papers**
- A multidisciplinary approach to clinical and applied research based on an exhaustive search of the year's literature
- A unique, cohesive summary of the state-of-the-art, written, not edited, by those making outstanding developments in the field
- A practical approach to a complicated and fast-moving subject designed to be read and used daily

## CARDIOLOGY:1982 is NOT

- A collection of unrelated reviews
- An abstracting service
- A rehash of materials readily available elsewhere

**CARDIOLOGY: 1982** provides in a concise and readable format and style fundamental and new information essential to understanding the current thinking on managing cardiovascular disease. It coordinates what's new with well-established data, arming the reader with a perspective on the field which is simply unavailable elsewhere. Its liberal use of illustrations and original tables condenses valuable information into instantly understandable knowledge.

### *Reviews of the first edition*

***"...recommend...to any reader interested in the literature of cardiology."***
Irwin R. Callen, M.D.
JAMA, November, 1981

***"It is more than merely a reference book, since it explains what to the average physician may be obscure....a treasure house of 1980 publications. It is highly recommended."***
Philip Reichert, M.D.
New York State Journal of Medicine, September, 1981

***"This is an excellent book, very well organized and written...should be on the shelf of the library, cardiologist, and internist."***
COL. Robert B. Franklin, MC, USA
Military Medicine, November, 1981

**SPECIAL DISCOUNT OFFER**

Place a standing order to receive each edition of CARDIOLOGY: 1982 on 30 day approval and receive a 10% discount on this and all future editions.

☐ **YES,** please enter my standing order for CARDIOLOGY: 1982. I understand that each edition (published once a year) will be automatically shipped to me on 30 day approval, and I will receive a 10% discount on this and all future editions. (1982 edition discount price $40.50)

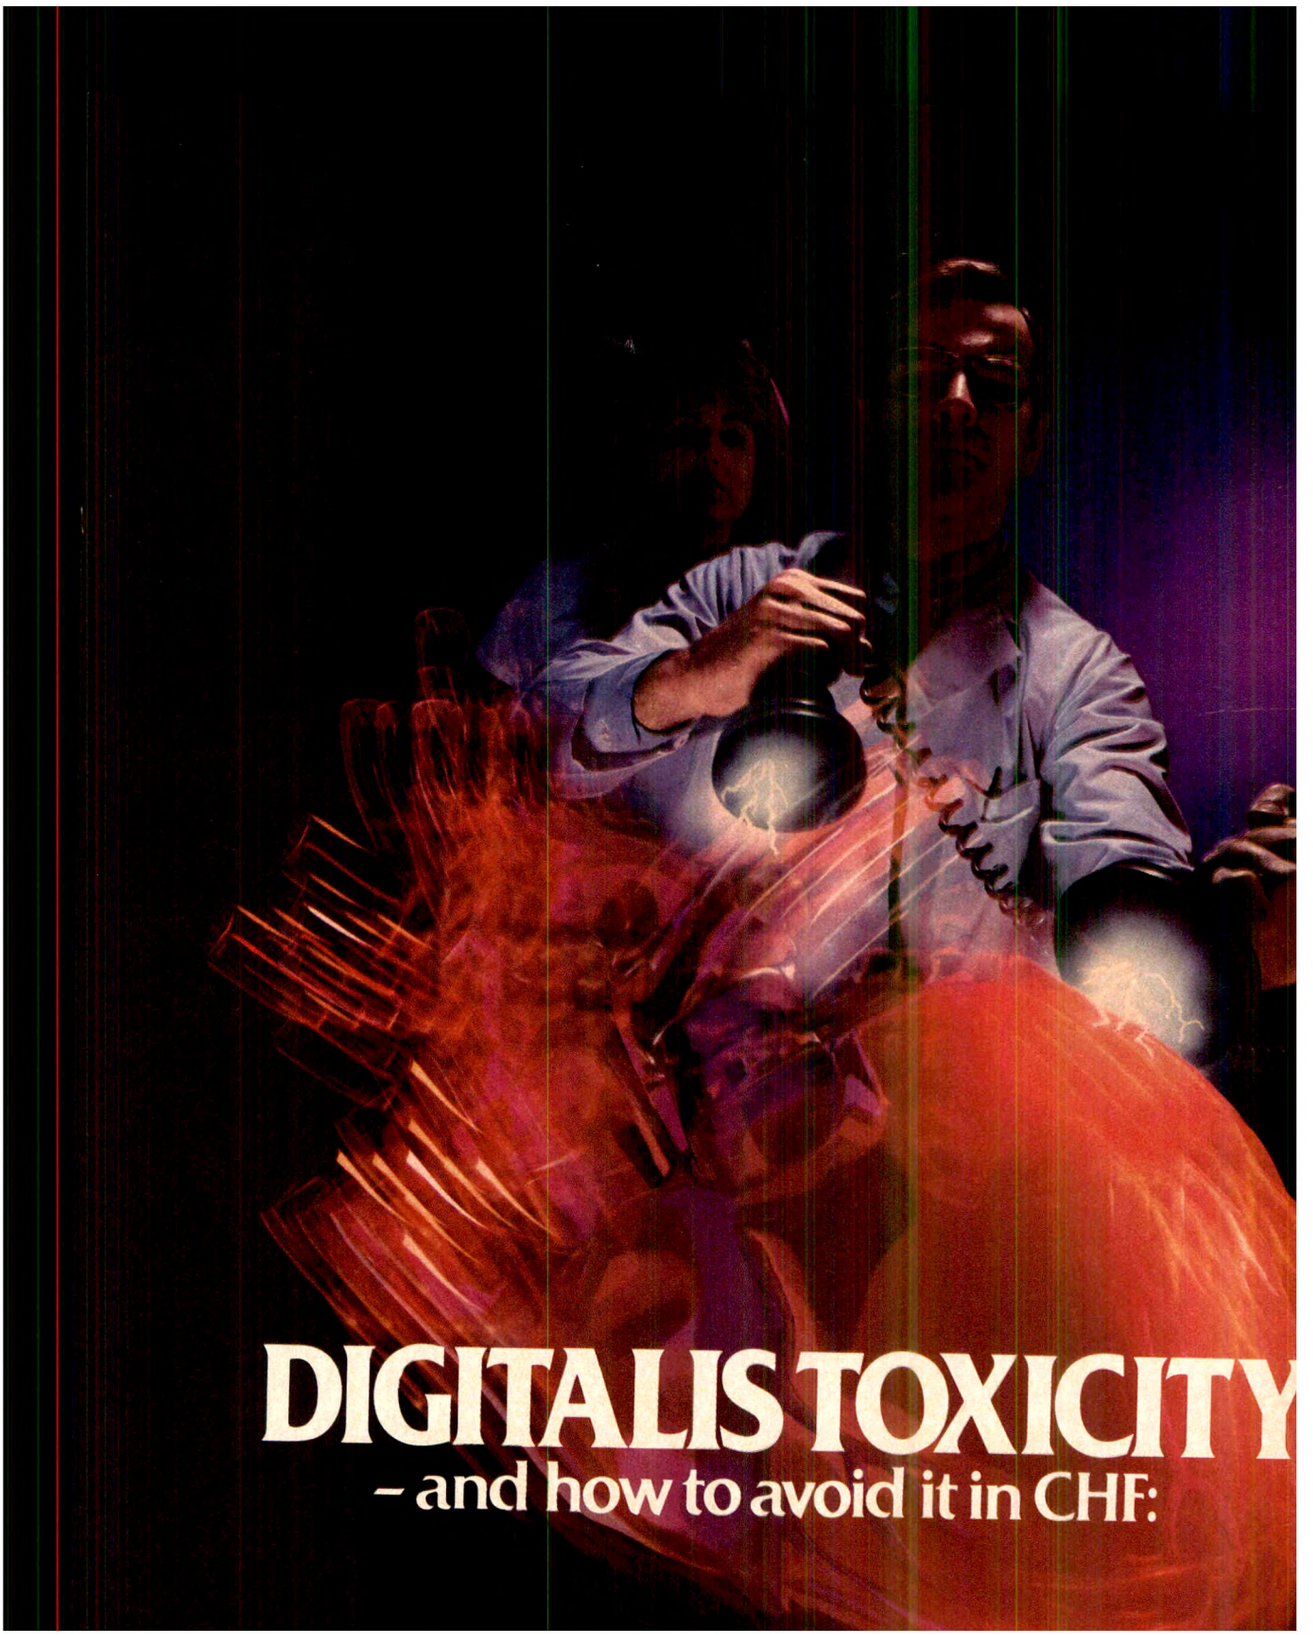
# A Pacesetter commitment:

**The Pacesetter Programalith® A-V. Smaller, with more sophisticated telemetry, and the first dual-chamber pacemaker that not only tells you what it *should* be doing, but also what it is *actually* doing.**

Multi-programmability, non-invasive monitoring and programming of *six* parameters—Pacesetter innovations—are standard to the Model 223 A-V. In addition, when coupled with our Model 388 Programming/Telemetry System, *measured* values of rate, pulse current, pulse voltage, pulse energy, pulse charge, battery voltage and A-V delay can be retrieved as well. And, a refined circuitry design results in less battery drain—meaning longer life for the pacemaker's energy system.

Lead impedance, battery impedance and battery current are shown both on the programmer's digital display and on the printout for your patient's permanent record.

DVI pacing has been shown to be desirable for those patients who require more than single-chamber pacing (VVI or AAI), yet do not require DDD pacing. In the innovative Programalith A-V sequential pacemaker, Pacesetter Systems, Inc. has created the most advanced such device available today.



Actual size.

# Dual-chamber pacing.

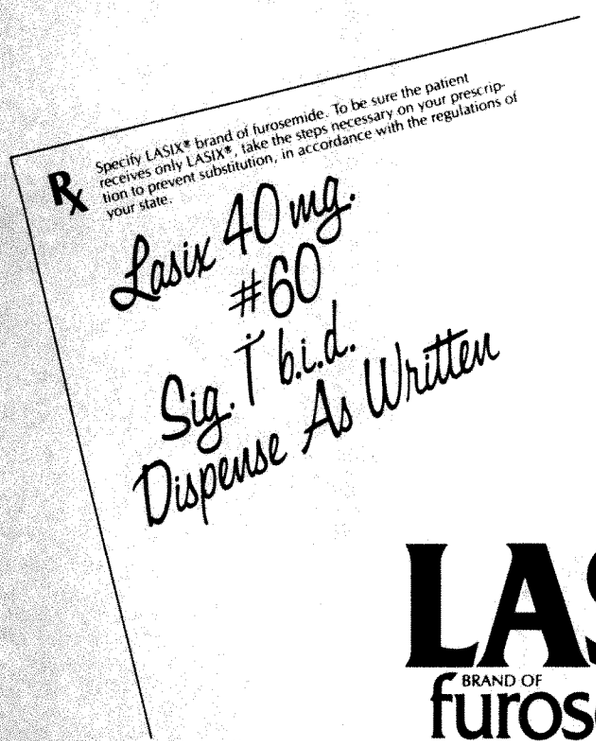
Pacesetter® Systems, Inc.

DIGITALIS TOXICITY
– and how to avoid it in CHF:

# Avoid any change in the classic digitalis-Lasix® regimen.

BRAND OF furosemide

Every CHF patient on a digitalis-diuretic regimen runs the risk of digitalis toxicity.



But many patients with impaired renal function are particularly vulnerable because their condition may predispose them to a toxic accumulation of digoxin.

These include the diabetic. The geriatric patient. The patient with renal disease. And the patient with advanced CHF who suffers from hepatic as well as renal complications.

Add to this group the patient on multiple medications with possible drug interactions.

Conditions like these that increase the risk of digitalis toxicity are generally outside the physician's control. But two of the most important *preventive* measures which are not outside the physician's control are precise titration of digitalis, *and the consistent use of one diuretic*.

As to the first, the narrow therapeutic-to-toxic range of digitalis is well known and requires no elaboration.

Naturally, increased renal problems necessitate increased vigilance to any signs of toxicity.

### Why the patient should be maintained on LASIX®

The second precaution is the unvarying use of a single diuretic for a given patient (consistent with proper potassium balance). Thus, if the choice is LASIX®—as it is in most successfully managed CHF cases—the logic behind it is beyond debate. LASIX® is the only diuretic for CHF whose effectiveness has been confirmed in no fewer than 6,000 published papers...which offers the most complete range of dosage forms and strengths for precise titration... and is the most widely available brand of furosemide for filling or refilling your prescription anywhere in the United States. In fact, according to a 1980 nationwide survey,[1] office-based physicians affirmed their confidence in LASIX® by naming it as the medication they prescribe most frequently in office practice.

### Protect your LASIX® prescription: prevent substitution

When you prescribe LASIX®, write the phrase "Do not substitute," or whatever your state requires on the prescription.

---

If you are in doubt about a particular generic furosemide, call the offices of the Food and Drug Administration's Bureau of Drugs, Consumer and Professional Relations staff at 301-443-1016.

---

**Before prescribing, please consult complete product information, a summary of which appears on the following page.**

# LASIX®

TABLETS: 20, 40 & 80 mg

BRAND OF furosemide

## The diuretic of choice for the digitalized patient.

**Lasix®** (furosemide)

A brief summary of the Prescribing Information for Lasix (furosemide) Tablets 20, 40 and 80 mg

**WARNING: Lasix (furosemide) is a potent diuretic which, if given in excessive amounts, can lead to a profound diuresis with water and electrolyte depletion. Therefore, careful medical supervision is required, and dose and dose schedule have to be adjusted to the individual patient's needs.**

**INDICATIONS:** Edema associated with congestive heart failure, cirrhosis of the liver, and renal disease, including the nephrotic syndrome. Hypertension when used alone or in combination with other antihypertensive drugs; patients not adequately controlled with thiazides also probably will not be adequately controlled with furosemide alone.

**CONTRAINDICATIONS: Anuria. History of hypersensitivity to the compound.**

**WARNINGS:** Excessive diuresis may result in dehydration and reduction in blood volume, with circulatory collapse and with the possibility of vascular thrombosis and embolism, particularly in elderly patients. Excessive loss of potassium in patients receiving digitalis glycosides may precipitate digitalis toxicity. Exercise care in patients receiving potassium-depleting steroids. Perform frequent serum electrolyte, $CO_2$, and BUN determinations during first few months of therapy and periodically thereafter, and correct abnormalities or temporarily withdraw the drug. Initial therapy of patients with hepatic cirrhosis and ascites is best carried out in the hospital. Closely observe cirrhotic patients for sudden fluid and electrolyte imbalances that may precipitate hepatic coma. Supplemental potassium chloride and, if required, an aldosterone antagonist are helpful in preventing hypokalemia and metabolic alkalosis. Discontinue furosemide if increasing azotemia and oliguria occur during treatment of severe, progressive renal disease. Observe patients regularly for possible blood dyscrasias, liver damage, or other idiosyncratic reactions. Patients with known sulfonamide sensitivity may show allergic reactions. Furosemide may potentiate the therapeutic effect of other antihypertensive agents. Potentiation occurs with ganglionic or peripheral adrenergic blocking drugs. Exacerbation or activation of systemic lupus erythematosus may occur. Furosemide appears in breast milk. If use of the drug is essential, the patient should stop nursing. Cases of tinnitus and reversible hearing impairment have been reported.

There have also been some reports of cases in which irreversible hearing impairment occurred. Usually ototoxicity has been reported when furosemide was injected rapidly in patients with severe impairment of renal function at doses exceeding several times the usual recommended dose and in whom other drugs known to be ototoxic were given. If the physician elects to use high-dose parenteral therapy in patients with severely impaired renal function, controlled intravenous infusion is advisable. (For adults, an infusion rate not exceeding 4 mg furosemide per minute has been used.)

**PRECAUTIONS:** As with any effective diuretic, electrolyte depletion may occur, especially in patients receiving higher doses and a restricted salt intake. Patients receiving furosemide should be observed for clinical signs of fluid or electrolyte imbalance; namely, hyponatremia, hypochloremic alkalosis, and hypokalemia. Serum and urine electrolyte determinations are particularly important when the patient is vomiting excessively or receiving parenteral fluids. Medication such as digitalis may also influence serum electrolytes. Hypokalemia may develop with furosemide as with any other potent diuretic, especially with brisk diuresis, when cirrhosis is present, or during concomitant use of corticosteroids or ACTH. Interference with adequate oral electrolyte intake will also contribute to hypokalemia. Digitalis may exaggerate metabolic effects of hypokalemia, especially with reference to myocardial activity. Asymptomatic hyperuricemia can occur and gout may rarely be precipitated. Increases in blood glucose and alterations in glucose tolerance tests with abnormalities of the fasting and two-hour postprandial sugar have been observed, and rare cases of precipitation of diabetes mellitus have been reported. Furosemide may lower serum calcium levels, and rare cases of tetany have been reported. Periodic serum calcium levels should be obtained. Reversible elevations of BUN may be seen. These have been observed in association with dehydration, which should be avoided, particularly in patients with renal insufficiency. Patients receiving high doses of salicylates in conjunction with furosemide may experience salicylate toxicity at lower doses because of competitive renal excretory sites. Furosemide has a tendency to antagonize the effects of tubocurarine and may potentiate the action of succinylcholine. Lithium generally should not be given with diuretics because they reduce its renal clearance and add a high risk of lithium toxicity. Diuretics such as furosemide may enhance the nephrotoxicity of cephaloridine. Therefore, furosemide and cephaloridine should not be administered simultaneously. Furosemide may decrease arterial responsiveness to norepinephrine. This diminution is not sufficient to preclude effectiveness of the pressor agent for therapeutic use. It has been reported in the literature that coadministration of indomethacin may reduce the natriuretic and antihypertensive effects of Lasix (furosemide) in some patients. This effect has been attributed to inhibition of prostaglandin synthesis by indomethacin. Indomethacin may also affect plasma renin levels and aldosterone excretion; this should be borne in mind when a renin profile is evaluated in hypertensive patients. Patients receiving both indomethacin and Lasix (furosemide) should be observed closely to determine if the desired diuretic and/or antihypertensive effect of Lasix (furosemide) is achieved.

**PREGNANCY:** Pregnancy Category C. Furosemide has been shown to cause unexplained maternal deaths and abortions in rabbits at 2, 4 and 8 times the human dose. There are no adequate and well-controlled studies in pregnant women. Furosemide should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

**ADVERSE REACTIONS:** Anorexia, oral and gastric irritation, nausea, vomiting, cramping, diarrhea, constipation, jaundice (intrahepatic jaundice), pancreatitis, dizziness, vertigo, paresthesias, headache, xanthopsia, blurred vision, tinnitus and hearing loss, anemia, leukopenia, agranulocytosis (rare), thrombocytopenia, aplastic anemia (rare), purpura, photosensitivity, rash, urticaria, necrotizing angiitis (vasculitis, cutaneous vasculitis), exfoliative dermatitis, erythema multiforme, pruritus. Orthostatic hypotension may occur and may be exaggerated by alcohol, barbiturates, or narcotics. Other adverse reactions include hyperglycemia, glycosuria, hyperuricemia, muscle spasm, weakness, restlessness, urinary bladder spasm, thrombophlebitis.

# TOPICS IN HYPERTENSION

Edited by

**John H. Laragh, MD**

*Master Professor of Medicine*
*Director, The Cardiovascular Center Chief, Cardiology Division The New York Hospital-Cornell Medical Center*

**644 pages. 36 chapters by 85 internationally known specialists. Illustrated. Comprehensively indexed. $49.00. Available on 30-day approval.**

High blood pressure is no longer only a problem of worldwide interest and relevance. It is now one in which the knowledge base has exploded to the point where the informed physician can do more and more about it in his daily practice...and can apply, to an ever-increasing extent, more sophisticated and individually tailored therapies.

Laragh's TOPICS IN HYPERTENSION places this kind of vital knowledge within instant reach of the physician. It presents a carefully selected array of discussions. It deals in depth with recent breakthroughs in understanding, diagnosing, and treating this problem.

This book is conveniently organized for effective consultation and reading:

- **Section 1** considers recently maturing biochemical and pathophysiologic aspects of the problem.
- **Section 2** deals with new physiologic approaches to diagnosis.
- **Section 3** discusses new perceptions of the clinical and prognostic aspects of hypertension.
- **Section 4** considers in detail the more recently introduced modes of therapy. These new agents presage the beginning of a new era of more selective and specific therapy for increasing numbers of patients.

**YORKE MEDICAL BOOKS** AJCB3
Box C-757, Brooklyn, New York 11205

Send me, on approval, _____ copies of Laragh's TOPICS IN HYPERTENSION at $49.00. I will consult and read this new manual for 30 days, then remit only if I consider it a necessary addition to my library. Otherwise I will return it without further obligation.

- ☐ Send bill, plus shipping cost.

# Intermittent, Continuous Outpatient Dobutamine Infusion In the Management of Congestive Heart Failure

MARK M. APPLEFELD, MD, KATHRYN A. NEWMAN, RN, MS, WILLIAM R. GROVE, MS, FREDERICK J. SUTTON, MD, DAVID S. ROFFMAN, PHARM D, WILLIAM P. REED, MD, and STEVEN E. LINBERG, PhD

**The use of outpatient dobutamine infusions by a small, portable infusion pump in 3 patients with intractable congestive heart failure (CHF) is described. With this therapy left ventricular function improved and CHF resolved in each. Tolerance to dobutamine was obviated by giving infusions twice weekly. Except for 3 mild infections around the catheter exit site, there have been no complications of this therapy in 58 cumulative patient weeks.**

Therapy of intractable CHF is a frustrating clinical problem. In addition to repeated hospitalizations, patients with CHF have significant early mortality.[1] The past decade has clarified the importance of preload and afterload in the pathophysiology of CHF,[2] and agents to manipulate these variables are now widely used.[3,4] Despite their beneficial effects, significant problems, that is, tolerance or adverse effects, remain with the long-term use of these drugs.[3,4] Newer oral inotropic agents[5,6] are investigational and thus are not viable alternatives in the management of chronic CHF.

Dobutamine is an efficacious inotropic agent in the short-term therapy of CHF. Although tolerance may develop to this drug,[7] its use is primarily limited by the need for intravenous administration. We recently began a clinical trial in which 24-hour infusions of dobutamine are given twice weekly to outpatients with intractable CHF. Dobutamine is given by a portable infusion pump (Cormed, model ML6-6) through a chronic indwelling venous catheter (Hickman) surgically inserted in the external jugular vein and located proximally to the right atrium. The distal end of this catheter exits in the parasternal area (Fig. 1). Patients are taught proper catheter care including techniques for daily irrigation with saline solution and heparin (total 1,500 units) and how to aseptically connect the catheter to the infusion pump (Fig. 2). Dobutamine is prepared in normal saline solution and the admixed drug placed into the pump reservoir (total final volume 55 ml) by a pharmacist. Patients connect the pump to the catheter and begin the infusion. Infusion rates are calibrated to deliver 2 ml/h. After 24 hours patients turn the pump off, disconnect the system, flush the catheter, and return the pump for filling for the second 24-hour infusion. Our initial success with this therapy—as well as issues raised by it—are the subject of our report.

## Case Reports

**Patient 1:** A 47-year-old woman had acute myocardial infarctions in 1973 at age 38 years. In 1980 she was admitted for CHF. Equilibrium-gated blood pool (Medical Data System $A^2$ modification) radionuclide angiocardiography showed a left ventricular ejection fraction (LVEF) of 10% at rest with global dysfunction and 14% on exercise (peak work load 450 kpm). Hydralazine was added and, although efficacious (Table I), was stopped when fever developed. Prazosin (2 mg every 8 hours) was tried but also stopped because of adverse effects.

Nocturnal dyspnea developed and the patient was readmitted in December 1981. Resting LVEF was 13%. Dobutamine therapy (2 μg/kg/min) was begun but the dose was decreased to 1.5 μg/kg/min when angina and premature ventricular contractions developed. On the latter dose, the patient improved hemodynamically, LVEF on radionuclide angiography increased to 27% (Table I), and the angina and premature ventricular contractions abated. After 5 days of dobutamine infusion, symptoms of CHF had resolved and resting LVEF was 27%. A venous access catheter was inserted and the patient was discharged.

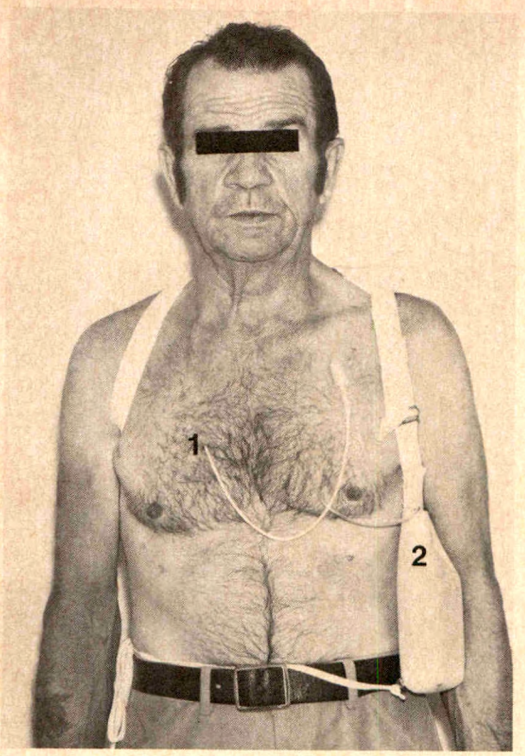

**FIGURE 1.** Patient with Hickman catheter exiting through skin (**1**) and connected to the infusion pump (Cormed) which is worn over the shoulder (**2**) in a soft padded sling.

Continuous dobutamine infusions were given 4 days weekly in addition to her usual daily doses of digoxin (0.25 mg), furosemide (80 mg), and nitroglycerin ointment (3 inches [7.62 cm] every 4 hours). Over the next 14 days she improved from New York Heart Association (NYHA) class 4 to class 2. Three weeks after starting dobutamine therapy the patient had fatigue and an increased jugular venous pressure. LVEF was 13%; dobutamine therapy was stopped. Ten days later she noted mild dyspnea on effort and administration of dobutamine (1.5 $\mu$g/kg/min) was resumed. Five hours later, resting LVEF was 22% and the dyspnea had resolved. To obviate presumed tolerance, we began to treat her with weekly 48-hour continuous dobutamine infusions. During the last 6 months on this therapy, she has not been admitted for CHF and remains in NYHA class 2. Two mild skin infections around the catheter exit site were promptly recognized and treated with oral antibiotic drugs.

**Patient 2:** A 57-year-old man was found to have poorly differentiated lymphocytic lymphoma. He was given chemotherapy (doxorubicin, total dose 550 mg/m$^2$; bleomycin and teniposide) and went into remission. Sixteen months later he noted symptoms of biventricular CHF. Therapy with daily digoxin (0.25 mg) and furosemide (20 mg) resulted in only slight improvement and he was hospitalized. Examination showed blood pressure 90/60 mm Hg, heart rate 80 beats/min and regular, increased venous pressure, a diffuse left ventricular impulse, and an $S_4$ gallop. Resting LVEF by radionuclide angiography was 15%. After drug trials (Table II), dobutamine was started. Resting LVEF was 26% on day 5 of continuous dobutamine (8 $\mu$g/kg/min) infusion and the CHF had resolved. He was discharged to receive continuous dobutamine 4 days each week. After 1 month of therapy tachypnea was noted. Resting LVEF on radionuclide angi-

Hemodynamic measurements were made 60 minutes after dobutamine was started. The radionuclide left ventricular ejection fraction was obtained 24 hours after dobutamine therapy (8 μg/kg/min) was begun. On day 5 of continuous dobutamine infusion (8 μg/kg/min), this value was 26%.
* Heart rate decreased to 72 beats/min and blood pressure remained unchanged after 24 hours on this dose.
† Measurements made 2 hours after dose.

ography was 15% and dobutamine therapy was stopped. Seven days later he underwent exercise radionuclide angiography (Table III). After this test, 48-hour continuous dobutamine infusions were given weekly. Over the last 22 weeks he has remained in NYHA class 2 and has had no complications from this therapy.

**Patient 3:** A 50-year-old woman had mitral valve replacement and tricuspid anuloplasty. Over the next 18 months she had recurrent biventricular CHF. She was treated with daily digoxin (0.125 mg), hydralazine (50 mg every 6 hours), furosemide (320 mg), and captopril (25 mg every 8 hours). The CHF was refractory to therapy and she was hospitalized. Administration of dobutamine (3 μg/kg/min) and hydrochlorothiazide (50 mg before the morning furosemide dose) was begun. On this therapy she had a diuresis of 45 lb over 3 weeks. There were no significant changes in ventricular function on radionuclide angiography before or during dobutamine therapy. She was discharged to receive continuous 48-hour dobutamine (3 μg/kg/min) infusions weekly as well as daily digoxin (0.125 mg), fuorsemide (240 mg), hydrochlorothiazide (50 mg), hydralazine (50 mg every 6 hours), spironolactone (150 mg), and warfarin. On this regimen her quality of life improved. A mild infection at the catheter exit site was successfully treated with oral antibiotic drugs.

## Discussion

Several aspects of outpatient continuous dobutamine infusions in our patients merit comment. The first is the development of tolerance during the prolonged drug infusions.[7] This occurred in 2 patients during 96- to 120-hour dobutamine infusions, was manifested by dyspnea or tachypnea, and was confirmed by a reduction in LVEF to predobutamine levels. Five to 7 days after dobutamine was stopped, infusions were resumed,

**TABLE III Oxygen Consumption Before, During, and After Treadmill Exercise Test (12 Minutes, Modified Bruce Protocol) in Patient 2**

| | Resting (ml/min) | Peak Exercise (ml/min) | Total Exercise (ml) | Oxygen Debt (ml) |
|---|---|---|---|---|
| Control (no dobutamine) | 216 | 699 | 2,804 | 1,792 |
| Dobutamine (5 hours, 1.5 μg/kg/min) | 250* | 887* | 4,808* | 1,712 |

* Significantly different from control, $p < 0.05$ (paired $t$ test).

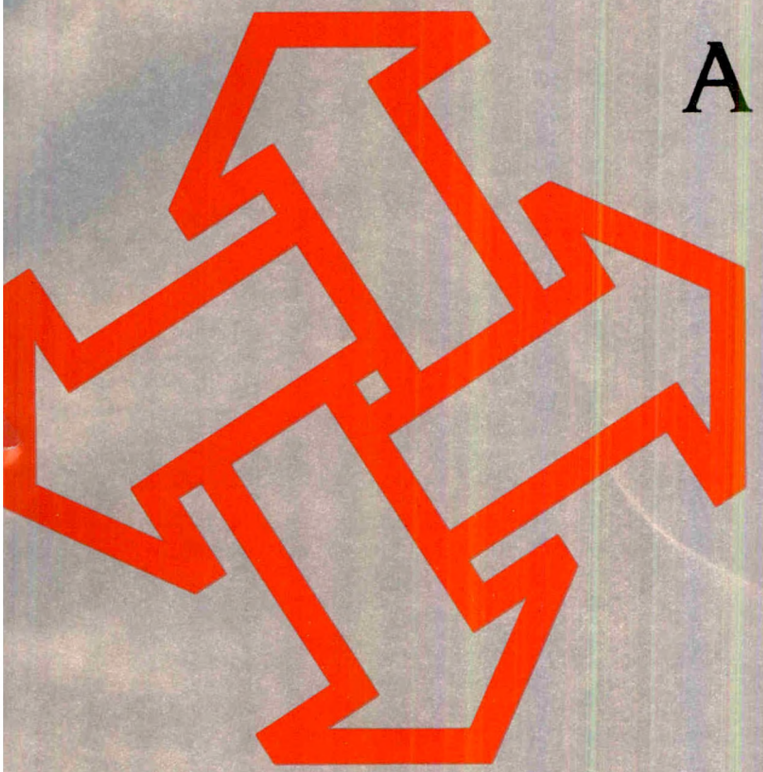
LVEF increased, and symptoms were promptly ameliorated. Based on these experiences and previous reports,[7,8] we now give weekly 48-hour continuous dobutamine infusions. During 15 cumulative patient months there have been no hospitalizations for CHF with this therapy. Further, drug tolerance seems to have been circumvented and the quality of life in these patients has improved.

The mechanisms responsible for the sustained clinical improvement in our patients on the days when they do not receive dobutamine are uncertain. However, there is precedence for these observations. Thus, Unverferth et al[9] noted improvement in myocardial function as determined by systolic time intervals and echocardiographic variables in 20 of 30 and 18 of 30 patients, respectively, studied 1 week after 72-hour dobutamine infusions. In that study, improvement was sustained as long as 10 months and has recently been ascribed to a conditioning effect of the drug.[10] Similar effects have been noted in dogs.[11]

It is possible that increased accessibility to medical care or more aggressive treatment of CHF, or both, rather than the chronic use of dobutamine was responsible for the clinical improvement in our patients. It seems unlikely, however, that the former mechanism played a role. Both patients (Cases 1 and 3) hospitalized repeatedly for intractable CHF are well-known to us, are assiduous in following their diets and taking their medications, and have received care by skilled physicians for several years. Also, noninvasive data in 2 patients (Cases 1 and 2) showed improvement in left ventricular function during dobutamine infusion. The role of more vigorous "conventional" therapy is less easy to dismiss. However, in patients (Cases 1 and 2) conventional therapy for CHF was not dramatically changed after dobutamine infusion was started. In Patient 3, such therapy undoubtedly contributed to—but, in our view, does not entirely explain—the clinical improvement observed after dobutamine was begun.

Patient acceptance of the catheter and infusion pump has been excellent. After a training period each patient has willingly assumed responsibility for the care of these appliances. The complication rates for the catheter system are acceptably low. In the initial 106 catheter insertions in our cancer center there have been only 3 instances each of bacteremia and thrombosis in 99 granulocytopenic, immunosuppressed patients. In our patients there have been 3 superficial infections with the use of this catheter. Each was promptly recognized, unassociated with bacteremia, and treated without need for hospitalization. While any infection in patients who may have valvular disease or a prosthetic valve is cause for concern, such risks seem acceptable in the absence of suitable alternatives to treat intractable CHF.

It is obvious that such "unconventional" therapy is not appropriate for every patient who has chronic CHF. However, given a willing patient in whom preload and afterload reducing agents have been unsuccessful, continuous dobutamine infusion should be seriously considered. The availability of a compact, reliable infusion pump[12] now allows such outpatient therapy to be given. Tolerance can apparently be circumvented by administering dobutamine 2 days each week. It is hoped that newer oral inotropic agents will become available to replace the need for this form of therapy. Until such time, however, the continuous intravenous infusion of dobutamine shows promise as an effective form of therapy to improve the quality of life in selected patients with intractable congestive heart failure.



**Acknowledgment:** The authors acknowledge the secretarial assistance of Bonnie J. Dooley. Michael Stewart, MD, and Jeffrey Cole, MD, referred 2 patients for this study. We also thank Cormed (Medina, New York) for partial support of this project.

# R-Wave Amplitude Change During Aerobic Exercise In Hypertensive Adolescents After Treatment

BONITA FALKNER, MD, DAVID T. LOWENTHAL, MD, MELTON B. AFFRIME, PharmD, and BARBARA HAMSTRA, RN

**This study attempts to determine whether the blunted reduction in R-wave amplitude during progressive aerobic exercise observed in adolescents with systemic hypertension could be altered by pharmacologic therapy to reduce blood pressure. Twenty-nine hypertensive adolescents were randomly assigned to treatment with either a diuretic, hydrochlorothiazide, or a centrally acting agent, clonidine. After 16 weeks of therapy, casual blood pressure was significantly reduced in both groups. Repeat exercise stress testing on therapy demonstrated a significant change in R-wave response. In both treatment groups the change in R-wave amplitude during exercise corresponded with the R-wave response pattern observed in normotensive control subjects. These observations indicate that the altered R-wave amplitude response to exercise observed in young hypertensive subjects is reversible and suggest that the altered R-wave response before treatment is related to a higher vascular resistance.**

Reports have demonstrated that essential hypertension in adolescence is a recognizable entity.[1,2] Although adolescent hypertension is mild, little is known regarding the hemodynamic components of this phase of hypertension. Studies of borderline hypertension in young adults have demonstrated an increased cardiac index and increased left ventricular ejection rates consistent with high cardiac output. However, some young adults with mild hypertension have increased vascular resistance or a combination of increased resistance and high cardiac output.[3,4] More recent investigations on adolescents with mild hypertension using noninvasive methods report myocardial hypertrophy and altered myocardial function. These observations suggest in some cases the presence of an increase in peripheral vascular resistance.[5,6] In a previous report we investigated the change in R-wave amplitude during aerobic exercise in adolescents. Normotensive adolescents demonstrated a decrease in R-wave amplitude with progressive exercise. Hypertensive adolescents did not demonstrate a similar decrease in R-wave amplitude with progressive exercise despite higher systolic blood pressure and heart rate at each exercise level.[7] This variation in myocardial function in hypertensive adolescents, as evidenced by a difference in R-wave response to exercise, may reflect a level of peripheral vascular resistance greater than that of normotensive subjects. Other possible explanations for the difference in R-wave response in hypertensive subjects were intrinsic myocardial dysfunction or excessive sympathetic stimulation. The objective of this study was to determine whether the R-wave response to exercise in hypertensive adolescents could be altered by pharmacologic intervention directed at lowering the blood pressure.

From the Department of Pediatrics, Medicine, and Likoff Cardiovascular Institute, Hahnemann University, Philadelphia, Pennsylvania. Manuscript received May 5, 1982; revised manuscript received August 25, 1982, accepted August 27, 1982.

Address for reprints: Bonita Falkner, MD, Department of Pediatrics, Hahnemann University, 230 North Broad Street, Philadelphia, Pennsylvania 19102.

## Methods

Twenty-nine hypertensive participants aged 13 to 19 years, who completed the program, constitute the study group. All had blood pressure measurements consistently above the 95th percentile[8] for >3 months before therapy. Basic evaluation excluded secondary causes of hypertension. Additionally, all participants were unresponsive to nonpharmacologic measures for blood pressure reduction. Normotensive control adolescents were healthy adolescent male subjects, all of whom had casual seated blood pressure below the 90th percentile for age. Written informed consent on an institutionally approved protocol was obtained from all participants before exercise testing and therapy were initiated. The first phase of treatment for the hypertensive participants was placebo therapy for 4 weeks. During the placebo phase, dynamic exercise testing was performed; after the placebo period, each subject was randomized into 1 of 2 treatment groups. Group I received

**TABLE I Baseline Values of Hypertensive and Normotensive Subjects**

| | Normotensive Control Subjects (n = 26) | Group 1 (n = 15) Hypertensive HCTZ Rx | Group 2 (n = 14) Hypertensive Clonidine Rx |
|---|---|---|---|

* Measurements reflect the average of these determinations for each subject in a seated position.
HCTZ = hydrochlorothiazide; Rx = treatment.

a diuretic, hydrochlorothiazide, at an initial dosage of 25 mg twice daily. Group II received a centrally acting antihypertensive agent, clonidine, with an initial dosage of 0.1 mg twice daily. After 12 weeks of this low dose therapy those patients who had not achieved blood pressure treatment goals of less than the 90th percentile were changed to a larger dose consisting of hydrochlorothiazide 50 mg twice daily or clonidine 0.2 mg twice daily. Those who had achieved blood pressure treatment goals at the low dose continued therapy at the same dosage. Dynamic exercise testing was repeated at 16 to 18 weeks of therapy. Total period of therapy for all participants was 24 weeks.

The method for exercise stress testing is similar to that previously described.[9] After a period of rest and instruction each participant underwent a progressive maximal treadmill test according to the Bruce protocol. A target heart rate of 200 beats/min was used as the predicted end point of exercise. Blood pressure was obtained by standard auscultation using a mercury column sphygmomanometer with an appropriate size cuff. Thus, blood pressure was determined at baseline in the standing position before exercise, at the second minute of each stage of exercise, and through the recovery period of 10 minutes. Heart rate was obtained at baseline and at 1 minute intervals throughout the study by a Quinton oscilloscope electrocardiographic monitor. The electrocardiogram was monitored continuously and a $V_5$ tracing was obtained at 1 minute intervals. In the recovery period measurements of blood pressure and heart rate were obtained with the subject in a seated position. As previously described,[7] the R-wave amplitude was measured from the isoelectric line to the peak of the R wave in millimeters and averaged from 10 consecutive beats. The average amplitude at the second minute of each exercise state was then used as the R-wave amplitude for that stage of the Bruce protocol. The difference in R-wave amplitude from the resting R-wave amplitude in the standing position was computed as the change in R-wave amplitude for each level of progressive exercise.

Pre- and post-treatment data were analyzed for significance by the paired $t$ test. Change in R-wave amplitude during exercise was evaluated by regression analysis. Normotensive and hypertensive exercise response data were compared by a 2-tailed $t$ test.

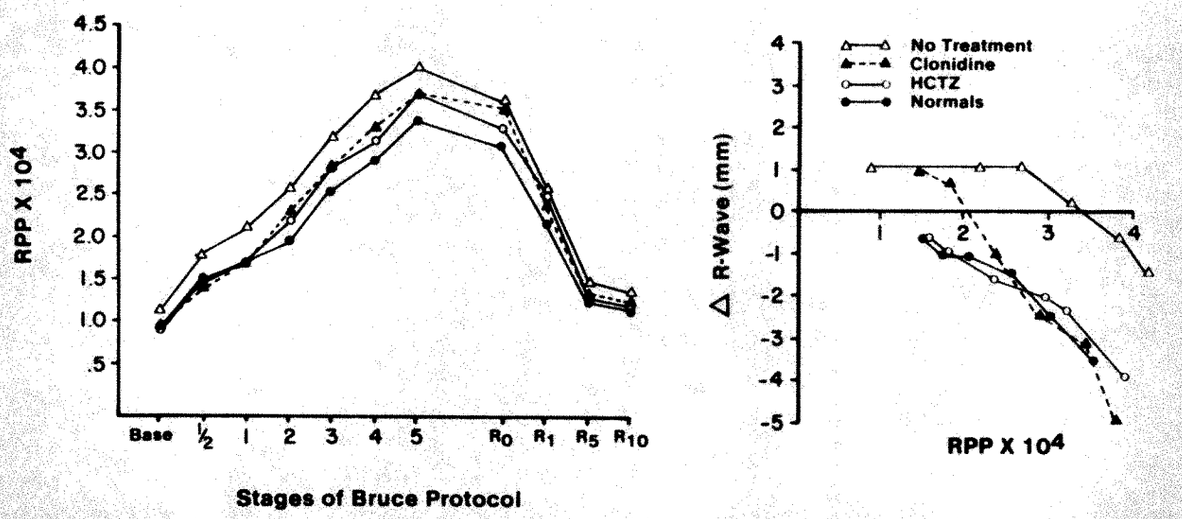

**FIGURE 1. Left panel,** the product of the systolic blood pressure × heart rate (RPP × $10^4$) at each stage of exercise and during the recovery period (R) in minutes. RPP was significantly reduced with clonidine and hydrochlorothiazide (HCTZ) treatment through stage 2 ($p < 0.01$). **Right panel,** the change in R-wave amplitude versus product of the systolic blood pressure × heart rate (RPP × $10^4$). The correlation coefficients are as follows: normotensive subjects RPP = −0.39 (ΔR) + 1.81; $r^2 = 0.88$. Hydrochlorothiazide RPP = −0.37 (ΔR) + 2.04; $r^2 = 0.98$. Clonidine RPP = −0.69 (ΔR) + 1.38; $r^2 = 0.91$.

## Results

Thirty adolescents who fulfilled the criteria for sustained hypertension participated in the treatment program. All subjects demonstrated a satisfactory level of compliance in taking medication as checked by pill counts. Fifteen adolescents, 9 male and 6 female, were treated with hydrochlorothiazide (Group I). During the second exercise test all were taking hydrochlorothiazide 50 mg twice daily. Group II, consisting of 15 adolescents, received clonidine. Exercise testing was complete in 14, including 12 males and 2 females. One male adolescent was unable to complete the exercise protocol because of exercise-induced asthma. On repeat testing during therapy, 5 subjects were receiving clonidine 0.1 mg twice daily and 9 were receiving clonidine 0.2 mg twice daily. After 14 weeks of therapy significant blood pressure and heart rate reduction had been achieved.

Table I provides the mean age, weight, and height as well as the casual seated blood pressure and heart rate before and during treatment at the time of repeat exercise study. There is no difference in age, height, and weight in the 2 treatment groups. Also, the age and body size of the hypertensive subjects are similar to those of the normotensive control group.

During graded treadmill exercise there was a progressive increase in systolic pressure and heart rate in all subjects. The left panel of Figure 1 depicts the product of systolic blood pressure and heart rate (SBP × HR) during exercise in normotensive, untreated hypertensive, and hypertensive subjects in the two treatment groups. SBP × HR is greater in untreated hypertensive subjects throughout the exercise. During treatment SBP × HR is significantly reduced ($p < 0.01$) and similar to normotensive control values in the early phase of exercise in both treatment groups. After exercise stage II of the Bruce protocol, SBP × HR of the treated hypertensive subjects is less than pretreatment values, but the reduction is not in a range of statistical significance. The right panel of Figure 1 depicts the correlation of change in R-wave amplitude with SBP × HR in the same groups.

Normotensive control subjects demonstrate a progressive decrease in R-wave amplitude which correlates with increasing product ($r^2 = 0.88$, $p < 0.01$). In hypertensive subjects, only at peak exercise does the R-wave amplitude decrease ($r^2 = 0.33$, is not significant). During therapy the correlation of change in R-wave amplitude with SBP × HR is similar to that in normotensive control subjects in both treatment groups (group I: $r^2 = 0.98$, $p < 0.001$; group II: $r^2 = 0.91$, $p < 0.005$). Correlations of R-wave amplitude change with both systolic pressure and heart rate resulted in a similar pattern.

Table II presents the absolute values of R-wave amplitude during exercise for the 2 treatment groups. Due to variation in R-wave amplitude within groups and variations in electrode placement between exercise tests the change in R-wave amplitude during exercise was used for analysis of the R-wave response to exercise. Figure 2 provides data demonstrating the change in R-wave amplitude at each exercise level. On therapy, hypertensive subjects as a group demonstrate a decrease in R-wave amplitude with graded exercise similar to the response observed in normotensive subjects. The change in R-wave response during treatment in both groups is similar and significantly different by 2-way analysis of variance from the pretreatment R-wave response to exercise ($p < 0.01$).

## Discussion

These results demonstrate a blunted decrease in R-wave amplitude in response to aerobic exercise in untreated hypertensive adolescents. The R-wave response to exercise appears to normalize after approximately 16 weeks of antihypertensive therapy with either hydrochlorothiazide or clonidine. Previous reports indicate that changes in the amplitude of the R wave during exercise may be a more sensitive indication of myocardial dysfunction in adults.[10] Failure of the ischemic ventricle to eject its volume during strenuous aerobic exercise may be responsible for absence of the usual reduction in R-wave amplitude.[11,12] R-wave amplitude change was studied previously in a group of hypertensive adolescents. Compared with age- and weight-matched normotensive subjects, hypertensive subjects did not manifest the decrease in R-wave amplitude with progressive exercise.[7] Because of the young age and the absence of any clinical signs of significant cardiovascular disease in these hypertensive juvenile subjects, mechanisms other than ischemic myocardial dysfunction must be present to account for the difference in R-wave amplitude response to exercise.

This difference in R-wave response was again observed in a group of hypertensive adolescents before

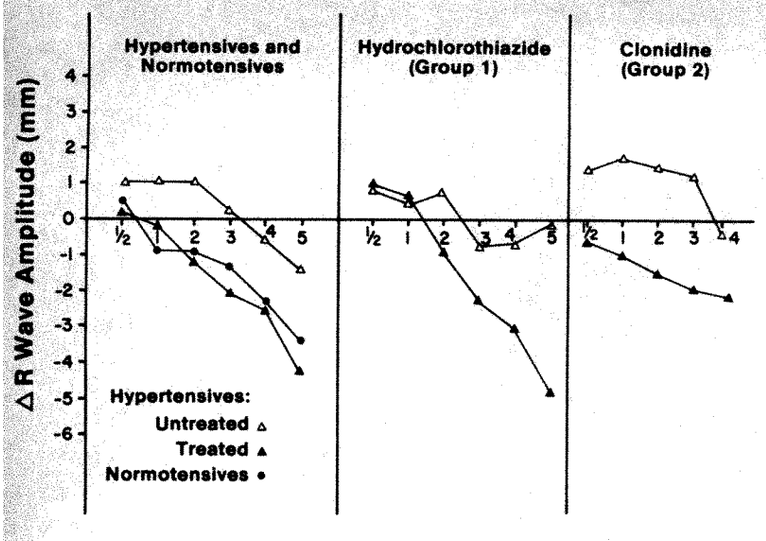

**FIGURE 2.** The mean R-wave amplitude change at each stage of progressive exercise. **Left panel,** normotensive control subjects, all untreated hypertensive subjects as a group, and all hypertensive subjects before and after treatment. **Middle panel,** the R-wave response before and during hydrochlorothiazide therapy. **Right panel,** the R-wave response before and during clonidine therapy.

initiation of pharmacologic therapy to decrease blood pressure. Chronic pharmacologic therapy resulted in significant blood pressure reduction in both treatment groups. Diastolic pressure reduction on clonidine therapy was highly significant. The effect of hydrochlorothiazide on diastolic pressure was less, but at the time of repeat exercise testing the diastolic pressure reduction in the seated position was significant. Therefore, there was a generalized reduction in blood pressure in both treatment groups during the 16 weeks of therapy before the second exercise test. With therapy the systolic pressure and heart rate response during progressive exercise was lower in both treatment groups. Similarly, the product (SBP × HR) was also lower during therapy, but these values were still greater than those of the normotensive control subjects particularly as exercise became more strenuous. Exercise capacity was unchanged after therapy. Each subject was able to exercise to the same level on therapy as they had before treatment.

Hemodynamic studies in hypertensive young adults demonstrated an increased cardiac index and increased left ventricular ejection rate.[13,14] The higher systolic pressure and heart rate in hypertensive adolescents during exercise before therapy relative to those of normotensive subjects matched for age and body size would be consistent with a hyperkinetic cardiovascular state. The hyperkinetic state of borderline hypertension is characterized by an increased cardiac output, increased blood pressure, and normal peripheral vascular resistance.[15] This phase is unlike later hypertension in which cardiac output is normal, blood pressure is increased, and vascular resistance is increased. It has been suggested that vascular resistance is inappropriately normal in early hypertension, when vascular resistance should be lower to offset the increased cardiac output.[16]

Changes in left ventricular mass have been reported in the early phases of hypertension which may be relative to hemodynamic function.[17,18] Echocardiographic studies in some mildly hypertensive adolescents demonstrated decreased left ventricular diastolic volumes,[19] increased posterior wall thickness,[20] increased ventricular septal thickness, and increased cross-sectional muscle area and mass.[5,6] These observations suggest a relative state of left ventricular hypertrophy. Echocardiographic studies in the young have demonstrated alterations in indexes of left ventricular mass. No functional abnormalities of the myocardium have been demonstrated by echocardiography. However, these echocardiographic reports in the young do suggest myocardial involvement in the very early stages of hypertension. The change in R-wave amplitude during progressive aerobic exercise is a measure that can be directly related to myocardial function.

Hypertensive adolescents manifest an R-wave response pattern quite different from that of normotensive control subjects.[7] Furthermore, pharmacologic therapy, which imposed an extended period of blood pressure reduction, resulted in normalization of the R-wave response to exercise despite levels of blood pressure which, although significantly reduced, are still not in the normotensive range.

In this study the normalization of the R-wave response to exercise may be due to a direct drug effect on the myocardium or indirectly to the hemodynamic effects of a lower blood pressure per se. The 2 different pharmacologic treatments had approximately the same effect in altering the R-wave response, although their antihypertensive mechanism differed. The centrally acting agent, clonidine, is a central alpha agonist that diminishes peripheral sympathetic activity. The diuretic hydrochlorothiazide results in salt and volume depletion and alters vascular sensitivity to sympathetic stimuli.[21] The degree of sympathetic nervous system activity involving the myocardium could not provide an explanation for the change in R-wave response. Baseline levels of plasma catecholamines dissociated in the 2 treatment groups after therapy. Resting plasma norepinephrine levels increased in the hydrochlorothiazide-treated group and decreased in the clonidine-treated group.[22] Furthermore, normalization of the

R-wave response was observed in the absence of beta-blocking agents that directly affect the myocardium. Therefore, it is hypothesized that normalization of the R-wave response to exercise observed in both treatment groups is related to the chronic hemodynamic effect of both treatments in lowering peripheral vascular resistance.

These observations need to be supported by further studies in young hypertensive subjects using other pharmacologic and nonpharmacologic measures. However, the findings do suggest the presence of variations of myocardial function in young hypertensive subjects. These variations appear to be reversible, and the results of this study suggest that the blunted R-wave response to exercise before treatment may be related to an increased, or inappropriately normal, vascular resistance.

# Increased Plasma Concentrations of Prostacyclin Metabolite 6-Keto-$PGF_{1\alpha}$ in Essential Hypertension

## Influence of Therapy With Labetalol

LOUIS ROY, MD, JAWAHAR MEHTA, MD, and PAULETTE MEHTA, MD, *With the technical assistance of* NANCY OSTROWSKI, CHRISTINE HORALEK, and GEORGIA KELLEY

**To evaluate the role of the vasoactive prostaglandins prostacyclin and thromboxane $A_2$ in essential hypertension, the stable metabolites 6-keto-$PGF_{1\alpha}$ and thromboxane $B_2$, respectively, were measured in plasma before and after therapy in 7 patients. During the placebo phase, plasma 6-keto-$PGF_{1\alpha}$ levels were significantly greater than normal. Plasma thromboxane $B_2$ levels were not statistically different from those in normal subjects. After intravenous administration of labetalol to the point of blood pressure reduction, neither plasma 6-keto-$PGF_{1\alpha}$ nor thromboxane $B_2$ values changed. With prolonged oral labetalol therapy and concurrent regulation of blood pressure, a significant decrease in plasma 6-keto-$PGF_{1\alpha}$ levels occurred while thromboxane $B_2$ values remained unaltered. Elevation of plasma 6-keto-$PGF_{1\alpha}$ in untreated hypertensive subjects suggests that enhanced vessel wall prostacyclin synthesis may be a protective mechanism to prevent organ damage. As blood pressure is controlled this increase is no longer needed, and prostacyclin generation returns to normal.**

Since the discovery of prostacyclin and thromboxane $A_2$,[1-3] these very labile prostaglandins[3,4] have been implicated in many cardiovascular diseases. The former, synthesized mostly in vessel walls, has potent vasodilatory and platelet aggregation inhibitory properties.[1,5] The latter, synthesized mainly in platelets,[2,6] is a powerful vasoconstrictor[7] and potent platelet aggregant.[2] Recent evidence has demonstrated that prostaglandins may also be involved in the regulation of blood pressure. The drugs interfering with cyclooxygenase activity have been reported to decrease the effectiveness of antihypertensive therapy.[8-11] Some investigators have described a decrease in urinary metabolites of prostacyclin in hypertensive subjects which suggests an imbalance of prostacyclin-thromboxane $A_2$ equilibrium in favor of the latter.[12] Impaired renal production of prostaglandin $E_2$ in essential hypertension has also been reported.[13] Vessels from spontaneously hypertensive rats have been shown to generate unusually large amounts of $PGI_2$.[14,15] Whether a similar phenomenon occurs in human subjects is not known.

This study was designed to evaluate the role of thromboxane $A_2$ and prostacyclin in hypertensive subjects before and after antihypertensive treatment with labetalol, which is an alpha- and beta-adrenoreceptor blocking drug.[16,17]

### Methods

**Patients and study protocol:** We evaluated 7 hypertensive men, aged 44 to 68 years (mean ± standard error of the mean 54 ± 7). Diastolic blood pressure was 95 mm Hg or higher after the patients had been untreated for at least 2 weeks. All secondary causes of hypertension were excluded. Other exclusion criteria were lung disease, symptomatic coronary heart disease, malignant hypertension, and cerebrovascular or renal impairment. No concomitant antihypertensive, platelet-active, or prostaglandin-active drugs were permitted during the study. All patients gave a written informed consent approved by Institutional Review Committees.

After a 2-week placebo phase, subjects were hospitalized and intravenous labetalol (0.5 to 1.0 mg/kg) was administered to achieve at least 10 mm Hg reduction in diastolic blood pressure. The subjects were then discharged on oral labetalol and readmitted for a second evaluation 6 weeks later. During long-term labetalol treatment, they were followed up on a weekly basis and given increasing doses of labetalol until appropriate blood pressure control (diastolic pressure ≤90 mm Hg) was obtained.

**Blood collection:** Blood samples were collected in the placebo phase, the intravenous labetalol phase, and at the end of oral labetalol phase. Each time, the first 2 ml of blood was

* $p < 0.05$ versus placebo phase. † $p < 0.01$ versus placebo phase. ‡ $p < 0.001$ versus placebo phase.

discarded, then 4 ml was gently withdrawn in a polystyrene syringe and immediately transferred into a tube containing aspirin and ethylene diaminetetraacetic acid (EDTA) (1 ml) at 4°C. The tube was centrifuged at 150 *g* for 8 minutes and plasma was transferred for 6-keto-$PGF_{1\alpha}$ and thromboxane $B_2$ determinations.

**Thromboxane $B_2$ and 6-keto-$PGF_{1\alpha}$ determination:** Plasma thromboxane $B_2$ and 6-keto-$PGF_{1\alpha}$ were measured by radioimmunoassay as previously described.[18,19] Lyophilized standards, $^3$H-thromboxane $B_2$ and $^3$H-6-keto-$PGF_{1\alpha}$, and the antibodies raised in rabbits were obtained from New England Nuclear, Boston, Massachusetts. With use of this method, the cross-reactivity of thromboxane $B_2$ antibody with other prostaglandins was as follows: $PGE_2$ 0.2%, $PGA_2$ 0.2%, $PGF_{2\alpha}$ <0.2%, and 6-keto-$PGF_{1\alpha}$ <0.2%. The cross reactivity of 6-keto-$PGF_{1\alpha}$ antibody with other prostaglandins was as follows: $PGF_{2\alpha}$ 2.7%, $PGE_2$ and $TXB_2$ <0.1%, $PGA_2$ 0.1%, and $PGA_1$ <0.3%. The results for both 6-keto-$PGF_{1\alpha}$ and thromboxane $B_2$ were expressed in pg/ml.

**Normal values:** Normal values for plasma 6-keto-$PGF_{1\alpha}$ and thromboxane $B_2$ were determined in venous blood samples withdrawn from 23 healthy subjects (mean age 47 ± 7 years). Blood was withdrawn from the antecubital vein, without tourniquet pressure. The samples were collected and processed in the same manner as described for the patients.

**Statistical analysis:** Results were expressed as mean ± standard error of the mean. Student's *t* test (paired and unpaired data), the Kruskal-Wallis rank sum test, and Wilcoxon signed rank sum tests were used for comparison. Data were examined with regard to relation between changes in prostaglandin values and the blood pressure (systolic, diastolic, and mean) by regression analysis. Data were also analyzed to identify any relation between blood pressure levels and 6-keto-$PGF_{1\alpha}$ concentrations before and after treatment. A p value <0.05 was considered significant.

## Results

**Labetalol and hemodynamic effects:** The hemodynamic effects of labetalol are summarized in Table I. Intravenous labetalol (mean dose 0.6 mg/kg) resulted in a mean plasma level of 105 ± 21 ng/ml of plasma. With this dose, mean blood pressure was lower in each subject, but cardiac output and heart rate were unchanged. The systemic vascular resistance (mean arterial pressure × 80/cardiac output) decreased significantly ($p < 0.025$). With oral labetalol for 6 weeks (1,200 mg/day in 3 subjects and 800 mg/day in 4 subjects), mean plasma levels of 176 ± 59 ng/ml were obtained. Diastolic and systolic blood pressures showed a mean decrease of 16 and 24 mm Hg, respectively. The heart rate decreased significantly. Cardiac output decreased in 6 patients and increased in the remaining patient. Systemic vascular resistance increased in 4 and decreased in 3 patients. Changes in cardiac output and vascular resistance were not significant compared with the placebo phase.

**Thromboxane $B_2$ concentrations (Fig. 1):** Plasma thromboxane $B_2$ concentrations in hypertensive subjects in the placebo phase showed a wide variation

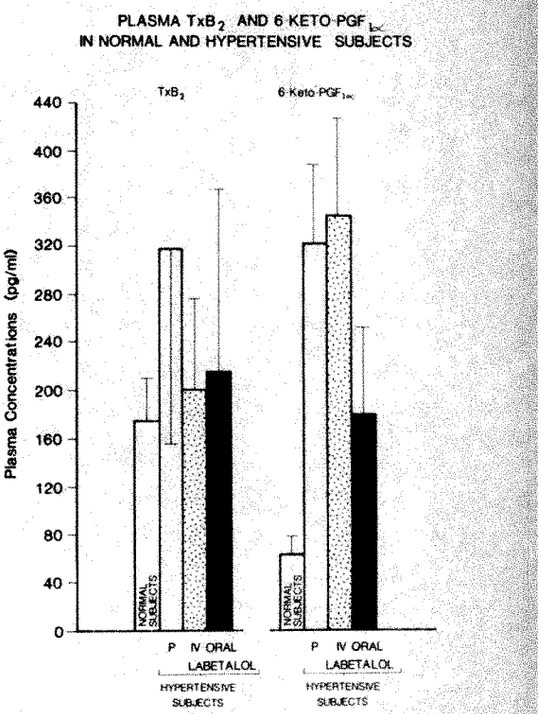

**FIGURE 1.** Plasma $TXB_2$ and 6-keto-$PGF_{1\alpha}$ concentrations in normal and hypertensive subjects. $TXB_2$ levels did not differ in the 2 populations. Plasma 6-keto-$PGF_{1\alpha}$ levels were higher in hypertensive subjects before therapy, and decreased significantly with long-term antihypertensive therapy. Data are expressed as mean ± standard error of the mean. IV = intravenous; P = placebo.

(range 82 to 1,220 pg/ml, mean 318 ± 183 pg/ml). One patient with very high plasma thromboxane $B_2$ concentrations, 1,220 pg/ml, continued to exhibit these high concentrations after short- and long-term labetalol administration (570 and 840 pg/ml, respectively) and on another occasion after discontinuation of labetalol (1,100 pg/ml). The mean plasma thromboxane $B_2$ concentrations in hypertensive subjects in the placebo phase were similar to those in the normal volunteers (175 ± 35 pg/ml). After short-term intravenous and long-term oral labetalol administration, the mean plasma thromboxane $B_2$ concentrations decreased to 200 ± 76 pg/ml and 215 ± 132 g/ml, respectively. None of these values were significantly different from each other or from the normal values.

**Concentrations of 6-keto-$PGF_{1\alpha}$ (Fig. 1):** In the 23 normal subjects, 6-keto-$PGF_{1\alpha}$ concentrations were extremely low: they were undetectable in 7 subjects, and the mean value was 64 ± 14 pg/ml. In contrast, 6 hypertensive subjects in the placebo phase had detectable and markedly elevated plasma 6-keto-$PGF_{1\alpha}$ concentrations (range 190 to 500 pg/ml), and 1 patient had undetectable concentrations throughout the study. The mean value was significantly higher in hypertensive subjects than in the normal volunteers (321 ± 67 versus 64 ± 14 pg/ml, $p < 0.01$). With immediate decrease in blood pressure after intravenous labetalol administration, plasma 6-keto-$PGF_{1\alpha}$ concentrations decreased in only 2 patients compared with the placebo phase, but were still very high (range 0 to 550 pg/ml, mean 344 ± 82 pg/ml; difference not significant compared with the placebo phase). With prolonged oral labetalol therapy and blood pressure reduction, plasma 6-keto-$PGF_{1\alpha}$ concentrations showed a significant decrease from the placebo phase in all 6 patients (range 0 to 500 pg/ml, mean 179 ± 74, $p < 0.05$) or from the short-term intravenous phase (mean 179 ± 74 versus 344 ± 82 pg/ml, $p < 0.05$). These plasma 6-keto-$PGF_{1\alpha}$ concentrations after oral therapy and prolonged blood pressure reduction did not differ significantly from those in the normal subjects.

Analysis of data showed no significant relation between levels of 6-keto-$PGF_{1\alpha}$ and blood pressure before and after treatment. Similarly, there was no correlation between changes in plasma concentrations of 6-keto-$PGF_{1\alpha}$ and reduction in systolic, diastolic, or mean arterial pressure.

## Discussion

**Increase in prostacyclin in hypertension:** This study shows that enhanced prostacyclin but normal thromboxane $A_2$ synthesis is present in patients with essential hypertension. With acute reduction of blood pressure, no significant changes in plasma concentrations occur. However, after prolonged treatment as the blood pressure is controlled for several weeks, prostacyclin metabolite in plasma decreases. Because 6-keto-$PGF_{1\alpha}$ is a major metabolite of prostacyclin, increased levels in the untreated hypertensive subjects could imply either enhanced degradation of prostacyclin with subsequent increased synthesis, or a primary increase in prostacyclin synthesis with concomitant increases in its metabolite concentration in plasma. The latter hypothesis is supported by animal experiments that demonstrate enhanced basal prostacyclin synthesis by vessels from spontaneously hypertensive rats.[14,15] The fact that plasma 6-keto-$PGF_{1\alpha}$ concentrations return to normal after prolonged antihypertensive therapy leads us to believe that enhanced prostacyclin synthesis by vessel walls in hypertensive patients may be a protective mechanism against organ damage. As blood pressure is adequately controlled, this compensatory mechanism is no longer necessary, and the prostacyclin synthesis by vessel walls may gradually return toward the normal state. In agreement with this "protective mechanism" concept is the observation that in stroke-prone, spontaneously hypertensive rats with an increase in vascular prostacyclin synthesis, prostacyclin-synthesizing capability is lost just before the evolution of stroke.[14]

**Mechanism of increased prostacyclin synthesis:** The mechanism of enhanced prostacyclin synthesis is still unclear. It is known that prostacyclin synthesis increases markedly with trauma[20] and increased intravascular stress.[14,15] Stress states such as exercise,[21] smoking,[22] ischemia, and venous stasis[23] also cause an increase in prostacyclin synthesis. Whether labetalol itself affects $PGI_2$ generation is not known. However, we observed no change in plasma 6-keto-$PGF_{1\alpha}$ with intravenous labetalol administration. With prolonged antihypertensive therapy, a marked decrease in blood pressure was accompanied by a decline in 6-keto-$PGF_{1\alpha}$ levels. It is tempting to postulate that a new state of prostacyclin synthesis develops with prolonged antihypertensive therapy. Although plasma concentrations of labetalol with oral therapy were similar to those with short-term intravenous administration, direct effects of labetalol on prostacyclin synthesis and release cannot be excluded. We found no correlation between decline in plasma concentrations of 6-keto-$PGF_{1\alpha}$ and decrease in blood pressure. Further studies are needed in a large number of patients to determine whether the decrease in plasma 6-keto-$PGF_{1\alpha}$ concentration is observed with other antihypertensive drug regimens and if plasma 6-keto-$PGF_{1\alpha}$ concentrations correlate with changes in blood pressure.

**Platelets and thromboxane $A_2$ in hypertension:** In some previous studies, certain platelet function variables have been reported to be abnormal in hypertensive patients.[24,25] These abnormalities may be corrected with control of blood pressure. However, plasma thromboxane $B_2$ concentrations in the normal range in treated or untreated hypertensive subjects as seen in this study do not suggest a primary role for thromboxane $A_2$ in the genesis of essential hypertension. In a recent study, Frishman et al[26] administered labetalol to patients with angina pectoris and hypertension, but failed to observe any significant antiplatelet effects of labetalol. This is in agreement with our observations of unchanged plasma thromboxane $B_2$ concentrations in hypertensive patients.

**Implications:** We therefore conclude that prostacyclin synthesis is increased in hypertensive human subjects; this may be a protective mechanism against

organ damage. Increase in prostacyclin synthesis occurs most probably in response to decreased blood flow and increased intravascular stress. As blood pressure is decreased, prostacyclin synthesis returns to normal levels. However, as in other biologic systems, the adjustment of vascular tone and regulation of prostaglandin synthesis by vessel wall does not occur immediately.

# Analysis of Ventricular Emptying and Filling Indexes During Acute Increases in Arterial Pressure

ROBERT A. SLUTSKY, MD, G. B. JOHN MANCINI, MD, KENNETH H. GERBER, MD, HOWARD C. DITTRICH, MD, and CHARLES B. HIGGINS, MD

**Using equilibrium radionuclide angiography, an evaluation was made of the response of left ventricular ejection and filling rates at rest and during acute increases in afterload in 8 normal volunteer subjects and 10 patients with previous transmural myocardial infarctions. Using the postatropine point for comparison, normal patients increased ejection time and decreased peak ejection rate (−3.90 ± 0.49 vol/s to −3.41 ± 0.95 vol/s) and peak filling rate (3.94 ± 0.88 vol/s to 3.51 ± 0.38 vol/s). Infarct patients had similar responses, although all indexes were lower than the corresponding values in the normal subjects. At rest, the ratio of peak filling to emptying rate was similar in the normal subjects and the infarct patients (1.01 ± 0.24 versus 0.99 ± 0.25, respectively) and maintained that relationship after atropine (0.91 ± 0.11 versus 0.81 ± 0.21) and at the peak increase in arterial pressure (1.07 ± 0.21 versus 1.02 ± 0.32). The ratio of time to peak filling/time to peak emptying behaved in similar fashion regardless of the differences in the absolute values.**

**In this study, left ventricular filling and emptying behaved in a similar fashion in response to the alteration in arterial pressure in normal subjects and in patients with previous myocardial infarctions.**

Numerous investigators have recommended the use of left ventricular velocity and acceleration indexes of left ventricular performance.[1–7] These variables are difficult to measure noninvasively and are influenced by changes in the compliance of the arterial vasculature and by aortic flow dynamics.[8–14] Difficulties with measurement of these variables have led others to investigate the rate of change of ventricular volume during ejection as an alternative.[15,16] Little data exist on the response of peak ejection rate, time to peak ejection rate, or ejection time to afterload stress.[17,18] Recently, we validated the accuracy of the peak rate of ventricular emptying (peak − dV/dt) derived from gated blood images as an accurate noninvasive radionuclide index of left ventricular systolic function.[19] Others have demonstrated the accuracy of the timing of systolic events during the ejection phase of the cardiac cycle from equilibrium radionuclide volume curves.[20]

In previous work, we examined the effects of curve-merging techniques in attempts to characterize diastolic performance derived from radionuclide volume curves[21] and subsequently applied these techniques to patients during supine bicycle exercise.[22] Recent studies have reported that diastolic performance may aid in discriminating subtle abnormalities in left heart performance in patients with coronary artery disease.[23–25]

The purposes of our present study were (1) to examine peak ejection rate (peak −dV/dt) and peak filling rate (peak +dV/dt) in normal subjects and in patients with previous myocardial infarctions; (2) to examine the time during ejection and filling that peak −dV/dt and peak +dV/dt occur in normal subjects and infarct patients; and (3) to assess the utility and response of these variables during acute increases in afterload.

## Methods

**Study:** The study was undertaken in 18 normotensive male volunteers. Ten subjects (mean age 50 years, range 41 to 69) had had a previous transmural myocardial infarction at least 6 months earlier, as evidenced by a typical history of chest pain, elevated serum creatinine kinase levels, and characteristic electrocardiographic changes. No patient had clinical evidence of valvular heart disease or peripheral vascular disease and none had ingested any medications except diuretics within 48 hours of the study. Six had anterior and 4 had inferior infarctions.

The other 8 subjects were normal control volunteers (mean age 36 years, range 19 to 58) with no clinical evidence of cardiovascular disease. They were taking no medications and had no abnormalities on resting or exercise electrocardiograms. Written informed consent was obtained from all subjects and the protocol was approved by the Committee on Investigations Involving Human Subjects of the University of California, San Diego. Smoking and the consumption of caffeine-containing beverages were not permitted for 4 hours before the study.

On arrival at the laboratory, subjects were instructed to lie in the supine position and remain still throughout the study. A 19 gauge "butterfly" needle was inserted into a vein in the right arm for administration of pharmaceuticals. An 18 gauge intravenous cannula (Jelco) was introduced into a forearm vein for blood sampling.

A single crystal gamma camera (Picker Dyna-Mo) fitted with a parallel hole, general purpose collimator was then positioned over the subject's chest wall in a 45° left anterior oblique position, with 5 to 10° caudal tilt. The camera position was then further adjusted if necessary so that the image of the left ventricle was clearly separated from that of the right ventricle and the left atrium. Thereafter, the camera position remained unchanged.

**Measurements:** One lead from a surface electrocardiogram was continuously displayed on a cardiac monitor (Hewlett-Packard). A precise heart rate was obtained at each phase in the study from the number of cardiac cycles recorded by the gamma camera during a 5 minute electrocardiogram gated left ventricular scintigram.

Blood pressure was measured in duplicate from the right arm every 60 seconds during left ventricular scintigraphy, using a standard mercury sphygmomanometer (Baumanometer). Systolic blood pressure was derived from the mean of 10 readings taken over a 5-minute period (blood pressure was also measured in the left arm at the beginning of the study and disparities between the 2 arms of >10 mm Hg were not found).

The patient's own red cells were labelled ex vivo with technetium-99m using the method of Smith and Richards.[26] Briefly, 4 ml of venous blood was drawn into a heparinized syringe and incubated for 5 minutes with freeze-dried stannous citrate in a sterile evacuated glass tube. The tube was then centrifuged upside-down for 5 minutes at 1,300 *g* and the red cells carefully removed by needle aspiration through the rubber stopper. Finally, the red cells were incubated in a sterile tube containing technetium-99m (Nuclear Pharmacy) for a further 5 minutes before the red cell suspension, containing 15 to 20 mCi of technetium-99m was reinjected by way of the butterfly needle to effect the blood pool label. Care was taken to ensure a sterile technique and also to minimize damage to the red cells during the labelling procedure.

**Protocol:** The protocol has been previously described.[27–29] After the subjects were in a basal hemodynamic state, a 5-minute equilibrium left ventricular scintigram, gated from a modified $V_5$ electrocardiographic lead, was obtained. Blood pressure was measured in duplicate each minute. At the midpoint of the scintigraphic acquisition, a 10 ml venous sample was withdrawn, from which 4 ml was pipetted for later gamma counting. Then, 1 mg of atropine sulphate (Abbott) was injected intravenously over 1 to 2 minutes. This was done to minimize the baroreflex mediated bradycardia that accompanies the infusion of pressor agents such as phenylephrine. After a further 10 minutes, left ventricular scintigraphy, blood sampling, and blood pressure measurements were repeated.

Next, an 80 μg/ml solution of phenylephrine hydrochloride in normal saline solution was infused by means of a variable delivery rate pump (Ivac). The infusion was commenced at 80 μg/min and titrated to produce target increments in systolic pressures of 15, 30, and 45 mm Hg. When each target level of systolic pressure had been reached, it was held stable for 5 minutes while left ventricular scintigraphy was repeated. The heart rate was maintained within 6 beats/min of the value achieved after the administration of atropine, by supplementary intravenous injections of atropine (0.1 to 0.3 mg) when necessary. In 4 patients with coronary artery disease, only 2 increments of phenylephrine were used because of the initial low blood pressure.

**Cardiac data analysis:** Equilibrium radionuclide studies were processed using a general purpose nuclear medicine computer ($A^2$ Medical Data Systems). Data recorded from each cardiac cycle during the 5 minutes of acquisition were divided into 54 equal time frames and integrated to construct a composite cardiac cycle. The raw data underwent frequency filtering (7 point temporal, and 5 point spatial) before region assignments and curve analyses. Once the filtered composite cycle was available, a rectangular region of interest was placed around the end-diastolic left ventricular image, and an edge detection program was used to define the boundary of the left ventricle throughout the cardiac cycle. (The edge detection algorithm uses both absolute count rate and the second derivative of the count rate change in each picture element for boundary location.) Background counts were automatically assigned in the end-systolic frame and subtracted from the left ventricular regions-of-interest to correct for noncardiac activity. The 5-minute (background subtracted) count rate exceeded 5,000 in the left ventricular region-of-interest at end-diastole in all studies. Thus, a background corrected time-activity curve from the left ventricle was obtained, from which ejection fraction was calculated using the following equation: Ejection Fraction = [(end-diastolic counts) − (end-systolic counts)]/(end-diastolic counts).

From the background-corrected time activity curve, a first-derivative curve (frame-by-frame dV/dt) could then be constructed (Fig. 1 and 2). Left ventricular ejection time (LVET) was determined directly from the radionuclide volume curve,[20] and defined as the time from the early apex to the lowest nadir of the curve. This was automatically determined by the computer. The time to peak −dV/dt and + dV/dt was defined from the onset of the QRS on the original count volume-time curve. During radionuclide data acquisition cardiac cycles that fell outside a ±10% range of the R-R interval were excluded to prevent distortion of the time-activity curve.

The "weighted forward backward break-up volume curve" was utilized in this study, and has become a standard commercial algorithm used by many laboratories for the evaluation of cardiac function. Methods for merging the forward and backward derived curves and the importance of a number of weighting techniques have been investigated in our laboratory. Ejection fraction as well as peak ejection and filling rates have been derived from either QRS-gated forward, reverse, or composite curves generated by both linear and exponential weighting of the forward and reverse break-up curves. These values were compared with results obtained from the mean heart rate volume curves. Linear weighting interpolation for deriving the composite curve provided a reasonable approximation of the mean heart rate volume curve. However, the correlation of filling rates and later portions of the diastolic volume curve could be more accurately characterized by the forward reverse break-up technique than by using the forward curve alone.[21] In the present study, for analysis of forward break-up, the radionuclide volume curves were gated with respect to the onset of QRS (end-diastole) and averaged with a symmetric weight distribution forward in time after the +10% R-R interval exclusion. Beats were weighted proportionately with respect to the mean heart rate beat with the mean heart rate beats receiving the greatest weight. The reverse break-up curve was obtained by aligning the tail end of the curves (backward in time) with the same weights. The forward and reverse generated curves were then combined to generate the composite volume curve. The composite curves were produced by assuming that the initial 25% portion of the forward curve and the terminal 25% portion of the reverse curve were accurate and that the remaining intermediate portions of the curves could be obtained by linear weighting of the forward and reverse curves. The ejection fraction, filling

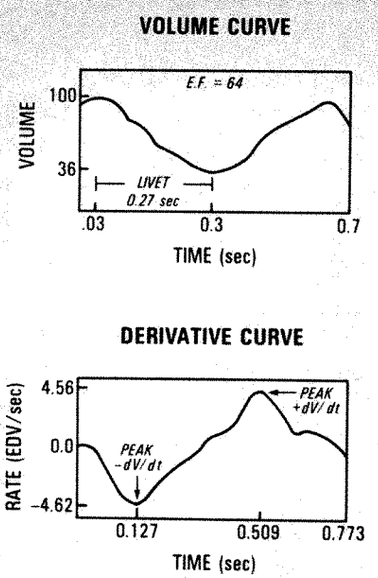

**FIGURE 1.** A volume and derivative curve are shown. +dV/dt = filling rate; −dV/dt = emptying rate; EDV = end-diastolic volume; LVET = left ventricular ejection time.

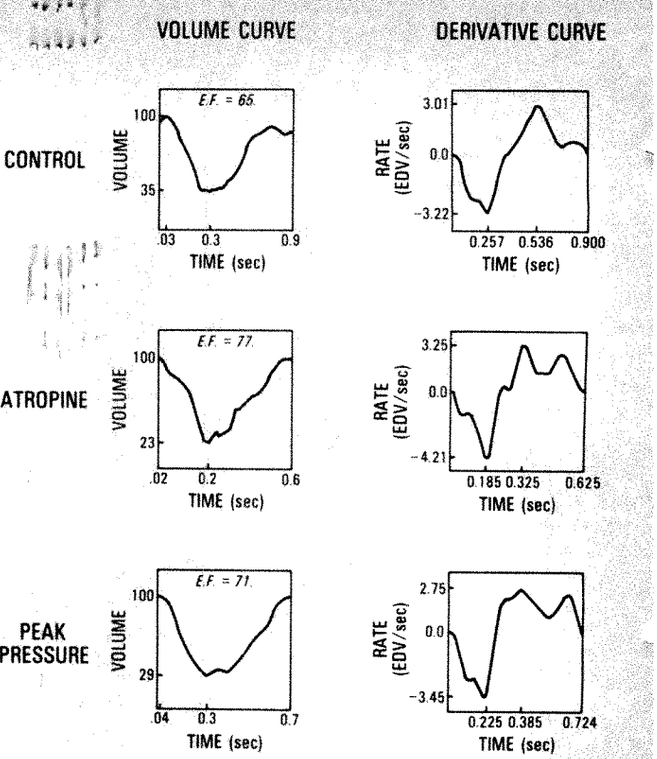

**FIGURE 2.** Response to pressure overload. First-derivative and volume curves are shown from a normal subject in the control state, after atropine administration, and at peak pressure.

fraction, peak filling rate, and the time from end-systole to peak filling rate were determined from the merged, composite (that is, interpolated) volume-time curves.

Left ventricular end-diastolic volume was calculated by a technique previously validated in our laboratory[27–29] and in others[30–35] as follows. Left ventricular counts at end-diastole (corrected for frame time and the number of cardiac cycles processed) were divided by counts from whole blood drawn at the midpoint of each study, corrected for background activity, elapsed time, and radioactive decay. In previous studies we have used a regression equation derived from previous radionuclide and contrast ventriculographic comparisons.[29] Because this equation was not available for the particular camera and collimator used in this study, relative volume units were used, rather than absolute volumes.

All volumes are given as units/$m^2$ body surface area. In our laboratories, the reproducibility over time of end-diastolic volume and ejection fraction using this method was ±6.1% and ±3%, respectively.[29] Inter- and intraobserver variability have both been found to be approximately 4%.[27–29]

**Statistics:** Data are given as the group mean ± 1 standard deviation. Comparisons within and among groups were performed by the appropriate paired or unpaired Student's *t* test. Correlations were tested by linear regression analysis. Differences within groups were tested with a repeated measures analysis of variance.[36]

## Results

**Resting hemodynamics (Tables I to III, Fig. 3 to 6):** Heart rate was similar in the control subjects and infarct patients (62 ± 4 beats/min versus 65 ± 11 beats/min, p = not significant [NS]), as was the arterial blood pressure (120/74 ± 7/6 mm Hg versus 119/77 ± 11/8 mm Hg, p = NS). Ejection fraction was greater in the normal control subjects (0.66 ± 0.07) than the infarct patients (0.52 ± 0.18, p <0.01), as was peak − dV/dt (−3.53 ± 0.32 vol/s versus −2.60 ± 1.01 vol/s, p <0.01). Left ventricular ejection time was similar in both groups (0.25 ± 0.03 second versus 0.29 ± 0.08 second in the infarct patients). The time to peak − dV/dt was similar in both groups (0.164 ± 0.04 second versus 0.19 ± 0.06 second in the infarct patients, p = 0.08), as was the time to peak +dV/dt (0.50 ± 0.03 second versus 0.51 ± 0.07 second in the infarct patients). Peak +dV/dt was greater in the normal subjects than in the patients (3.56 ± 0.83 vol/s versus 2.60 ±1.01 vol/s, p<0.01). However, the ratio of filling rate to emptying rate was similar in both groups (1.01 ± 0.24 in normal subjects and 0.99 ± 0.25 in the infarct patients), as was the ratio of time to peak filling/time to peak emptying (3.20 ± 0.85 versus 3.07 ± 1.38 in the infarct patients).

End-diastolic volume was greater (4.33 ± 1.29 versus 3.90 ± 0.83 units/$m^2$, p <0.05), stroke volume lower (2.25 ± 1.0 versus 2.59 ± 0.98 units/$m^2$, p <0.05), and cardiac index lower (146.3 ± 20.2 versus 160.6 ± 24.3 units/min/$m^2$, p <0.05) in the infarct patients when compared with the normal subjects.

**Atropine response (Tables I to III, Fig. 3 to 6):** Heart rate increased similarly in both groups (88.9 ± 4.6 beats/min in the normal subjects and 83.3 ± 8.5 beats/min in the infarct patients, p = NS), as did arterial blood pressure (123/77 ± 16/13 mm Hg in the normal subjects and 125/76 ± 17/9 mm Hg in the infarct patients).

Ejection fraction remained unchanged in the normal subjects (0.66 ± 0.07 to 0.65 ± 0.06) and in the infarct patients (0.52 ± 0.18 to 0.49 ± 0.17). Ejection time declined in the normal subject (0.25 ± 0.03 second to 0.19

* $p < 0.05$ versus normal subjects.
See Table II for explanation of abbreviations. ED − ER = time from end-diastole (peak of volume curve) to peak − dV/dt; ES − FR = time from end-systole (nadir of volume curve) to peak + dV/dt. DT = diastolic time (R-R interval—time from peak of QRS to nadir of volume curve); ET = ejection time.

± 0.03 second), as well as in the infarct patients (0.29 ± 0.08 second to 0.24 ± 0.07 second, both $p < 0.05$). Once again, peak −dV/dt (3.90 ± 0.49 vol/s versus 3.28 ± 1.34 vol/s, $p < 0.05$) and peak +dV/dt (3.95 ± 0.88 vol/s versus 2.54 ± 0.89 vol/s, $p < 0.01$) were greater in the normal subjects than in the patients. In addition, the ratio of peak +dV/dt to peak −dV/dt was similar in the 2 groups after atropine (0.91 ± 0.11 versus 0.81 ± 0.21 in the infarct patients) and the time to peak filling/time to peak emptying was also not different (2.56 ± 0.47 versus 2.55 ± 0.67).

End-diastolic volume index decreased in both normal subjects (3.12 ± 1.60 versus 3.90 ± 0.83 units/$m^2$, $p < 0.05$) and in the infarct patients (3.86 ± 1.46 versus 4.33 ± 1.29 units/$m^2$, $p < 0.05$). In addition, stroke volume declined in the normal subjects (2.03 ± 0.43 versus 2.59 ± 9.8, $p < 0.05$) and infarct patients (1.89 ± 0.9 versus 2.25 ± 1.0, $p < 0.05$), although cardiac output increased (180.3 ± 30.1) in the normal subjects and in the infarct patients (157.6 ± 24.2).

**Peak phenylephrine infusion data (Tables I to III):** The total increase in systolic pressure was similar in both groups (43.4 ± 7.2 mm Hg for the normal subjects and 40.3 ± 8.6 mm Hg for the coronary patients). At the peak pressure point, ejection fraction declined in the normal subjects (0.56 ± 0.08, $p < 0.05$ versus atropine and control) but did not decrease markedly in the infarct patients (0.45 ± 0.17 versus 0.49 ± 0.17 atropine and 0.52 ± 0.18 control, peak pressure $p < 0.05$ versus control). Peak −dV/dt and peak + dV/dt both declined significantly but, as before, the ratio of velocity indexes and the ratio of the times of peak filling to peak emptying did not significantly differ between the 2 groups.

End-diastolic volume increased in both groups when compared with the atropine data point (4.43 ± 0.69 versus 3.12 ± 1.60 units/$m^2$ in the normal subjects, $p < 0.01$; and 5.04 ± 1.81 versus 3.86 ± 1.46 in the infarct patients, $p < 0.01$). Stroke volume increased significantly in both groups ($p < 0.05$), resulting in a significant increase in cardiac output ($p < 0.05$).

In general, the time to peak ejection occurred somewhat earlier in the normal subjects than in the infarct patients, when estimated as a measure of absolute time or as a percentage of the left ventricular ejection. This tended to be less evident when phenylephrine was infused. Nonetheless, the differences were small, the overlap was relatively large, and the clinical utility minimal.

## Discussion

Variations in systemic arterial pressure have been demonstrated to have direct effect on measurements of a variety of indexes of left ventricular performance.[1–8,27–29,37] The effects of sequentially induced alterations in afterload have recently received sub-

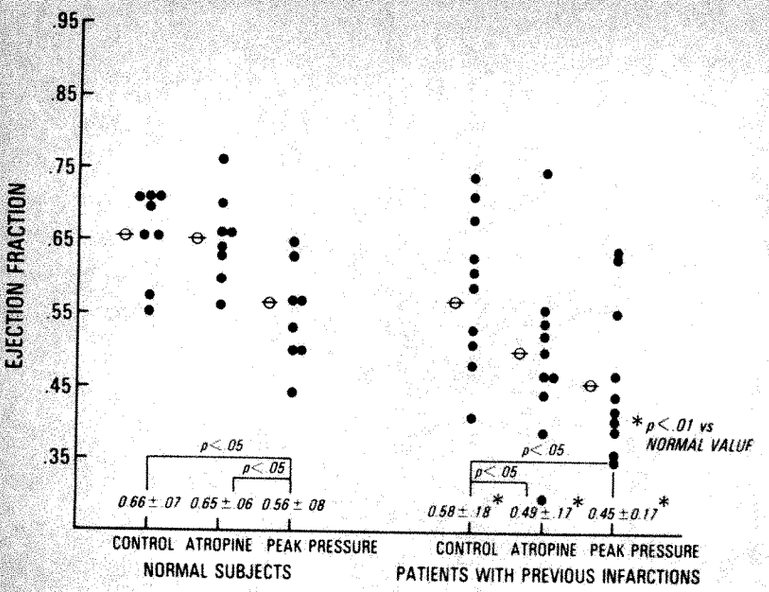

**FIGURE 3.** Response to pressure overload. The response of ejection fraction to atropine and afterload are given for both groups studied.

stantial attention,[27–29] particularly its effects on measures of left ventricular function in patients with asynchronous left ventricular contraction patterns. In the present study, the utility of an index of mid-ventricular systolic contractile events was examined,[38–40] as was an index of left ventricular diastolic filling.[23–25]

Peak ejection rate behaved in a fashion similar to ejection fraction, and was, by itself, neither more useful nor discriminating at rest or during interventions than ejection fraction alone. This is similar to the report of Bianco et al,[41] and corresponds to similar results from others.[42–46] In the present study, afterload stress induced delays in the timing of peak ejection rate in both normal subjects and infarct patients. Whether this represents the limits of preload reserve,[47] and an inability to generate velocity as quickly at greater left ventricular wall stress, remains unclear.

Similar to Hammermeister et al,[15] we found that peak normalized ejection rate occurred somewhere near the mid-portion of ejection. Normal subjects reach their peak ejection rate slightly earlier in systole than infarction patients, though not substantially so or with great enough uniformity to be a clinically useful finding. The effect of aortic compliance might substantially alter outflow impedance and aortic flow rates, as well as ventricular emptying rates.[9–14]

With afterload elevation, ejection time increased, in all likelihood due to reduced ejection rates and increased stroke volumes. In previous phenylephrine infusion studies using radionuclide angiography, we

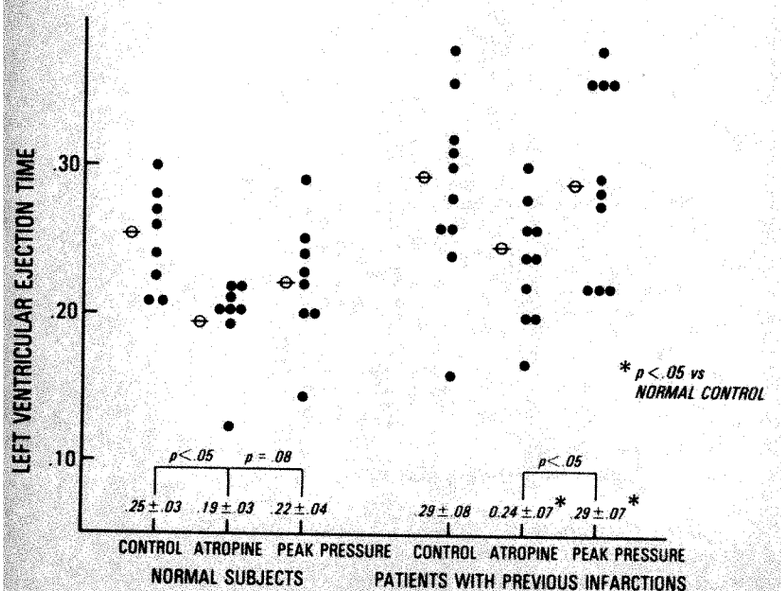

**FIGURE 4.** Response to pressure overload. The change in ejection time during atropine and phenylephrine administration is given.

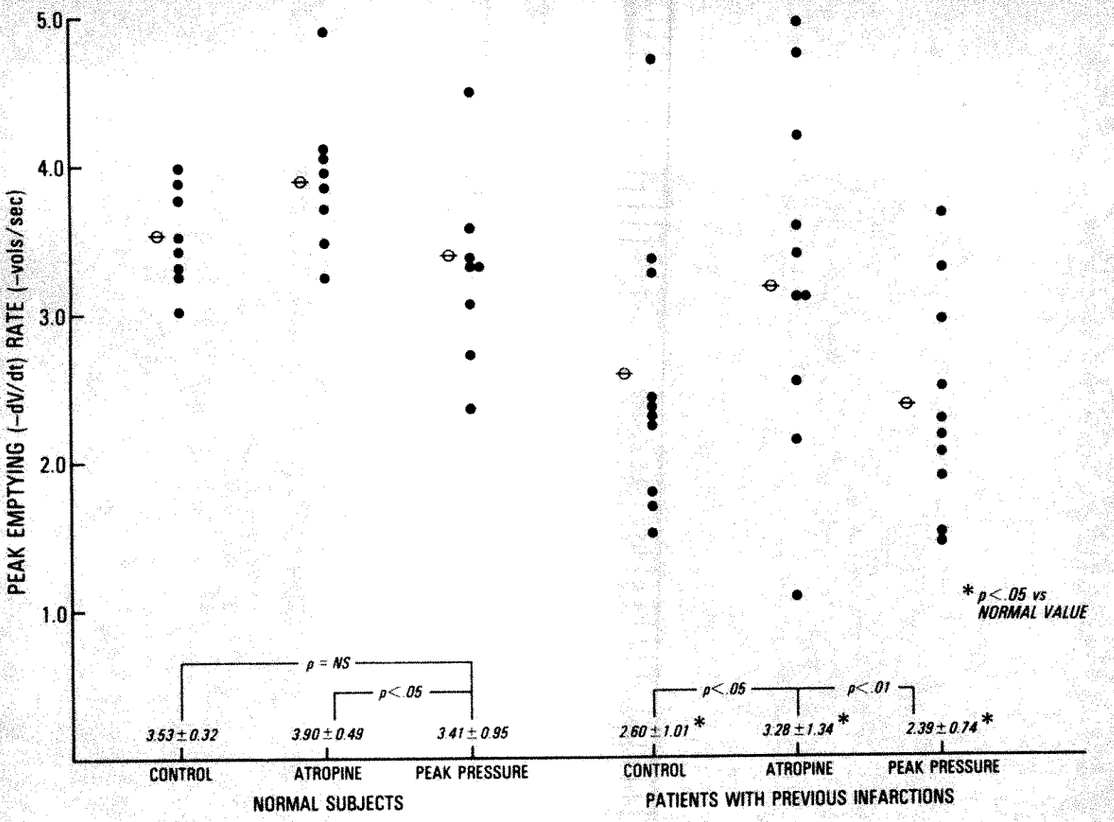

**FIGURE 5.** Response to pressure overload. The response of peak ejection rate to atropine and pressure overload in both groups.

found it uncommon to demonstrate an actual reduction in stroke volume with increases in arterial pressures.[27–29] This probably reflected adequate Frank-Starling reserve capacity in these subjects. Ejection rates have been known to decline with afterload elevations.[6]

Bonow et al[23] described ejection rates and times to peak ejection rate in normal subjects and patients with coronary heart disease at rest. They found that both time to peak ejection rate and ejection time were similar in normal subjects and coronary patients. However, heart rates were not available to review, and data are not given as a percentage of the R-R interval or ejection time. In any event, our coronary population was composed of patients with previous myocardial infarctions, who might be expected to differ from patients with ischemic disease without previous infarctions.

The pressure-volume relation of the normal ventricle in diastole is curvilinear, such that in the normal ventricle at low volumes, moderate changes in volume are associated with small pressure changes, whereas at larger volumes, small volume increases produce substantial changes in pressure. Thus, the ventricle is relatively compliant at low volumes but becomes progressively less so as volumes increase. Thus, it might be expected that as left ventricular volumes increase, filling rates might slow. In addition, patients with coronary disease may manifest both acute and chronic alterations in the diastolic pressure-volume relation. In some patients, elevation in diastolic pressure is noted despite normal left ventricular volumes.[47–49]

Radionuclide techniques only approximate measures of diastolic function. Noninvasive data were not related to intraventricular pressures in the present study. In addition, it is well-known that mere changes in ventricular volumes without ischemia can increase chamber stiffness without implying a change in muscle stiffness.[50] Furthermore, the mechanisms involved in abnormalities of timing of events during various phases of the cardiac cycle cannot be specifically delineated without knowing the timing of valvular opening and closing. This is not provided by analysis of the time-activity curve alone. The time from the peak of the QRS to peak −dV/dt includes isovolumic contraction time, and the time to peak +dV/dt includes both isovolumic relaxation and contraction time. Anomalies in these intervals may be difficult to interpret not only because of the combination of these 2 distinct phases of the cardiac cycle, but also because changes in the velocity of chamber blood flow may be affected by aberrations of myocardial relaxation.[51] Nevertheless, these methods provide an attractive qualitative approach to the measurement of diastolic function.

Relatively little data exist presently on the radionuclide assessment of diastolic function in normal subjects and coronary patients at rest and during alterations in afterload. Our determination of peak left ventricular filling rates using gated equilibrium radionuclide an-

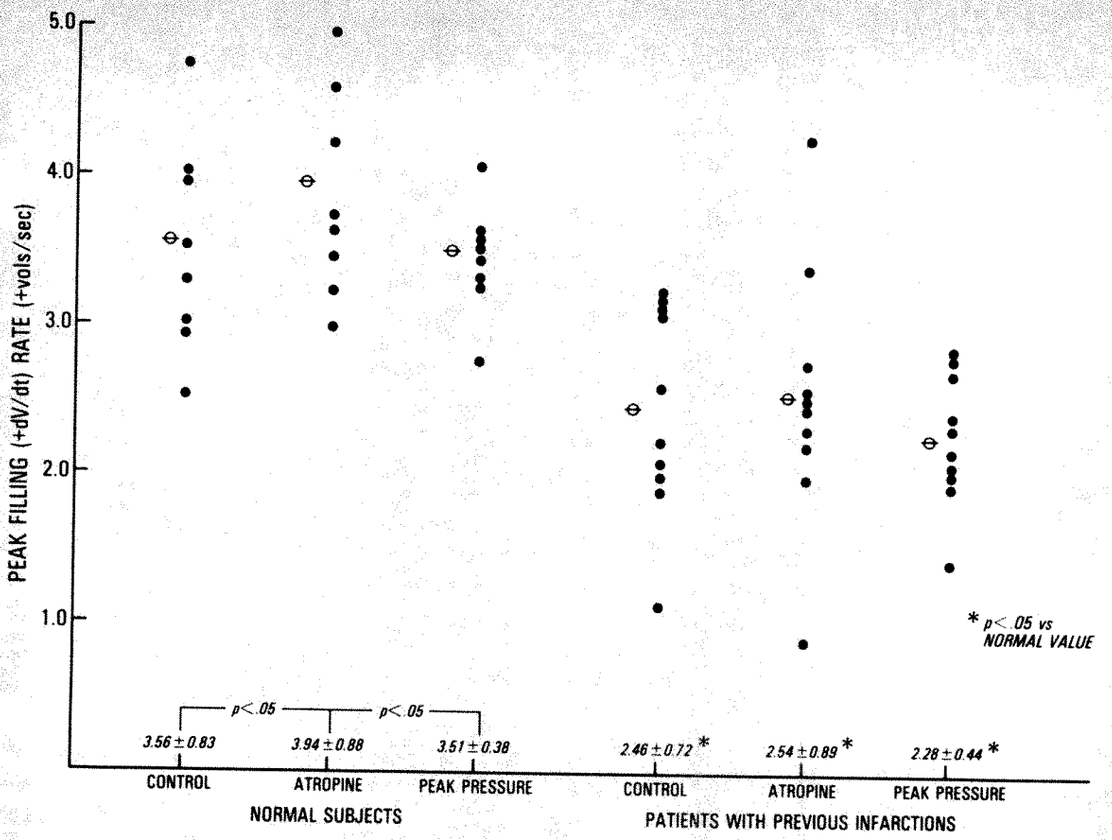

**FIGURE 6.** Response to pressure overload. The change in peak filling rate is shown in all subjects at control, atropine, and peak pressure points.

giography at rest is in close agreement with that of Bonow et al[23] and Reduto et al[5] and comparable to the angiographic results reported by Hammermeister et al.[15] The peak filling rate at rest in the coronary patients was lower than in the normal subjects, even when systolic function at rest was normal.

It appears that peak filling rate is a sensitive marker of cardiac dysfunction due to coronary disease in patients with a previous myocardial infarction. However, when a systolic variable employing differentiation is assessed, such as peak ejection rate, it appears to also be abnormal and has behavior which is similar to filling rates during acute alteration in afterload. This is in agreement with the work of Hammermeister et al,[15] who noted that in the absence of valvular disease, peak rate of volume change was similar in both systole and diastole and both were lower in coronary patients when compared with normal subjects.

We conclude that the normal left ventricle shows a decrease in ejection fraction and peak ejection and filling rates with increases in arterial pressure. This occurs in association with a slight but significant prolongation of ejection time and the times to peak ejection and filling rate. Similar findings occurred in patients with previous infarctions. Global indexes of mid- and total systole appeared to be of similar discriminatory value for normal subjects versus infarct patients at rest and during pressure intervention, as emphasized recently by others.[41–46,52] Diastolic portions of the cardiac cycle, as well as patterns of left ventricular emptying, can be easily evaluated during acute hemodynamic interventions.

# Serial Changes in Left Ventricular Function After Correction of Chronic Aortic Regurgitation

## Dependence on Early Changes in Preload and Subsequent Regression of Hypertrophy

JOHN D. CARROLL, MD, WILLIAM H. GAASCH, MD, MICHAEL R. ZILE, MD, and HERBERT J. LEVINE, MD

**Surgical correction of chronic aortic regurgitation generally results in a substantial decrease in left ventricular (LV) volume and mass. To assess the functional significance of these structural changes, serial noninvasive tests of LV function from 23 patients were examined after aortic valve replacement. Three independent tests of LV function were used: (1) the ratio of the LV preejection period (PEP) to the LV ejection time (LVET), (2) the echocardiographic fractional increase in LV wall thickness (FT), and (3) the mitral E point to septal separation (ESS). Studies were performed before surgery and at 0.3 (early), 3 to 6 (mid), and 9 to 12 (late) months after surgery.**

**In the early postoperative studies, LV end-diastolic dimension decreased to normal or near-normal and the PEP/LVET ratio increased substantially in 17 patients. Ten of the 17 (group 1) had complete regression of LV hypertrophy and the average values for all 3 indexes of LV function were normal at the time of the late postoperative study (PEP/LVET = 0.41 ± 0.05, FT = 73 ± 14%, ESS = 6.2 ± 0.9 mm). Seven patients (Group 2) with incomplete regression of LV hypertrophy showed borderline to moderately abnormal function indexes at the late study. Six patients had persistent LV enlargement and no postoperative regression of hypertrophy (Group 3). These patients did not show the substantial early changes in the function indexes observed in Groups 1 and 2; moreover, the indexes remained markedly abnormal at the time of the late postoperative study (PEP/LVET = 0.52 ± 0.10, FT = 47 ± 13%, ESS = 22.3 ± 7.2 mm). Patients in Group 3 had preoperative evidence of abnormal LV function which was more marked than that observed in Groups 1 and 2. Thus, the early postoperative changes in LV preload and the subsequent regression of LV hypertrophy are associated with evidence of early LV dysfunction and subsequent improvement. Postoperative LV enlargement and persistent LV hypertrophy are associated with persistent LV dysfunction. These serial data provide a framework for the rational timing and interpretation of postoperative ventricular function tests.**

Left ventricular chamber size and myocardial mass usually decrease after the surgical correction of chronic aortic regurgitation.[1–24] Perhaps the most dramatic of these changes is the marked reduction in LV *volume* which is seen within a week of surgery. Over the subsequent 6 months, a gradual decrease in LV *mass* may occur, but the regression of LV hypertrophy is incomplete in many patients. Studies of LV *function* in the weeks and months after aortic valve replacement indicate variable results; some patients appear to have normal or borderline LV function while others show persistent postoperative LV enlargement and depressed function. Much of the reported data on postoperative LV function have not been obtained serially, and for this reason the time course of such changes has not been fully appreciated. Moreover, it is not known whether or not postoperative regression of LV hypertrophy has significant functional consequences: that is, whether the patient with complete regression of LV hypertrophy has a better functional result than the patient with incomplete regression of hypertrophy.

From the Department of Medicine, Tufts University School of Medicine, New England Medical Center Hospitals, and the Veterans Administration Medical Center, Boston, Massachusetts. This study was done during Dr. Carroll's tenure as a Samuel A. Levine Fellow of the American Heart Association, Massachusetts Affiliate, and supported by Grant 13-405-798 from the Northeast Division of the Massachusetts Affiliate, Boston, Massachusetts. Manuscript received March 29, 1982; revised manuscript received August 10, 1982, accepted August 13, 1982.

The present study was designed to define the functional changes associated with the structural changes known to follow surgical correction of chronic aortic regurgitation. We made serial postoperative measurements of 3 independent noninvasive indexes of LV function and examined these data relative to the observed changes in LV size and myocardial mass; we especially emphasized the time course of these changes during the first year after aortic valve replacement. In addition, we examined the preoperative data in an attempt to identify noninvasive variables that might be useful in predicting the results of surgery.

## Methods

Twenty-three patients who underwent aortic valve replacement for chronic aortic regurgitation between January 1975 and December 1980 were invited to participate in the study. Admission to the study required high-quality echocardiographic LV studies and externally recorded systolic time intervals. Before surgery, all patients had typical clinical and hemodynamic findings of significant aortic regurgitation. Echocardiograms were obtained with a Smith Kline ultrasonoscope and a 2.25 MHz transducer. LV end-diastolic dimension was measured at the R wave of the electrocardiogram and the end-systolic dimension was measured as the smallest vertical dimension between left septal echocardiogram and the posterior wall echocardiogram at end-systole. Relative wall thickness was determined as one-half the end-diastolic dimension divided by the wall thickness.[9] Markedly abnormal septal motion was a uniform finding in the early postoperative studies, and for this reason fractional shortening of the LV internal dimension was not used as an index of LV function in postoperative studies. The fractional increase in LV posterior wall thickness (FT) from end-diastole to end-systole was calculated as follows: $FT = [(Th_{ed} - Th_{es})/Th_{ed}] \cdot 100$, where $Th_{ed}$ is end-diastolic posterior wall thickness and $Th_{es}$ is end-systolic wall thickness.[9,25–27] Fractional thickening is expressed as a percentage.

Echocardiographic estimation of LV muscle mass is known to be dependent on several assumptions regarding ventricular geometry. To avoid these potential problems, we used muscle cross-sectional area (CSA) as an index of LV myocardial mass which does not require major geometric assumption.[9,15] This index (in $cm^2/m^2$) was calculated from the echocardiographic dimension and wall thickness data, as follows: $CSA = \pi [(EDD/2) + Th_{ed}]^2 - \pi (EDD/2)^2$, where EDD = end-diastolic dimension.

The distance between the E point of the mitral valve anterior leaflet to the LV edge of the interventricular septum was used as an index of global LV function. ESS was measured according to the technique described by Massie et al.[28] This variable reflects global ejection fraction and is only minimally influenced by heart size.[28–30]

Systolic time intervals were obtained at the same time as the echocardiographic studies. They were derived from an electrocardiogram (lead II), a carotid pulse tracing (Statham P23Db), and a phonocardiogram. Total electromechanical systole ($QS_2$), preejection period (PEP), and LV ejection time (LVET) were measured and corrected for heart rate as described by Lewis et al[31] and Weissler.[32] The ratio of PEP to LVET was calculated for all patients. Four patients were excluded from this portion of the study due to left bundle branch block (n = 2) and permanent right ventricular endocardial pacing (n = 2).

Preoperative studies were performed in all patients. Postoperative studies were performed at 7 to 10 days after surgery (early), at 3 to 6 months postoperative (mid), and again at 9 to 12 months (late).

The 23 patients were divided into 3 groups for data analysis. Group 1 patients (n = 10) had a very satisfactory surgical result which we defined as a normal end-diastolic dimension (decreasing to within 2 standard deviations of normal, that is, $<3.3$ cm/m$^2$) and normal LV mass (cross-sectional area $<10$ $cm^2/m^2$). Group 2 patients (n = 7) attained a normal end-diastolic dimension postoperatively, but still had evidence of LV hypertrophy (cross-sectional area $>10$ $cm^2/m^2$). Group 3 patients (n = 6) had persistent postoperative LV enlargement (end-diastolic dimension $>3.3$ cm/m$^2$) and lack of regression of LV hypertrophy. None of our patients had paraprosthetic regurgitation.

Systolic time intervals, ESS, and FT data were analyzed within each group by analysis of variance for serial data; in this manner, we tested the hypothesis that significant temporal changes in LV function occurred postoperatively. Differences between groups at specific times were also tested by analysis of variance. Tabular data are presented as the mean ± 1 standard deviation.

## Results

The preoperative echocardiographic data are presented in Table I. The serial pre- and postoperative data are presented in Tables II to IV and Figures 1 to 4.

**LV end-diastolic dimension and muscle cross-sectional area:** Serial echocardiographic measurements of LV end-diastolic dimension and muscle cross-sectional area are presented in Table II and Figure 1. In Group 1, LV end-diastolic dimension and cross-sectional area decreased to normal levels in all 10 patients. The change in end-diastolic dimension at the time of the early postoperative study was highly significant (p

CSA = cross-sectional area; Early = 7 to 10 days; EDD = end-diastolic dimension; Late = 9 to 12 months; Mid = 3 to 6 months; Preop = preoperative.

<0.001), but the small changes thereafter did not achieve statistical significance. There was no significant change in muscle cross-sectional area at the time of the early postoperative study; cross-sectional area declined thereafter ($p < 0.01$ at 3 to 6 months after operation), and at the time of the late study was normal in all 10 patients in this group. In Group 2, end-diastolic dimension also declined postoperatively ($p < 0.05$ at the early study); there was an additional small decrease in end-diastolic dimension ($p < 0.01$) at the time of the late study so that end-diastolic dimension reached the normal range in all Group 2 patients. Although cross-sectional area declined postoperatively ($p < 0.01$ at the mid study), all 7 patients in this group had persistent LV hypertrophy (cross-sectional area greater than normal) at the time of the late postoperative study. Despite a modest reduction in end-diastolic dimension at the time of the late postoperative study ($p < 0.05$), all

| ESS (mm) (n = 6) | 23.0 ± 2.7 | 23.3 ± 3.7 | 23.8 ± 3.7 | 22.3 ± 7.2 |

FT = fractional thickening of the LV posterior wall; format and other abbreviations as in Table II.

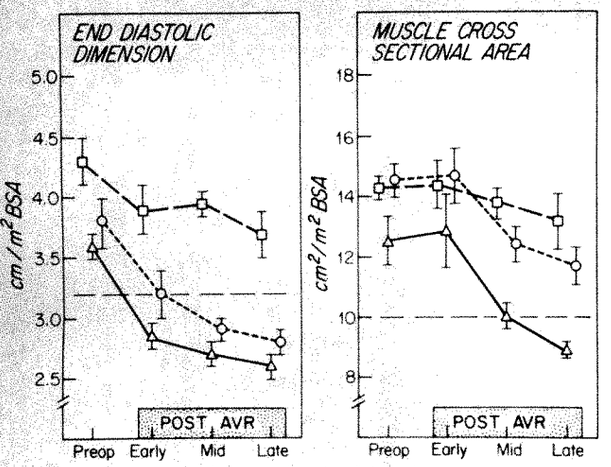

**FIGURE 1.** Serial changes in LV end-diastolic dimension and muscle cross-sectional area. The early, mid, and late postoperative studies were performed at 0.3, 3 to 6, and 9 to 12 months, respectively. All patients in Groups 1 (**triangles**) achieved a normal LV chamber dimension and a normal muscle cross-sectional area. Although LV end-diastolic dimension decreased to normal in Group 2 (**circles**) evidence of persistent LV hypertrophy was present at the late postoperative studies. The patients in Group 3 (**squares**) had persistent LV enlargement and no significant change in muscle cross-sectional area. The **broken horizontal line** indicates the upper limit of normal for these variables. AVR = aortic valve replacement; BSA = body surface area.

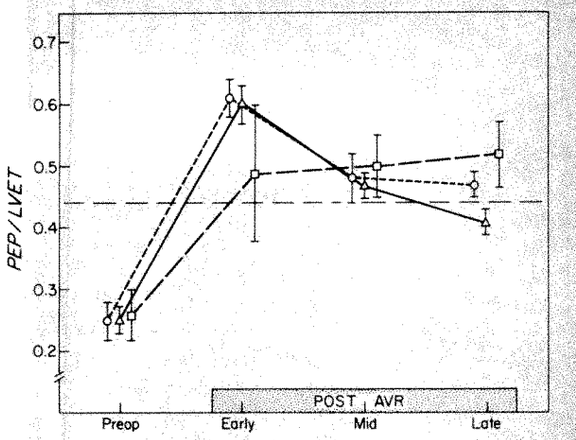

**FIGURE 2.** Serial changes in the LV PEP/LVET ratio. In the early postoperative study, the PEP/LVET ratio increased substantially in Groups 1 (**triangles**) and 2 (**circles**); this change was coincident with the early reduction in LV preload. With the regression of LV hypertrophy (mid to late), the PEP/LVET ratio decreased to normal values in Group 1 and remained moderately increased in Group 2. The PEP/LVET ratio in Group 3 (**squares**) progressively increased to markedly abnormal levels at the time of the late study. Thus, in addition to changes in the PEP/LVET ratio that are related to valve replacement alone, postoperative LV function is temporally related to the presence or absence of changes in preload and LV mass (see text). AVR = aortic valve replacement.

6 patients in Group 3 had persistent LV enlargement. Moreover, there were no significant postoperative changes in muscle cross-sectional area in this group.

**LV systolic time intervals:** The average values for the LV systolic time intervals are presented in Table III, and the serial measurements of the PEP/LVET ratio are shown graphically in Figure 2. Group 1 patients demonstrated an early postoperative increase in PEP ($p < 0.001$), a decrease in the LVET ($p < 0.01$), and an increase in the PEP/LVET ratio ($p < 0.001$). The marked increase in PEP/LVET which was observed at the time of the early study declined thereafter; it was significantly lower at the time of the mid versus early postoperative study ($p < 0.05$) and at the time of the late study ($p < 0.01$). The average values for the LV systolic

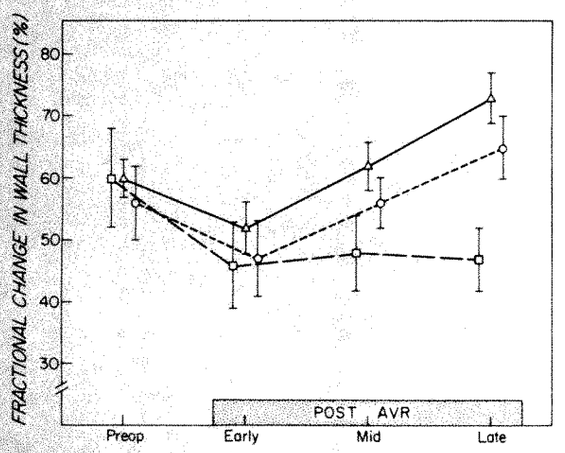

**FIGURE 3.** Serial measurements of the fractional increase in LV posterior wall thickness during systole. In the early postoperative period, there was a tendency for fractional thickening to decrease in all 3 groups. Thereafter, fractional thickening increased only in Groups 1 (**triangles**) and 2 (**circles**); fractional thickening remained low in Group 3 (**squares**). These data are consonant with the systolic time interval data; they indicate that patients with complete regression of LV hypertrophy (Group 1) show gradual improvement in fractional thickening, whereas those with persistent LV enlargement and no regression of LV hypertrophy show persistently depressed thickening.

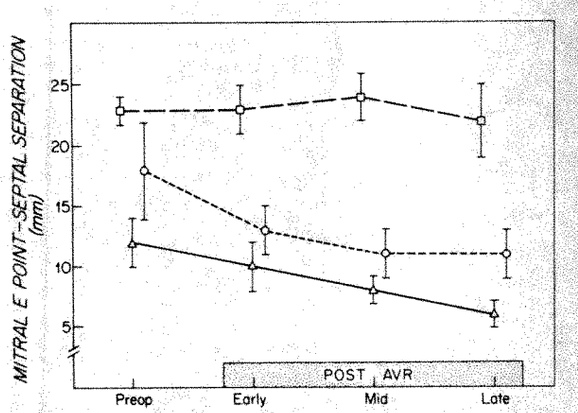

**FIGURE 4.** Serial changes in the echocardiographic ESS. In Group 1 (**triangles**), ESS declined to normal values at the time of the late postoperative study, while Group 3 (**squares**) showed a persistent and marked abnormality of ESS. Group 2 data (**circles**) were intermediate between 1 and 3. Thus, a postoperative normalization of chamber dimension and LV mass is associated with a normal ESS; however, with incomplete regression of LV hypertrophy, ESS may remain abnormal despite a significant decrease in LV size.

time intervals in Group 1 were all within the range of normal at the time of the late postoperative study. Group 2 patients had similar changes in the LV systolic time intervals at the early and mid postoperative studies (PEP, LVET, and PEP/LVET; all p = NS [not significant] versus Group 1). However, the average values for PEP remained above normal and LVET remained below normal at the time of the late postoperative study. The PEP/LVET ratio declined significantly by the time of the late versus early study ($p < 0.01$), but in contrast to the normal ratio achieved in the Group 1 patients, the average PEP/LVET in Group 2 remained above normal. In Group 3, the early increase in PEP and the decrease in LVET did not achieve statistical significance. The early increase in PEP/LVET ($p < 0.05$) was not as pronounced as that observed in Groups 1 and 2; 3 of the 4 patients in Group 3 had a PEP/LVET <0.45, while the ratio in all Group 1 and 2 patients was >0.47. There was a tendency for PEP/LVET to increase thereafter, and by the time of the late study the ratio was significantly higher ($p < 0.05$) than that seen in Group 2.

**Fractional change in LV wall thickness:** Fractional thickening data are shown in Table IV and Figure 3. All 3 groups demonstrated a small decrease in fractional thickening at the time of the early study (all p = NS versus preoperative values). Group 1 patients showed a tendency to increase thereafter so that the late postoperative values for fractional thickening were greater than those measured preoperatively ($p < 0.01$) and early postoperatively ($p < 0.05$). Fractional thickening also increased in Group 2 ($p < 0.01$ early versus late), but in contrast to Group 1, late fractional thickening was not significantly greater than preoperative levels. In Group 3, there was a tendency for fractional thickening to remain lower than preoperatively but this difference did not achieve statistical significance. The late postoperative fractional thickening in Group 3 was significantly lower than that observed in both Groups 1 and 2 (both $p < 0.05$), but the difference between Groups 1 and 2 did not reach statistical significance.

**Mitral E point to septal separation (ESS):** The ESS data are presented in Table IV and Figure 4. In Group 1, there was a gradual decrease in ESS which was statistically significant at the time of the late postoperative study ($p < 0.01$). Although a similar decrease was seen in Group 2, this trend did not reach statistical significance. The ESS was lower in Group 1 than in Group 2 ($p < 0.05$) at the time of the late postoperative study. There was no ESS change in the Group 3 patients, and this index remained markedly abnormal at the time of the late postoperative study.

**Preoperative differences between groups:** There was no significant difference between Groups 1 and 2 for any of the preoperative variables. In contrast, there were highly significant differences between most of the variables in Groups 1 and 2 versus Group 3 (see Table I).

## Discussion

LV function in chronic aortic regurgitation has been studied before and after surgery by a number of investigators, but with few exceptions, postoperative ventricular function has been assessed only at a single point in time. For this reason, time-dependent changes in postoperative function have not generally been appreciated. The serial postoperative data presented herein indicate that LV function is not stable in the first year after surgery and that the observed functional changes are not only related to the aortic valve replacement per se, but also to the 2 major structural changes which usually follow the surgical correction of chronic aortic regurgitation, namely a decrease in LV chamber size and a regression of LV hypertrophy. Our data and those of others indicate that most patients achieve a normal or near normal LV end-diastolic dimension or volume within 1 or 2 weeks of surgery. Subsequently, over the next 6 to 9 months, a significant regression of LV hypertrophy occurs; however, even in the late postoperative studies, many patients have evidence of persistent LV hypertrophy. It therefore appears that there are 3 major structural outcomes after the surgical correction of chronic aortic regurgitation: (1) a normal LV end-diastolic dimension or volume and a normal LV mass, (2) a normal end-diastolic dimension with incomplete regression of hypertrophy, or (3) persistent LV enlargement and no reduction in LV mass. The purpose of the present study was to define the changes in LV function which evolve during the development of these structural changes.

The early functional consequences of an abrupt postoperative decrease in LV end-diastolic dimension are evident in the Group 1 and Group 2 patients. The marked preload reduction which occurred in these 2 groups was associated with a prominent increase in the PEP/LVET ratio, whereas the increase was much less marked in the patients with persistent postoperative LV enlargement (Group 3). We interpret these data to suggest that the early increase in the PEP/LVET is related not only to correction of the valvular leak, but especially to a reduction in LV preload. Over the subsequent months, the PEP/LVET ratio declined in Group 1 and Group 2, while the Group 3 patients demonstrated a tendency to increase (Fig. 2). Thus, this early postoperative abnormality does not predict a poor outcome; in fact, the opposite seems to be true—patients with the highest early PEP/LVET ratio had the most satisfactory late result. Furthermore, our data suggest that the absence of an early postoperative increase in the PEP/LVET ratio might indicate persistent LV enlargement and a poor prognosis.

Externally recorded LV systolic time intervals have been used to assess LV function under a wide variety of clinical conditions, but these measurements have not previously been made serially after aortic valve replacement, as was done in the present study. Our data support the generally accepted idea that the PEP/LVET ratio is influenced by the presence of aortic valve disease independent of LV function. In fact, it appears that there is little relation between the preoperative PEP/LVET and preoperative LV function in chronic aortic regurgitation. However, in the postoperative period the ratio does appear to reflect the functional status of the left ventricle. Correction of aortic regurgitation directly increases aortic diastolic pressure and

decreases the LV stroke volume; consequently, the preejection period increases and the LV ejection time decreases.[33,34] Since the aortic regurgitation was corrected in all 3 groups, this mechanism cannot explain the observed differences between the groups. The effects of anesthesia, cardiopulmonary bypass, and myocardial ischemia have been implicated,[6] but our data indicate that the early postoperative changes in the systolic time intervals are due at least in part to a decrease in LV preload (end-diastolic dimension). Relative to Groups 1 and 2, the small change in preload in Group 3 was associated with relatively smaller changes in the systolic time intervals during the early postoperative period. Similarly, Boudoulas et al[35] suggested that an early postoperative decrease in LV preload contributes to early LV dysfunction after the surgical correction of mitral regurgitation; such changes did not occur after correction of mitral stenosis. These investigators also emphasized the benign nature of this temporary postoperative increase in the PEP/LVET ratio.

The systolic time interval data are supported by the mitral ESS and fractional thickening data which also indicate that early LV dysfunction should not be taken to indicate long-term functional abnormalities. In spite of a decrease in heart size in Groups 1 and 2, the mitral ESS remained abnormal in the early postoperative studies. While ESS as an index of global LV function has been said to be relatively independent of heart size,[28-30] it remains possible that the early ESS may have been greater if not for the early decrease in end-diastolic dimension. The fractional change in LV wall thickness showed a tendency to decline in the early studies, and in general these FT data tend to parallel the PEP/LVET data. All 3 indexes of LV function improved by the time of the late study. These findings are consonant with published radionuclide data that indicate a temporary decrease in the LV ejection fraction during the early postoperative period. Boucher et al[21] reported data from 7 patients in whom the systolic ejection fraction fell from a preoperative average of 56 to 42% at 2 to 4 weeks and subsequently increased to 52% at 1 to 2 years after surgery.[21]

The functional consequences of a gradual regression of LV hypertrophy are also apparent in the serial studies of these 3 groups of patients. As we and others have previously reported, there is no significant change in muscle cross-sectional area during the early postoperative period.[9,15] Thereafter, a significant decrease in cross-sectional area occurred only in Groups 1 and 2. Those patients who eventually achieved a normal muscle cross-sectional area (Group 1) achieved normal values for all 3 indexes of LV function. The patients with persistent LV enlargement and no regression of LV hypertrophy had marked and persistent abnormalities of all 3 indexes of LV function. The Group 2 values were intermediate. It appears, therefore, that a gradual regression of volume overload hypertrophy is associated with a parallel improvement in ventricular function.

Having thus defined the postoperative time course of changes in LV function in 3 distinct subgroups of patients, we then searched for differences in the preoperative data (Table I). There were no significant differences between the preoperative parameters in Group 1 versus those in Group 2. Because the muscle cross-sectional area tended to be higher in Group 2 than in Group 1, it is possible that the Group 2 patients had incomplete regression of LV hypertrophy simply because they started with higher values. However, we did not find a statistically significant difference in cross-sectional area between these 2 groups. In contrast, there were significant differences between several of the parameters in Group 1 versus 3 and Group 2 versus 3. In general, the Group 3 patients had larger values for end-diastolic and end-systolic dimension, higher values for relative wall thickness, and reduced values for fractional shortening. Our findings and those of others confirm the utility of echocardiography in the identification of high-risk patients with chronic aortic regurgitation.[9,18,19,36,37]

We conclude that the early postoperative LV dysfunction which is seen in many patients after correction of chronic aortic regurgitation is a temporary finding, due to an acute reduction in LV preload. The gradual improvement in LV function which occurs over the subsequent 6 to 9 months is at least partly related to the regression of LV hypertrophy. Since LV volume, mass, and function are not stable during most of the first year, the optimal assessment of LV function requires serial studies during this period.

# Radionuclide Ventriculographic Study of Adaptations To Exercise in Aortic Regurgitation

RICHARD M. STEINGART, MD, CORINE YEE, MD, LAWRENCE WEINSTEIN, MD, and JAMES SCHEUER, MD

**Exercise-gated radionuclide ventriculography has been proposed as a method to evaluate cardiac reserve in patients with aortic regurgitation (AR). Characterization of ventricular function, however, in AR is complicated by the dynamic nature of the leak in individual patients and by variations in severity among patients. Twenty patients with isolated AR were studied to assess the effects of exercise on the regurgitant index. The regurgitant index (left ventricular ÷ right ventricular stroke counts) estimates the severity of the leak. The regurgitant index at rest was significantly higher in patients with AR than in patients without AR (3.46 ± 1.25 versus 1.08 ± 0.16, $p < 0.001$). In patients with AR, the regurgitant index decreased during exercise to 2.6 ± 0.8 ($p < 0.001$), whereas it did not change in the control group (1.16 ± 0.21, difference not significant). Further, in patients with AR, the greater the regurgitant index at rest, the greater the decrease during exercise ($y = 0.56x - 1.08$, $r = 0.78$, $p < 0.001$). End-diastolic counts and stroke count responses from rest to exercise were highly variable, but were explained in part by the decreasing regurgitant index. These data support previous catheterization studies and confirm gated radionuclide ventriculography as a useful tool for monitoring adaptations to exercise in AR.**

The timing of appropriate therapeutic intervention in aortic regurgitation is controversial.[1-3] Because ventricular dysfunction in AR is slowly progressive,[4,5] noninvasive technology capable of serial, comprehensive, and accurate evaluation of ventricular functional reserve would be helpful in resolving this controversy. Characterization of functional reserve is complicated by the dynamic nature of the volume load in individual patients and the variations in severity among patients. Gated blood pool scanning at rest has been applied to estimate ventricular volume, systolic function,[6,7] and the magnitude of regurgitation by means of the regurgitant index (left ventricular ÷ right ventricular stroke counts).[8-12] However, it is reasonable to assume that surgical intervention at a time when resting function is preserved but exercise reserve is somewhat diminished would be most appropriate.[13-15] To date, radionuclide studies during exercise in patients with AR have emphasized the ejection fraction response.[13,14] The present study was undertaken to characterize more completely the rest to exercise response in patients with AR with use of gated blood pool scanning.

## Methods

The study group consisted of 20 consecutive patients referred for exercise radionuclide ventriculographic evaluation of isolated, chronic aortic regurgitation. The determination of an isolated valvular abnormality was determined in 10 patients with cardiac catheterization. No catheterized patient had >30% stenosis of a major coronary artery. The remaining 10 patients had isolated diastolic murmurs of aortic regurgitation, and diastolic fluttering of the mitral valve on echocardiography. Because these patients had no symptoms of chest discomfort, the maximal probability of coronary artery disease in any single patient was <4% based on age, sex, symptomatic status, and electrocardiographic stress testing.[16] Sinus rhythm was a prerequisite for entry into the study.

Six patients with chest pain syndromes but no structural or functional abnormalities at cardiac catheterization served as a normal control group for the radionuclide ventriculographic response to exercise.

Five patients with significant coronary artery disease and elevated resting left ventricular end-diastolic pressure at catheterization, but no valvular abnormalities, served as an additional control group for the effects of exercise on the regurgitant index.

## Radionuclide Determination of Left Ventricular Function

**Blood pool labelling with technetium-99m:** Red blood cells were labelled with 25 mCi of technetium-99m using an in vivo method. Percent labelling by this method was 69.8 ± 14.6 (mean ± standard deviation [SD]) and the effective half-life of the technetium-99m red blood cell complex was 4.5 hours.

**End-diastolic counts, end-systolic counts, stroke counts, count cardiac output, and ejection fraction:** Data were acquired using a mobile, standard field of view gamma camera with a high sensitivity collimator (Picker, North Ford, Connecticut) interfaced with a minicomputer dedicated to the acquisition and processing of nuclear medicine data (Digital Equipment, Marlborough, Massachusetts). Data were acquired in the modified left anterior oblique projection that best separated the left and right ventricles and left ventricular activity from left atrial activity. Studies from this laboratory[17] have shown that averaging the data from multiple, relatively brief acquisitions more effectively reduces statistical error than prolonging the time of a single acquisition, while maintaining high intra- and interobserver reproducibility. Therefore, for the present study, triplicate baseline and duplicate exercise acquisitions were obtained, and radionuclide data were averaged from these acquisitions. Each acquisition consisted of 28 frames per R-R cycle and a total of approximately $3 \times 10^6$ counts. Data were acquired in the zoom mode in 64 × 64 matrices. Typical acquisition times were 90 seconds per study depending on body habitus and labelling efficiency.

End-diastolic count data were determined by adding the first 3 frames of the 28-frame study. An end-diastolic region of interest was computer generated, and the minimal count rate in the time-activity curve from this region identified. The counts in this minimal frame, and those from frames immediately preceding and following it were summed and used as end-systolic count data. End-systolic and paraventricular regions of interest were then computer-generated and the unsmoothed data from within these 3 regions of interest plotted over the course of the cardiac cycle. Background-corrected end-diastolic and end-systolic count data were calculated from mathematically smoothed time-activity curves and corrected for frame duration and normalized to 20 ms. Stroke counts were determined as the difference between end-diastolic and end-systolic counts and count cardiac output was determined as the product of stroke counts and heart rate. All count data were then corrected for the 4.5 hour effective half-life of the technetium-99m red blood cell complex. In this way, all count data for each patient were referrable to the initial data acquisition. In this laboratory, in patients without valvular regurgitation, the correlation between

* $p < 0.001$ versus rest; † $p < 0.02$ versus rest.

changes in stroke counts and in thermodilution stroke volume during intervention is r = 0.90, p <0.001.[18] Because gated radionuclide ventriculography measures total ventricular stroke volume, characterization of the rest-exercise response in AR also requires an estimate of the magnitude of the regurgitant volume.

Left ventricular ejection fraction was calculated according to the formula LVEF = (ED − ES)/ED, where ED = end-diastolic counts and ES = end-systolic counts, corrected for background. Correlation between left ventricular ejection fraction determined with this method and contrast cineangiography in this laboratory has been demonstrated to be r = 0.90, p <0.001.[19]

### Calculation of Regurgitant Index

The regurgitant index (LV ÷ RV stroke counts) was determined with use of operator-defined fixed end-diastolic regions of interest without background subtraction. This method estimates the regurgitant fraction determined with electromagnetic flow meter in an animal model and by catheterization techniques in patients with high intra- and interobserver reproducibility.[8,9,11] The correlation between radionuclide regurgitant index and catheterization regurgitant fraction for the patients in this study was r = 0.78, p <0.001.

### Exercise Protocol

Exercise was performed on a bicycle ergometer imaging table combination (Nuclear Associates, Carle Place, New York), which allowed the subject to exercise vigorously while maintaining a stable position under the gamma camera. For exercise patients are placed in the supine position with their feet up in pedals so that their legs are held approximately 15 cm above the level of the heart. We have found no consistent difference in end-diastolic counts, end-systolic counts, stroke counts, cardiac output, or ejection fraction with feet up when compared with positioning of the legs at the level of the heart. Ten minutes after the patient was in this starting position, triplicate baseline data were acquired. Bicycle exercise was then begun at 150 kpm. Pedal speed was held constant at 60 to 70 rpm. One minute after the onset of exercise, duplicate consecutive gated studies were acquired. Immediately on completion of the second acquisition, the work load was increased by 150 kpm. One minute later an acquisition was again initiated. Exercise levels were increased until termination of the study. Criteria for terminating the study were extreme fatigue, severe angina, shortness of breath, complex ventricular arrhythmias, or a decrease in systolic blood pressure. Care was taken to exercise each patient to his or her symptomatic maximum. Pulse, blood pressure, and electrocardiograms were recorded each minute throughout exercise.

### Statistical Analysis

All data are presented as means ± 1 standard deviation. Changes in count data are expressed as percent of supine rest. Comparisons among groups were done using a grouped *t* test. Comparisons in individual subjects from rest to peak exercise were done using paired *t* tests. Relations between variables were tested with linear regression and the significance of these relations were tested by one-way analysis of variance.[20] A p value ≤0.05 was considered significant.

## Results

**Patient group:** There were 13 men and 7 women (aged 49 ± 15 years) in the study group. Ten patients were in New York Heart Association[21] clinical class I, 4 patients were in class II, and 6 patients were in class III (Table I). At the time of the study, 8 patients were receiving digitalis preparations, and 3 were taking antiarrhythmic agents. All other cardioactive drugs were discontinued for the purpose of testing.

The 6 subjects (4 men and 2 women) with chest pain but no demonstrable coronary or valvular abnormalities at cardiac catheterization averaged 44 years of age. All 5 patients with coronary artery disease (4 men and 1 woman), mean age 51 years, had previous myocardial infarctions, elevated left ventricular end-diastolic pressures at rest (18 ± 4 mm Hg), and multivessel coronary artery disease. No control subject was taking medication at the time of the test.

**Exercise testing (Table II):** For the study group, exercise duration averaged 12 ± 7 minutes and peak work load 431 ± 215 kpm. Eighteen patients stopped exercising because of leg fatigue, whereas 2 stopped because of shortness of breath. Heart rate increased significantly with exercise from 73 ± 17 to 137 ± 26 beats/min (p <0.001) or to 84 ± 13% of maximal predicted heart rate. Systolic blood pressure increased significantly from 145 ± 16 to 211 ± 29 mm Hg (p <0.001) as did diastolic pressure (72 ± 14 to 89 ± 13, p <0.001).

For the normal control group, the heart rate was 75 ± 11 beats/min at rest and increased to 140 ± 18 beats/min (p <0.001) or 85 ± 4% of maximal predicted heart rate with exercise. Systolic blood pressure increased from 127 ± 9 to 195 ± 39 mm Hg (p <0.001) as did diastolic blood pressure, from 84 ± 12 to 100 ± 13 mm Hg (p <0.02). Exercise duration averaged 14.8 ± 6.7 minutes and peak work load 500 ± 182 kpm.

For the patients with coronary artery disease, the heart rate was 89 ± 21 beats/min at rest and increased significantly with exercise to 140 ± 20 beats/min (p <0.001) or to 83 ± 11% of the maximal predicted heart rate. Systolic blood pressure was 124 ± 12 mm Hg at rest and increased to 162 ± 9.6 mm Hg (p <0.001). Diastolic blood pressure also increased from 84 ± 16 to 103 ± 15 mm Hg (p <0.02). Exercise duration averaged 10.4 ± 7 minutes and peak work load 390 ± 171 kpm.

### Radionuclide Count Data

**Normal control:** With exercise, end-diastolic counts increased to 123 ± 20% of control values (p <0.05). Stroke counts and count cardiac output increased for all subjects (p <0.001), averaging 148 ± 28 and 252 ± 47% of control values. Ejection fraction also increased in all subjects, on the average from 72 ± 10 to 82 ± 11% (p <0.02).

**Aortic regurgitation (Table I):** The end-diastolic count response to exercise in patients with aortic regurgitation was highly variable, averaging 98.3 ± 16% of the resting value (p = NS [not significant], range 64 to 132%). Similarly, stroke count response was variable, averaging 96.5 ± 19% (p = NS, range 65 to 127%) of control values. Ejection fraction at rest was 64 ± 11 and 64 ± 16% at peak exercise (p = NS). Again responses were variable, ranging from an 11 unit increase to a 12 ejection fraction unit decrease. Count cardiac output increased in all patients, on average 89 ± 57% (p <0.001, range 123 to 316% of control values).

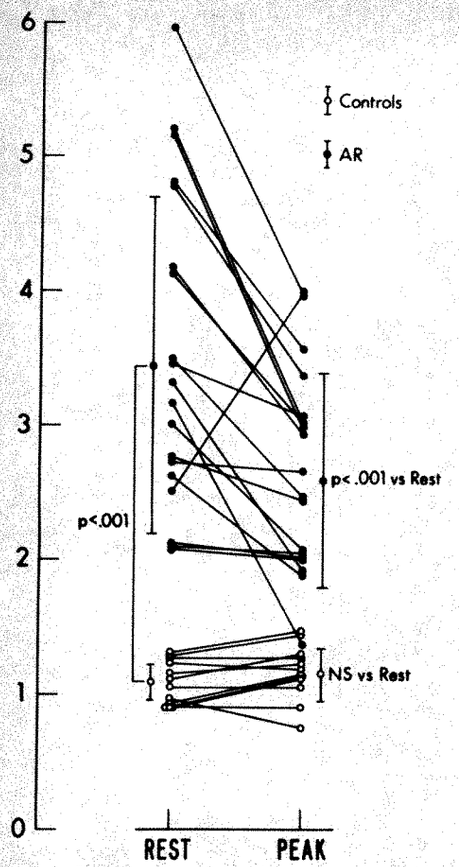

**FIGURE 1.** Regurgitant index at rest and during peak exercise in patients with aortic regurgitation (AR) and in the normal and coronary disease control group. At rest, the regurgitant index was significantly greater ($p < 0.001$) in patients with AR than in the control patients. With exercise, the regurgitant index decreased ($p < 0.001$) in patients with AR but did not change in the control group.

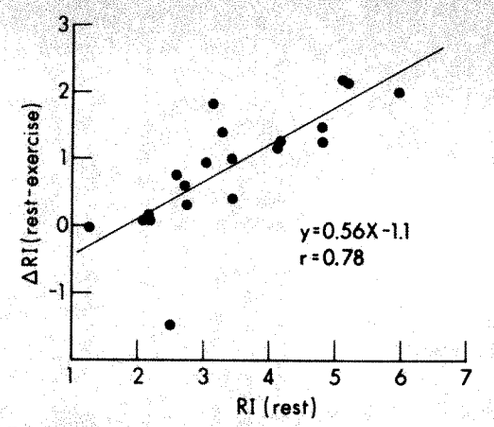

**FIGURE 2.** Relation between the regurgitant index (RI) at rest and its response to exercise. The greater the RI at rest, the greater the decrease with exercise ($r = 0.78$, $p < 0.001$).

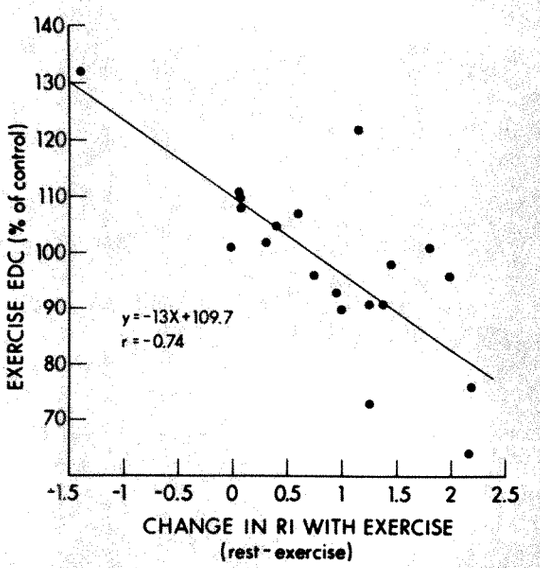

**FIGURE 3.** Relation between the decrease in the regurgitant index (RI) and the end-diastolic count (EDC) response. As the regurgitant index decreased (or increased in 1 patient) so did end-diastolic counts ($p < 0.001$).

**Regurgitant index:** As the regurgitant index at rest and during exercise was similar in normal subjects and patients with coronary disease, the 2 groups of patients were combined for analysis. The regurgitant index was $1.08 \pm 0.16$ at rest, and with exercise did not differ significantly: $1.16 \pm 0.21$.

In contrast, in patients with AR, the regurgitant index at rest was greater than in the control group ($3.46 \pm 1.25$, $p < 0.001$) and decreased with exercise to $2.6 \pm 0.8$ ($p < 0.001$) (Fig. 1, Table I). The magnitude of the decrease in the regurgitant index was directly related to the regurgitant index at rest as described by the equation $y = 0.56x - 1.08$, $r = 0.78$, $p < 0.001$ (Fig. 2).

**Impact of changing regurgitant index during exercise on radionuclide ventriculographic count data and ejection fraction in patients with AR:** With exercise the percent change in end-diastolic counts was directly related to changes in the regurgitant index (Fig. 3) as given by the equation $y = -13x + 110$, $r = -0.74$, $p < 0.001$; that is, as the regurgitant index decreased, so did the end-diastolic counts, explaining in part the variability in the end-diastolic count response in this group. Furthermore, the stroke count response to exercise was related to the end-diastolic count response. Linear regression analysis revealed a correlation of $r = 0.81$, $y = 0.98x - 0.22$, $p < 0.001$ (Fig. 4). However, changes in ejection fraction with exercise did not correlate with the end-diastolic count response.

## Discussion

The purpose of this study was to examine in detail the ventricular response to exercise in AR using gated radionuclide ventriculography. The most striking finding was great interpatient variability resulting in no change in mean end-diastolic counts, stroke counts, or ejection fraction with exercise.

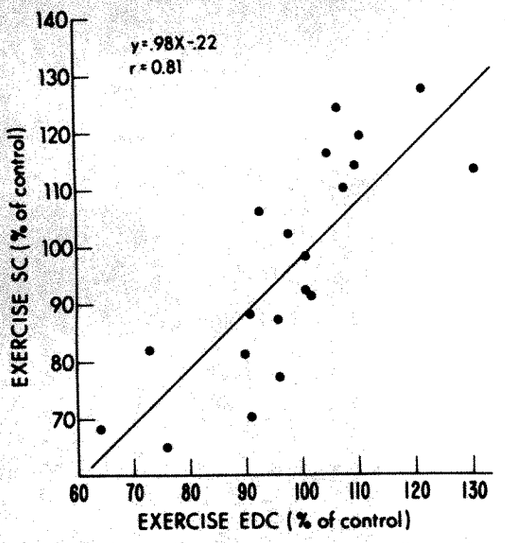

**FIGURE 4.** Relation between changes in end-diastolic counts and total ventricular stroke counts with exercise in patients with aortic regurgitation. Changes in stroke counts (SC) were related to changes in end-diastolic counts (EDC) ($p < 0.001$).

In normal subjects, all 3 radionuclide variables increase with exercise, as shown in this and other studies.[22,23] The observed variability in stroke counts and end-diastolic counts in patients with AR[24] may in part represent physiologic adaptations to varying degrees of regurgitation. The greater the regurgitant index at rest, the greater the decrease with exercise. The decrease in regurgitant index with stress partly accounted for the changes in end-diastolic counts. The stroke count changes were, in turn, related to changes in the end-diastolic counts. For the group, because the regurgitant index decreased and stroke counts did not change, forward stroke output per beat necessarily increased, a "normal" response to exercise.[25,26] Therefore, a more complete understanding of the response to exercise in AR should include an estimation of the regurgitant volume both at rest and during exercise.

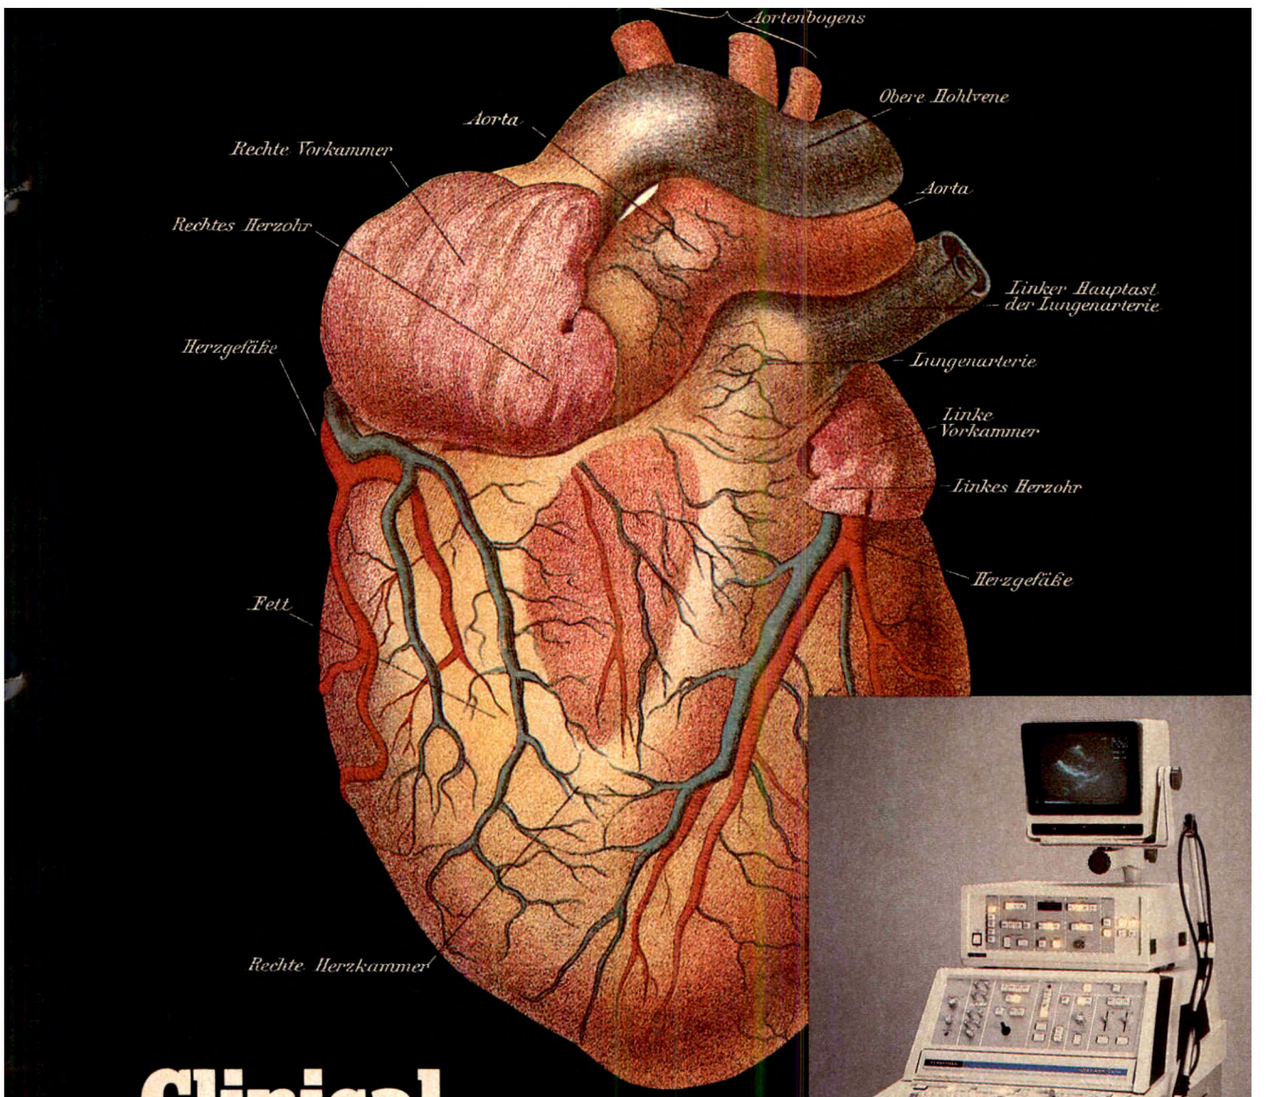
Gated radionuclide ventriculography is being increasingly applied to the study of patients with AR. In addition to the variables of end-diastolic volume, stroke volume, and ejection fraction, several groups have reported on the regurgitant index, an estimate of the severity of valvular regurgitation.[8–12] In our study, in the control group at rest the regurgitant index was 1.08 ± 0.16, similar to values previously reported for groups without left heart regurgitant lesions or left to right shunts.[10–12] Values greater than unity reflect the inability of the method to completely separate atrial from ventricular activity. During exercise in the control group, there was no significant change in the regurgitant index. In contrast, in patients with AR, the regurgitant index averaged 3.46 at rest (compatible with moderate to severe regurgitation[10]), and decreased significantly with stress. In a preliminary report, Horowitz et al[27] also noted that the regurgitant index decreases during isotonic exercise in patients with AR.

The decrease in the regurgitant index with a consequent decrease in end-diastolic volume has been suggested clinically for more than a century as the mechanism behind preservation of exercise tolerance[28] and has previously been demonstrated with use of catheterization techniques. Levinson et al[29] used indocyanine green dye to show that the regurgitant fraction decreased from rest to exercise in patients with AR. Similar results have been reported in patients with combined aortic stenosis and regurgitation.[30] Bristow et al[31] used thermal techniques to demonstrate a reduction in end-diastolic volume during exercise in most patients with AR. Borer et al,[13] using gated radionuclide techniques, noted a 6% reduction on average in end-diastolic volume in patients with severe AR. Recently, Dehmer et al[24] reported highly variable gated radionuclide end-diastolic volume responses to supine exercise in patients with AR, with several patients showing a marked decrease.

Thus, using divergent methods several groups have demonstrated that left ventricular end-diastolic volume can decrease during exercise in patients with AR. The shortened diastolic filling period during exercise coupled with a lowered peripheral resistance are postulated mechanisms leading to decreased backflow and diastolic volumes.[29] Judge et al[32] used rapid atrial pacing to shorten the diastolic filling period and demonstrated decreases in end-diastolic volume (contrast angiographic), end-diastolic pressure, and regurgitant flow per beat in most patients. The ejection fraction also decreased. More recently, Firth et al[33] studied the effects of increments in atrial pacing rate among patients with AR. The regurgitant volume was calculated as the difference between gated radionuclide ventriculographic total stroke volume and simultaneously measured thermodilution forward stroke volume. Progressive increases in heart rate resulted in progressive decreases in regurgitant flow per stroke and end-diastolic volume. However, ejection fraction and regurgitant fraction responses were highly variable and unchanged for the group.

We have no ready explanation for the 1 patient in our series who showed an increase in end-diastolic volume and regurgitant index with stress. Noninvasive data suggested the presence of isolated AR, and she remains in clinical class I at 1 year of follow-up. Theoretically, an increase in regurgitant valve area with exercise could explain these findings.[32]

As noted earlier, the phenomenon of decreasing regurgitant index during exercise provides an explanation for the dramatic changes in end-diastolic counts seen in our patients with AR. Although not dictating the ejection fraction response (no correlation in this study or that of Dehmer et al[24]), large changes in end-diastolic counts may compromise the ejection fraction as an index of contractility.[34,35] In normal hearts, the tachycardia and increased afterload of exercise tend to decrease the ejection fraction. These effects are offset by increased venous return and enhanced contractility, resulting in an increase in ejection fraction.[36] In patients with AR, the effect of tachycardia may be greatly exaggerated if end-diastolic volume decreases precipi-



tously, as might be anticipated in patients who have large regurgitant indexes at rest. With such large volume loads at rest, when gross ventricular stroke volume is nearly maximized, failure of the ejection fraction to increase or even a frank decrease with exercise may reflect the influence of decreasing end-diastolic volume rather than decreased contractility as such.

*In summary*, we have shown that radionuclide ventriculography can evaluate the physiology of the ventricular response to exercise in AR, as previously demonstrated with more invasive techniques. Measurement of radionuclide regurgitant index at rest and during exercise and tracking the end-diastolic volume and ejection fraction responses will help to characterize these patients more completely.

# Clinical versatility redefined.

The TOSHIBA SSH-40A Cardiac Phased Array Sector Scanner brings new meaning to clinical versatility. The SSH-40A offers superb image quality, extensive computational capability, and the ability to perform a wide variety of examinations. It incorporates advanced technological developments such as: Automatic Electronic Focusing, the field's first Two Dimensional Gate Array Doppler, and a very powerful on-board computer. From neonates to adults, from standard views to special flow studies, from simple imaging to functional calculations, the new SSH-40A is truly a new generation in phased array.

You expect new innovations from TOSHIBA. We're the Total Imaging Company with over 12,000 ultrasound scanners in use throughout the world.

# Designed with the patient in mind.

**People move, bend, stretch, perspire.**
When we designed Nitro-Dur™ (nitroglycerin) Transdermal Infusion System, we designed it with features to accommodate these human factors. Because of the size of Nitro-Dur it has features that other nitroglycerin systems don't have.

**It's big because it's the only one with a wide adhesive strip.**
If angina patients were supine for 24 hours, adhesion would be a minor concern. But people move, bend, stretch, and turn while awake and asleep. A system has to stay put throughout all these movements.

In developing Nitro-Dur, we tested dozens of tapes before we settled on a microporous tape known for its excellent adhesion, one that doesn't leave the skin macerated and is relatively painless on removal.

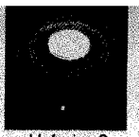
The Nitro-Dur adhesive strip is wider than that on any other system. Wide enough to stay put during a 24-hour day of walking, showering, bending, standing or sleeping. Wide enough to prevent leaking or falling off.

**It's big because it's the only one with an absorbent pad.**
Because perspiration could affect adhesion, we added an absorbent pad behind the matrix. Nitro-Dur is the only system with this feature.

**Surface area determines the dose.**
The stratum corneum regulates the absorption of cutaneously applied nitroglycerin. Therefore, as the surface area of application is increased the dose of nitroglycerin also increases. To insure a fixed surface area, we offer a solid—a gel polymer matrix that contains the active drug.

**The only transdermal to offer you greater dosage flexibility.**
Nitro-Dur has four dosage strengths—5, 10, 15 and 20 $cm^2$. Other systems limit your options to two strengths.

**The only place it's smaller—the cost to your patients.**
Your patients can save up to $75 a year using Nitro-Dur rather than competitive products. Considering that they may be taking the product for years, that's a very important advantage![1]



The human factor made us big. You made us the largest-selling transdermal nitroglycerin system.

**The most widely prescribed transdermal nitroglycerin system.**

**Nitro-Dur™**
(nitroglycerin)
Transdermal Infusion System

Please see next page for a summary of prescribing information.

# Nitro-Dur™
(nitroglycerin)
Transdermal Infusion System

**DESCRIPTION:** The Nitro-Dur Transdermal Infusion System contains nitroglycerin in a gel-like matrix composed of glycerin, water (purified), lactose, polyvinyl alcohol, povidone and sodium citrate to provide a continuous source of the active ingredient. Nitro-Dur is available in dosage sizes 5cm², 10cm², 15cm² and 20cm², containing 26 mg, 51 mg, 77 mg and 104 mg of nitroglycerin, respectively, thereby providing precise dosing levels of nitroglycerin. Nitro-Dur has a rated release *in vivo* of approximately 0.5mg/cm²/24 hours. Each unit is sealed in a polyester-foil-polyethylene laminate. The bandage portion consists of a medical grade non-woven, heat sealable, microporous tape.

**CLINICAL PHARMACOLOGY:** When the Nitro-Dur system is applied to the skin, nitroglycerin is absorbed continuously through the skin into the systemic circulation. This results in active drug reaching the target organs (heart, extremities) before deactivation by the liver. Nitroglycerin is a smooth muscle relaxant with vascular effects manifested predominantly by venous dilation and pooling. The major beneficial effect of nitroglycerin in angina pectoris is a reduction in myocardial oxygen consumption secondary to vascular smooth muscle relaxation with resultant reduction in cardiac preload and afterload. In recent years there has been an increasing recognition of a direct vasodilator effect of nitroglycerin on the coronary vessels.

In bioavailability studies[2] transdermal absorption of nitroglycerin from the gel-like matrix achieved steady state venous plasma levels comparable to that of sublingual nitroglycerin and maintained these levels for 24 hours. Therapeutic effect is achieved within 30 minutes after application of the unit, and persists about 30 minutes after removal of the unit.

**INDICATIONS AND USAGE:** Prevention and treatment of angina pectoris due to coronary artery disease.

**CONTRAINDICATIONS:** Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

**WARNINGS:** The Nitro-Dur system should be used under careful clinical and/or hemodynamic monitoring in patients with acute myocardial infarction or congestive heart failure.

In terminating treatment of angina patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks in order to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

**PRECAUTIONS:** Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension, may be due to overdosage. If during the course of treatment these symptoms occur, the dosage should be reduced.

Nitro-Dur is not intended for use in the treatment of acute anginal attacks. For this purpose, occasional use of sublingual nitroglycerin may be necessary.

**ADVERSE REACTIONS:** Transient headache is the most common side effect, especially when higher doses of the drug are administered. Headaches should be treated with mild analgesics while continuing Nitro-Dur therapy. If headache persists, the Nitro-Dur dosage should be reduced.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. Except for dermatitis, these symptoms are attributed to the pharmacologic effects of nitroglycerin. However, they may be symptoms of overdosage. When they persist, the Nitro-Dur dosage should be reduced or use of the product discontinued.

**HOW SUPPLIED:** Nitro-Dur Transdermal Infusion System, 5cm², 10cm², 15cm² and 20cm², is available in unit dose packages of 28.

**CAUTION:** Federal law prohibits dispensing without a prescription.

**PATIENT INSTRUCTIONS FOR APPLICATION:** Patient instructions are furnished with each unit dose package.

# MYOCARDIAL REVASCULARIZATION

## MEDICAL AND SURGICAL ADVANCES IN CORONARY DISEASE

## The most up-to-date reference on the state of the art of medical and surgical myocardial revascularization in clinical coronary disease available today.

Written by 130 selected authorities, MYOCARDIAL REVASCULARIZATION represents the first comprehensive coverage of the subject, presenting many new therapeutic modalities not previously published anywhere. This volume is an outgrowth of the recent International Symposium on Myocardial Revascularization held in Nassau, The Bahamas. It is edited by two internationally renowned specialists, Dean T. Mason, MD, and John J. Collins, Jr., MD.

## Myocardial Revascularization features the latest on:

- Streptokinase - Thrombolysis in AMI (Percutaneous Transluminal Coronary Recanalization (PTCR)
- Percutaneous Transluminal Coronary Angioplasty (PTCA)
- New Calcium Blocking Drugs
- Cardiac Benefits of Coronary Rehabilitation Programs
- Coronary Bypass Surgery for Angina, Unstable Angina, AMI

In Holter studies...

# An office-based system gives you the clinical data you're used to getting...without specially-trained operators.

*After more than six years of development and rigorous clinical evaluation, a microcomputer based system called AEGIS™ is now available for ambulatory monitoring.*

AEGIS has been designed to analyze in real time: ventricular ectopic beats (VEB), ventricular couplets (VC), ventricular tachycardia (VT), supraventricular premature beats (SVPB), and supraventricular tachycardia (SVT). Missed beats, marked pauses, sustained ventricular tachycardia, bradycardia and tachycardia are also differentiated by the system. When the 24-hour monitoring activity is completed, AEGIS provides the attending physician with a comprehensive summary report and confirming rhythm strips in minutes. The system is fully-automated so no specially-trained office staff is required, therefore turnaround time and cost of the procedure are substantially reduced.

**Microcomputer Technology**

The AEGIS Real Time Analyzer, a powerful 8 bit microcomputer system, combines the recording and analyzing activities in one unit that analyzes each heartbeat in real time, detecting, categorizing and counting arrhythmias as they actually occur. Because the analysis is in real time, the system is able to apply substantially more instructions per QRS than much more powerful computer systems operating at 60 to 240 times real time.

**Accurate, consistent arrhythmia detection**

AEGIS analyzes arrhythmias detecting departures in rate, rhythm and morphology from each patient's normal reference. The AEGIS computer can find and reference a patient's "normal" beat in less than two minutes even under a wide variety of difficult conditions such as chronic bigeminy, atrial fibrillation and bundle branch block. Furthermore, the "normal" reference beat is continually updated throughout the analysis period to account for changes in the position of the heart due to body movement.

Abnormal morphologies are detected via both feature extraction and template matching. (AEGIS is unique in its use of both methods of analysis.) When deviations exceed specified criteria, a morphology change is noted.

Rate, rhythm and morphology information is then applied to decision algorithms to determine the classification of each specific morphology change.

**Overcoming problems caused by artifacts**

To overcome the problem of artifacts and interference distorting information, AEGIS utilizes a series of highly refined classification algorithms developed from a data base of several hundred patients with a variety of morphologies, amplitudes and artifacts. A dual channel system, AEGIS also has the unique capability of being able to sense when artifacts are overwhelming the usefulness of information and to switch automatically to the other lead signal for processing.

**Decision-making capability**

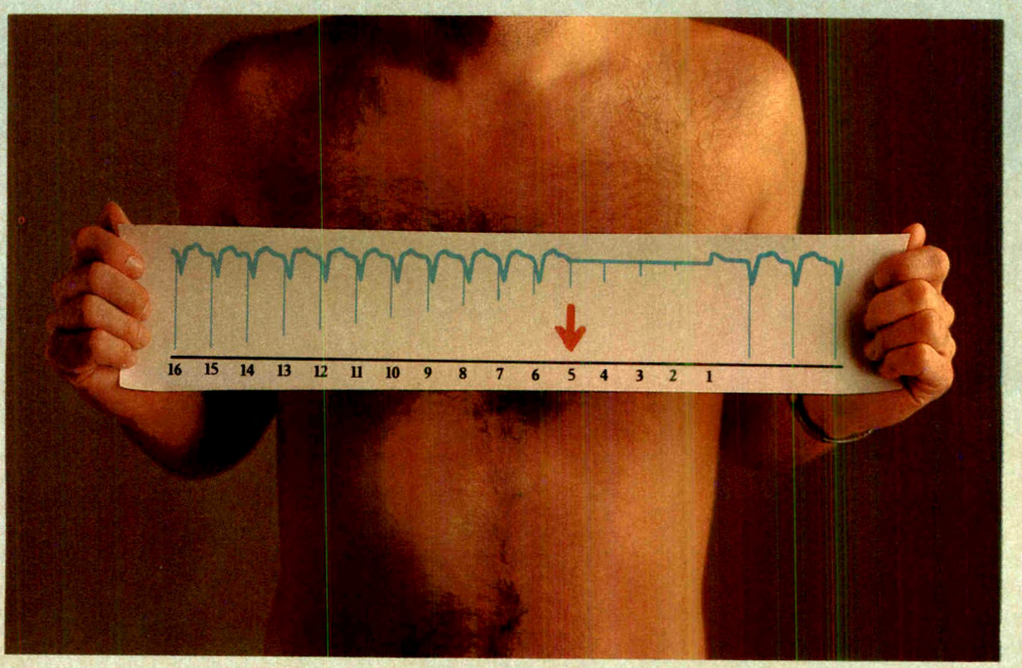
The AEGIS 8 bit microcomputer system is augmented by an analog preprocessor which performs filtering, automatic gain control and QRS detection functions. Thus, the microcomputer has more time and memory available for real time decision making. In fact, AEGIS is able to apply many more computer cycles in this decision making than far more expensive scanner systems operating at high speeds.

**Simplification**

Because all analysis occurs within the compact 2.2 pound AEGIS Real Time Analyzer, the conventional high-speed scanner is replaced by a simple, automatic playback unit called a Report Generator. The need for a specially trained operator is eliminated.

Also eliminated are the dependence of reports on the qualitative perceptions of individuals and the inaccuracies or inconsistencies that result from operator variability and fatigue.

**Advantages to the physician**



The AEGIS System eliminates the turnaround time involved in using a scanning service—diagnostic results are printed in the physician's office, almost immediately.

All components have built-in quality control checks for rigorous verification of the system's integrity. Patient hook-up is identical to that of conventional Holter ECG recording systems; and, with minimal training, anyone can operate the Report Generator. Once begun, the printout process requires no operator attendance and rhythm strips as well as summary categorization reports are completed in minutes.

AEGIS can significantly reduce the cost of complete Holter analysis, and since it is a software based system, the physician can keep it updated as new technological advances are made. **AEGIS Ambulatory Monitoring Systems, Medical Concepts, Inc., 137 Gaither Drive, Mt. Laurel, New Jersey 08054.**

SIEMENS

# VARIO®...the diagnostic true voltage thresholds.

5 pulses without ventricular response here indicate a threshold value of 5 x 0.15 or 0.75V. The pacer is programmed to 2.5V output.

# system that gives you Non-invasively.

The Vario® principle is based on a lowering of the pulse amplitude of the pacer in 16 distinct steps. This step-down is achieved by applying a magnet to the skin over the implanted unit.

The true voltage threshold is obtained by simply counting the pulses on the EKG strip. The number of pulses, which do not depolarize the heart, are then multiplied by the voltage difference.

The pacemaker returns to normal functioning the moment the test magnet is removed.

The unique Vario® system has been in clinical use since 1971 and has become an invaluable diagnostic tool. It is now incorporated in almost all Siemens-Elema pacers.

**NOTE:**
For proper instructions and application refer to physicians manual.

Consistent control counts...

# in hypertension, too. LOPRESSOR®

metoprolol tartrate

**For consistent BP control...**

*...during physical and mental stress*
Lopressor competes with catecholamines at beta-one receptor sites in the heart which usually lessens stress-induced rises in BP in hypertensive patients.

*...throughout the day*
Generally provides continuous reduction in systolic and diastolic pressures, including good reduction during the night.*

*...with excellent patient acceptance*
Adverse effects mostly mild and transient. Tiredness, dizziness about 10%, depression, diarrhea about 5%. See brief summary of Prescribing Information on next page.

*Mann S, et al. *Clin Sci* 1979; **57**:375s-377s.

Geigy

# Lopressor®
**metoprolol tartrate**

An antihypertensive beta-blocking agent

Tablets of 50 mg
Tablets of 100 mg

*Brief Summary of Prescribing Information*

**Indications** Lopressor is indicated in the management of hypertension. It may be used alone or in combination with other antihypertensive agents, especially thiazide-type diuretics.
**Contraindications** Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see **Warnings**).
**Warnings** ***Cardiac Failure:*** Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive patients who have congestive heart failure controlled by digitalis and diuretics, Lopressor should be administered cautiously. Both digitalis and metoprolol slow AV conduction.
***In Patients Without a History of Cardiac Failure:*** Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Lopressor therapy should be withdrawn.
***Ischemic Heart Disease:*** Following abrupt cessation of therapy with certain beta-blocking agents, exacerbations of angina pectoris and, in some cases, myocardial infarction have been reported. Even in the absence of overt angina pectoris, when discontinuing therapy, Lopressor should not be withdrawn abruptly, and patients should be cautioned against interruption of therapy without the physician's advice.
***Bronchospastic Diseases:*** **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. Because of its relative beta$_1$ selectivity, however, Lopressor may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta$_1$ selectivity is not absolute, a beta$_2$-stimulating agent should be administered concomitantly and the lowest possible dose of metoprolol should be used. It may be prudent initially to administer metoprolol in smaller doses three times daily, instead of larger doses two times daily, to avoid the higher plasma levels associated with the longer dosing interval. (See Dosage and Administration.)**
***Major Surgery:*** The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.
Metoprolol, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported with beta blockers.
***Diabetes Mellitus:*** Beta-adrenergic blockade may mask symptoms of hypoglycemia (e.g., tachycardia) and may potentiate insulin-induced hypoglycemia. Lopressor should therefore be used with caution in diabetic patients, especially those with labile diabetes.
***Thyrotoxicosis:*** Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.
**Precautions** ***Impaired Hepatic or Renal Function:*** The drug should be used with caution in patients with impaired hepatic or renal function.
***Drug Interactions:*** Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Lopressor plus a catecholamine depletor should therefore be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.
***Long-Term Animal Studies:*** Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In a one-year study in dogs, there was no evidence of drug-induced toxicity at or below oral doses of 105 mg/kg per day. Two-year studies in rats at three oral dosage levels of up to 800 mg/kg per day did not indicate an increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes which appeared to be drug-related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. Neither finding represents symptoms of a known disease entity in man. In a 21-month study in mice at three oral dose levels of up to 750 mg/kg per day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant lung tumors or total (benign plus malignant) lung tumors. The overall incidence of tumors or malignant tumors was also unaffected by metoprolol administration.
***Usage In Pregnancy:*** Reproduction studies in animals did not reveal any evidence of impaired fertility or of teratogenic potential. There was evidence in the rat of increased postimplantation loss and decreased neonatal survival (threshold between 50 and 500 mg/kg). Distribution studies in mice confirm exposure of the fetus when metoprolol is administered to the pregnant animal. There are no well-controlled studies in pregnant women. Lopressor should be used in pregnant women only when clearly needed.
***Nursing Mothers:*** It is not known whether this drug is excreted in human milk. Since most drugs are excreted in human milk, nursing should not be undertaken by mothers receiving metoprolol.
***Usage in Children:*** Safety and effectiveness in children have not been established.
**Adverse Reactions** Most adverse effects have been mild and transient.
***Central Nervous System:*** Tiredness and dizziness have occurred in about 10 of 100 patients. Depression was reported in about 5 of 100 patients. Headache, nightmares, and insomnia have also been reported but drug relationship is not clear.
***Cardiovascular:*** Shortness of breath and bradycardia have occurred in approximately 3 of 100 patients. Cold extremities; arterial insufficiency, usually of the Raynaud type; palpitations and congestive heart failure have been reported. See **Contraindications, Warnings,** and **Precautions.**
***Respiratory:*** Wheezing (bronchospasm) has been reported in less than 1 of 100 patients. See **Warnings.**
***Gastrointestinal:*** Diarrhea has occurred in about 5 of 100 patients. Nausea, gastric pain, constipation, flatulence, and heartburn have been reported in 1 of 100 or less.
***Allergic:*** Pruritus has occurred in less than 1 of 100 patients.
***Miscellaneous:*** Peyronie's disease has been reported in less than 1 of 100,000 patients. The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with Lopressor during investigational use and foreign marketing experience.
***Potential Adverse Effects:*** In addition, a variety of adverse effects not listed above have been reported with other beta-adrenergic blocking agents, and should be considered potential adverse effects of metoprolol.
*Central Nervous System:* Reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.
*Cardiovascular:* Intensification of AV block (see **Contraindications**).
*Hematologic:* Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.
*Allergic:* Erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.
*Miscellaneous:* Reversible alopecia.
*Clinical Laboratory Test Findings:* Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.
**Dosage and Administration** Dosage of Lopressor should be individualized. The usual initial dose is 50 mg twice daily whether used alone or added to a diuretic. The dosage may be increased at weekly (or longer) intervals until optimum blood pressure reduction is achieved. In general, the maximum effect of any given dosage level will be apparent after one week of therapy. Usual maintenance dosage is approximately 100 mg twice a day, with a range of 100 to 450 mg per day. Dosages above 450 mg per day have not been studied. While twice-daily dosing is effective and can maintain a reduction in blood pressure throughout the day, some patients, especially when lower dosages are used, will experience a modest rise in blood pressure toward the end of the 12-hour dosing interval. This can be evaluated by measuring blood pressure near the end of the dosing interval to determine whether satisfactory control is being maintained throughout the day. If control is not adequate, a larger dose, or three times daily therapy, may achieve better control. Beta$_1$ selectivity diminishes as dosage of Lopressor is increased.
This drug should be stored at controlled room temperature and protected from moisture.
**How Supplied** Tablets of 50 mg (capsule-shaped, scored, light red, film-coated) and 100 mg (capsule-shaped, scored, light blue, film-coated) are supplied in bottles of 100 and 1,000 and Unit Dose Packages of 100.
Store at controlled room temperature and protect from moisture.
*Dispense in tight, light-resistant container (USP).*

# Indexes of Intravascular Hemolysis, Quantification of Coagulation Factors, and Platelet Survival in Patients With Porcine Heterograft Valves

MARK E. THOMPSON, MD, JESSICA H. LEWIS, MD, FREDERICK L. PORKOLAB, MD, UTE HASIBA, MD, and JOEL A. SPERO, MD, *With the technical assistance of* JOHN WILSON, MT and MICHAEL SNYDER, BS

**Ten patients with porcine heterograft valves who were not receiving anticoagulant agents were evaluated to determine the effect of the valve on red blood cell survival and on platelet activation and consumption as measured by (1) quantification of the coagulation mechanism, (2) platelet function studies, and (3) 51-chromium platelet survival time. There was no evidence of significant intravascular hemolysis as determined by the reticulocyte count, serum iron and iron binding capacity, serum bilirubin level, or lactic dehydrogenase activity. The coagulation profile and the platelet function studies were normal. No statistically significant difference was found in the platelet survival time in the 10 patients with porcine heterograft valves (half-life 3.2 ± 0.8 days) and the 11 normal control subjects (half-life 3.6 ± 0.6 days) ($p > 0.2$). The finding of a normal platelet survival time in patients with porcine heterograft valves is consistent with clinical experience indicating that this device is associated with a low incidence of systemic embolization, approximating 3% per year.**

Embolic and hemolytic complications after cardiac valve replacement represent a substantial cause of morbidity and mortality.[1–6] Since 1970, approximately 75,000 patients have undergone bioprosthetic valve replacement with the glutaraldehyde-preserved porcine valve. The major advantage of the porcine valve is the low incidence of intravascular hemolysis and systemic embolization.[7] This study evaluates the effect of the porcine heterograft valve on red blood cell destruction as measured by indexes of intravascular hemolysis, and its effect upon platelet activation and consumption as measured by (1) quantification of the coagulation mechanism, (2) platelet function studies, and (3) 51-chromium platelet survival time. The latter allows estimation of the thrombogenic potential of a prosthetic valve.[8,9]

From the Divisions of Cardiology and Coagulation, Department of Medicine, University of Pittsburgh; and the Central Blood Bank of Pittsburgh, Pittsburgh, Pennsylvania. This study was supported by National Institutes of Health Grants HL 02254 and 5-M01-RP000-56-20 from the General Clinical Research Center, University of Pittsburgh, and a grant from the Western Pennsylvania Heart Association, Pittsburgh, Pennsylvania. Dr. Porkolab was supported by a research fellowship from the York-Adams Chapter of the Pennsylvania Affiliate, American Heart Association, York, Pennsylvania. Manuscript received March 22, 1982; revised manuscript received August 19, 1982, accepted August 20, 1982.

Address for reprints: Mark E. Thompson, MD, 789 Scaife Hall, University of Pittsburgh, School of Medicine, Pittsburgh, Pennsylvania 15261.

## Methods

All 10 patients had Hancock porcine heterograft valve (Vascor, Anaheim, California) replacement 7 to 49 months before participation in the study: 8 had mitral valve replacement alone (model 342) and 2 had mitral and aortic valve replacements (model 242). Eight were in sinus rhythm at study (Table I). The bioprosthetic valve or valves were functioning normally without evidence of regurgitation or stenosis. Congestive heart failure and a history of systemic embolization, either before or after valve replacement, were not present. No patient was receiving the anticoagulant agent warfarin or any drug known to affect platelet function at study.

The following variables were used to judge the extent of intravascular hemolysis: hemoglobin, hematocrit, reticulocyte count, serum iron and iron binding capacity, serum haptoglobin, and lactic dehydrogenase activity, the latter 2 being the most sensitive and specific (Table II).[10,11]

Coagulation profiles, assays of coagulation factors, and platelet function studies were performed in 9 patients (Tables III to V). These studies were performed using previously described or standard methods.[12–14] A modification of the method described by Saltzman[15] was used to determine the glass bead retention index.

Platelet survival studies were carried out in 11 normal volunteers and the 10 patients utilizing autologous 51-chromium–labeled platelets. The platelets were obtained by manual plasmapheresis, and the survival studies were performed in accordance with the report of the International Committee for Standardization in Hematology.[16] The platelet survival times in the patients were compared with those determined in 11 normal volunteers. Student's $t$ test was used for statistical analysis.[17]

**TABLE I Patient Profile**

| Patient | Age (yr) & Sex | Valve Age (mo) | Rhythm | Valve Replaced | Platelet Survival (Days Half-Life) |
|---|---|---|---|---|---|
| 1 | 29M | 7 | S | A/M | 3.0 |
| 2 | 66F | 11 | S | M | 2.4 |
| 3 | 57M | 12 | S | M | 3.2 |
| 4 | 62M | 14 | S | M | 2.0 |
| 5 | 47F | 15 | S | M | 3.7 |
| 6 | 34F | 16 | S | M | 3.4 |
| 7 | 47M | 22 | AF | M | 2.5 |
| 8 | 66F | 31 | S | M | 3.0 |
| 9 | 51M | 39 | AF | A/M | 4.7 |
| 10 | 52M | 49 | S | M | 3.8 |

A = aortic; AF = atrial fibrillation; M = mitral; S = sinus rhythm.

## Results

The results are summarized in the accompanying tables. There was no evidence of significant intravascular hemolysis (Table II). The screening tests of coagulation (Table III) gave normal results. Likewise, there was no evidence of intravascular coagulation. Assays of coagulation factors (Table IV) and platelet function studies (Table V) gave normal findings.

The platelet half-life in 11 normal control subjects was 3.6 ± 0.6 days. In the 10 patients with porcine heterograft valves who were not receiving anticoagulant therapy, the platelet half-life was 3.2 ± 0.8 days (Table I). No statistically significant difference was observed in the platelet survival time in the patients with porcine heterograft valves and in the normal control subjects ($p > 0.2$).

## Discussion

Intravascular hemolysis as a result of trauma to red blood cells is a common complication of prosthetic heart valves.[18–20] In evaluating patients for intravascular hemolysis, the most sensitive and specific indexes are serum lactic dehydrogenase activity >500 IU and a depressed level of serum haptoglobin.[10,11] No patient with a porcine bioprosthesis in this study had evidence of significant intravascular hemolysis. The degree of intravascular hemolysis associated with the porcine bioprosthesis is comparable to that demonstrated for the newer tilting disc-type valves (Björk-Shiley) and is of no clinical significance.[21]

Study of the effects of artificial heart valves on the coagulation profile has been limited due to the necessity for long-term anticoagulant therapy. Patients with porcine bioprostheses have not required anticoagulation; hence, a study of their coagulation and platelet activity is feasible. The tests of the plasma coagulation mechanism were normal and suggested no abnormality resulting from the prosthetic device. Platelet function has been studied in patients with prosthetic heart valves by several investigators and also was reported to be normal.[8,9,22] Platelet function studies, in contrast to

**TABLE II Evaluation of Intravascular Hemolysis**

ADP = adenosine diphosphate.

platelet survival studies, are not predictive of future thromboembolism in patients with prosthetic heart valves.[8,9]

Kinetic platelet survival studies have been useful in predicting future thromboembolic events.[8,9] Platelet survival (half-life 3.2 ± 0.8 days) in our 10 patients with Hancock porcine valves who were not receiving anticoagulant therapy did not differ significantly from the platelet survival time determined in 11 normal subjects (half-life 3.6 ± 0.6 days) ($p > 0.2$). Lee et al[23] determined the platelet half-life in 10 patients with the Hancock porcine valve who were not receiving anticoagulant agents to be 2.9 ± 0.6 days, which was significantly shorter than the platelet half-life of 5.1 ± 0.5 days observed in 7 normal control subjects ($p < 0.05$). The statistical differences observed in these 2 reports may be explained by the relatively small number of subjects in each study. The finding of a normal platelet survival time in patients with Hancock porcine heterograft valves complements the normal platelet survival time found in patients with homograft prosthetic valves.[8,9] The similarities in tissue composition between the homograft valve and the Hancock valve lends credence to this observation and is consistent with clinical experience indicating this device is associated with a low incidence (approximately 3% per year) of systemic embolization.[7]

# Rheumatic Tricuspid Valve Disease: Two-Dimensional Echocardiographic, Hemodynamic, and Angiographic Correlations

STEVEN J. DANIELS, MD, GARY S. MINTZ, MD, and MORRIS N. KOTLER, MD

**From March 1977 through April 1982, 2-dimensional echocardiography detected 372 patients with rheumatic mitral valve disease. Of these patients, 23 (6%) had tricuspid valve involvement. Two-dimensional echocardiographic criteria of rheumatic tricuspid valve disease included thickened leaflets with restriction in motion, diastolic doming, and encroachment of the leaflet tips on the ventricular inlet. These criteria provided a sensitivity of 100%, a specificity of 90%, a predictive accuracy of 21%, and a negative predictive value of 100% in diagnosing hemodynamically significant tricuspid stenosis.**

**Hemodynamic variables in patients with rheumatic tricuspid valve disease (Group I) were compared with those in patients with no rheumatic tricuspid disease (Group II). The only significant difference was mean right atrial pressure (15 ± 7 mm Hg versus 11 ± 5 mm Hg, p <0.02). Both groups were classified into patients with (A) and without (B) significant tricuspid regurgitation (TR). There was no significant difference in any hemodynamic variable when Group IA was compared with Group IIA. In addition, there was no difference in any hemodynamic variable when patients with functional TR (Group IIA) were compared with those with rheumatic mitral valvular disease without TR (Group IIB). Two-dimensional echocardiography and cardiac catheterization provide complementary diagnostic information in these patients.**

In patients with rheumatic heart disease, the reported incidence of tricuspid valve involvement varies, ranging from 3.5[1] to 67%.[2] Most reports are from the preantibiotic era and from underdeveloped nations. One recent report[3] claims that finding a thickened and restricted tricuspid valve on 2-dimensional echocardiographic study is predictive of hemodynamically significant tricuspid stenosis (TS). In this report we attempt to (1) define the incidence of rheumatic tricuspid valve disease in the present era, (2) determine the sensitivity, specificity, predictive accuracy, and negative predictive value of the 2-dimensional echocardiographic criteria of rheumatic TS, (3) evaluate the hemodynamic consequences of rheumatic tricuspid valve disease, and (4) determine whether hemodynamic variables can differentiate primary rheumatic TR from secondary TR in patients with rheumatic mitral valve disease.

From the Cardiac Catheterization Unit, Likoff Cardiovascular Institute of Hahnemann University and Hospital, Philadelphia, Pennsylvania. Manuscript received July 8, 1982; revised manuscript received September 8, 1982, accepted September 17, 1982.

Address for reprints: Gary S. Mintz, MD, Likoff Cardiovascular Institute, Hahnemann University, 230 North Broad Street, Philadelphia, Pennsylvania 19102.

## Methods

The 2-dimensional echocardiographic reports from Hahnemann University and Hospital from March 1977 through April 1982 were reviewed. Of 372 patients with rheumatic mitral valve disease, 23 also had rheumatic tricuspid valve involvement. An additional 7 patients with prosthetic mitral valves had rheumatic tricuspid valve disease. The echocardiographic, hemodynamic, and angiographic findings in these patients were reviewed retrospectively.

**Echocardiography:** Two-dimensional echocardiographic studies were performed with the patient in the supine or left lateral decubitis position. These patient studies were done using either a Grumman Health Systems RT 400 or Varian V 3000, 3000R, or 3400 phased array sector scanner. A complete study consisted of the parasternal long- and short-axis views, the apical 2- and 4-chamber views, and the parasternal right ventricular inflow tract view. Images were recorded on videotape for analysis. Illustrations were obtained from Polaroid® photographs of stop-action single frame images made from the videotape recordings.

Rheumatic mitral valve disease was defined as increased thickening of the mitral valve leaflets, restricted leaflet motion, encroachment of the leaflet tips into the left ventricular inlet, and diastolic doming of the leaflets (particularly an obtuse angular bend of the anterior leaflet). Similar findings of increased thickening, restricted motion, encroachment of leaflets on the right ventricular inlet, and diastolic doming defined rheumatic tricuspid valve disease. The 2-dimensional

echocardiographic criteria were compared with hemodynamic and angiographic findings.

**Catheterization techniques and interpretation:** Of the 379 patients, 151 underwent cardiac catheterization. The hemodynamic and angiographic findings were reviewed. Hemodynamic data were available for all 151 patients, but patients with a mitral prosthesis or an echocardiographically normal tricuspid valve and no right ventriculography were excluded from hemodynamic analysis. These exclusions left 50 patients: 15 with 2-dimensional echocardiographic features of rheumatic tricuspid valve involvement (Group I), 31 with rheumatic mitral valvular disease and no echocardiographic tricuspid valve involvement who had undergone right ventriculography during catheterization (Group II), and 4 with a prosthetic mitral valve and echocardiographic rheumatic tricuspid valve disease. There were 7 men and 43 women, aged 22 to 72 years (mean ± standard deviation 55 ± 12). The patients in Groups I and II were subdivided according to the presence (A) or absence (B) of significant TR. Eight patients in Group I had right ventriculography performed as part of the catheterization; 7 had significant TR and formed Group IA. (The other 7 patients in Group I did not have a right ventriculogram. Whether or not they had TR is not known. Therefore, they are excluded from this part of the data analysis.) All patients in Group II had right ventriculography. Eleven of the 31 patients in Group II had significant TR, and, thus, formed Group IIA. Twenty patients in Group II had no or insignificant TR and formed Group IIB. Right atrial, right ventricular, pulmonary artery, pulmonary capillary wedge or left atrial, and left ventricular pressures were recorded using Bentley Transtec or Statham P23DP transducers. Cardiac output was determined using the indocyanine green dye dilution. Pulmonary vascular resistance was calculated. Mitral stenosis was considered hemodynamically significant if the calculated mitral valve area was $\leq 1.5$ cm$^2$. Right atrial and right ventricular pressures were measured simultaneously. TS was considered hemodynamically significant if there was at least a 2 mm Hg diastolic gradient across the tricuspid valve, regardless of the presence of TR.

Left ventriculography was performed using either biplane (right anterior oblique and left anterior oblique views) or single plane (right anterior oblique view) technique. Right ventriculography was performed using either biplane (right anterior oblique and left anterior oblique views) or single plane (right anterior oblique) techniques. If the procedure was performed by way of the transfemoral route, a pigtail catheter with a preformed curve was used so that the catheter coursed from a superior to inferior direction across the tricuspid valve. If the procedure was performed by brachial cutdown, a model 7 NIH catheter was used for right ventriculography. The degree of mitral insufficiency or TR was classified according to the following scale, suggested by Grossman[4]: 1+ (regurgitant contrast material essentially clears with each beat and never opacifies the entire atrium), 2+ (regurgitant contrast does not clear with 1 beat and generally opacifies the entire atrium after several beats, but the degree of opacification does not equal that of the ventricle), 3+ (regurgitant dye completely opacifies the atrium and equals opacification with the ventricle), and 4+ (opacification of the atrium occurs in 1 beat and becomes progressively more dense with each beat). Valvular insufficiency (either mitral or tricuspid) of ≥2+ was considered significant.

Using the data from the 151 patients who had hemodynamic study, the sensitivity, specificity, predictive accuracy, and negative predictive value of the 2-dimensional echocardiographic diagnosis of hemodynamically significant TS were calculated as follows: Sensitivity = [true positive/(true positive + false negative)] × 100; Specificity = [true negative/(true negative + false positive)] × 100; Predictive accuracy = [true positive/(true positive + false positive)] × 100; Negative predictive value = [true negative/(true negative + false negative)] × 100.

Statistical analysis was performed using the Student's $t$ test. Probability values $<0.05$ were considered significant.

## Results

**Echocardiographic findings:** Of 372 patients with 2-dimensional echocardiographic features of rheumatic mitral valve disease, 23 patients also had echocardiographic features of rheumatic tricuspid valve disease (incidence = 6.2%). Simultaneous right ventricular and right atrial pressure measurements were recorded in 19 patients with echocardiographic tricuspid valve involvement (15 patients from Group I and 4 patients with a mitral prosthesis), 4 patients (21%) had TS (Fig. 1 and 2); and 15 patients had no diastolic tricuspid valve gradients. Hemodynamic data were available in 132 patients without echocardiographic tricuspid valve involvement; no patient had hemodynamic TS. Thus,

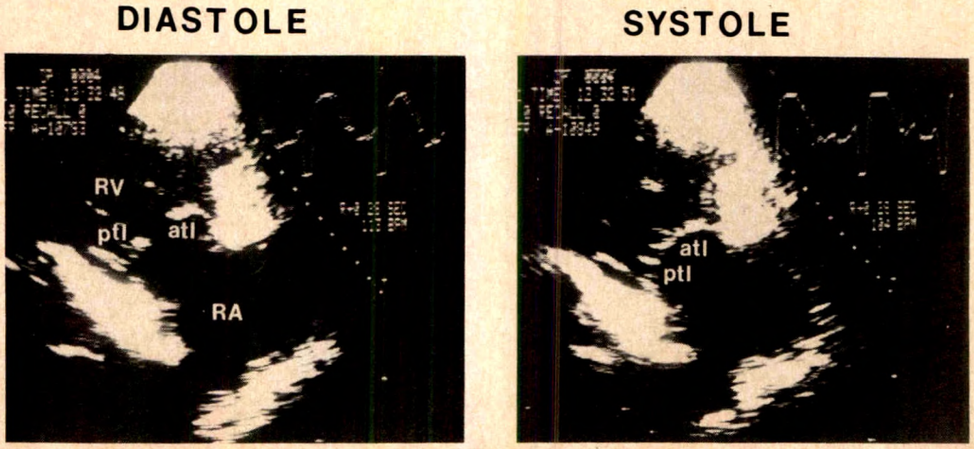

**FIGURE 1.** Two-dimensional echocardiographic study of a patient with rheumatic tricuspid valve disease. The right ventricular inflow tract view is shown. The anterior and posterior tricuspid leaflets (atl, ptl) are thickened and restricted in motion during diastole. The patient had pure TS. RA = right atrium; RV = right ventricle.

**TABLE I Hemodynamic Values in Patients With (Group I) and Without (Group II) Rheumatic Tricuspid Valve Disease**

| | Group I (n = 15) | Group II (n = 31) | p |
|---|---|---|---|
| Mean PCWP (mm Hg) | 26 ± 9 | 25 ± 8 | NS |
| PA systolic (mm Hg) | 60 ± 26 | 52 ± 19 | NS |
| PA mean (mm Hg) | 40 ± 16 | 37 ± 13 | NS |
| RVDP (mm Hg) | 13 ± 6 | 11 ± 5 | NS |
| RA mean (mm Hg) | 15 ± 5 | 11 ± 5 | <0.02 |
| PVR (dynes s $cm^{-5}$) | 409 ± 316 | 262 ± 204 | NS |

NS = not significant; PA mean = mean pulmonary arterial pressure; PA systolic = pulmonary arterial systolic pressure; PCWP = pulmonary capillary wedge pressure; PVR = pulmonary vascular resistance; RA mean = right atrial mean; RVDP = right ventricular end-diastolic pressure.

**TABLE II Hemodynamic Values in Patients With "Primary" (Group IA) and "Secondary" (Group IIA)**

| | Group IA (n = 7) | Group IIA (n = 11) | p |
|---|---|---|---|
| Mean PCWP | 25 ± 6 | 28 ± 11 | NS |
| PA systolic (mm Hg) | 59 ± 28 | 55 ± 21 | NS |
| PA mean (mm Hg) | 39 ± 17 | 39 ± 16 | NS |
| RA mean (mm Hg) | 16 ± 8 | 11 ± 5 | NS |
| PVR (dynes s $cm^{-5}$) | 400 ± 397 | 283 ± 227 | NS |

Abbreviations as in Table I.

2-dimensional echocardiography has a sensitivity of 100%, a specificity of 90%, a predictive accuracy of 21%, and a negative predictive value of 100% in identifying patients with hemodynamically significant TS. Twelve patients with echocardiographic rheumatic tricuspid valve involvement had right ventriculography performed during cardiac catheterization. Nine patients (75%) had significant TR (Fig. 3 and 4).

**Hemodynamic variables (Fig. 5):** Analysis of the hemodynamic variables in patients with rheumatic tricuspid valve disease (Group I) showed a significantly higher mean right atrial pressure than in patients without rheumatic tricuspid valve disease (Group II) (Table I). However, there was no significant difference between the groups in mean pulmonary capillary wedge pressure, pulmonary arterial systolic pressure, mean pulmonary arterial pressure, right ventricular end-diastolic pressure, or pulmonary vascular resistance. There was no significant difference in any of the hemodynamic variables when patients with rheumatic TR (Group IA) were compared with those with functional (Group IIA) (Table II), nor when patients with functional TR (Group IIA) were compared with those with rheumatic mitral valvular disease and no functional TR (Group IIB) (Table III).

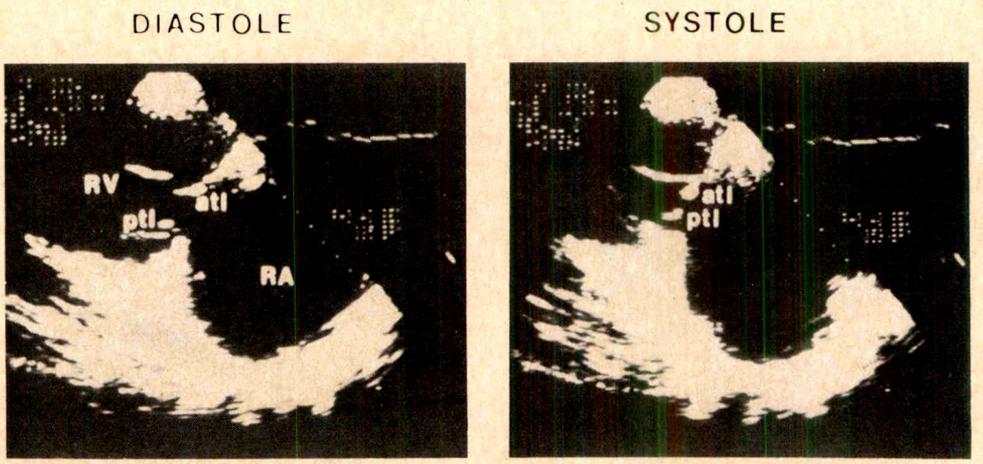

**FIGURE 3.** Two-dimensional echocardiographic study of a patient with rheumatic tricuspid valve disease. The right ventricular inflow tract view is shown. The anterior and posterior tricuspid leaflets (atl, ptl) are thickened and restricted. The patient had pure TR. RA = right atrium; RV = right ventricle.

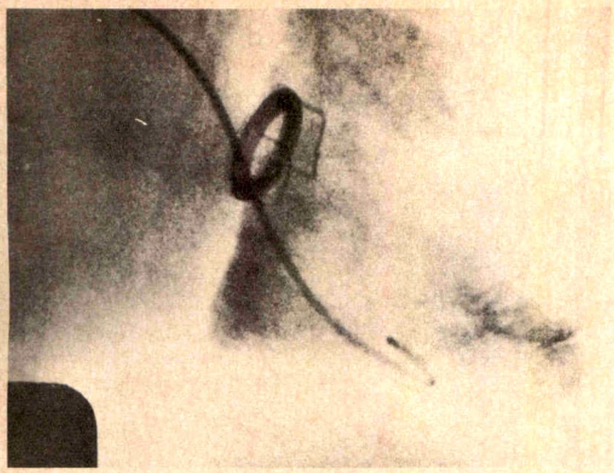

**FIGURE 4.** Right ventriculogram (from the patient in Fig. 3) showing severe TR.

Abbreviations as in Table I.

## Discussion

In our 2-dimensional echocardiographic study, the incidence of rheumatic tricuspid valve involvement in patients with rheumatic mitral valve disease is 6.2%. This incidence is somewhat different from that noted in previous studies. Autopsy studies have shown the incidence of rheumatic tricuspid valve involvement in patients with rheumatic heart disease to range from 3.5%[1] (in a series published in 1940) to 67%[2] (in a series published in 1923). However, most pathologic series[5–11] have shown tricuspid valve involvement in approximately 30 to 50% of people with rheumatic heart disease. Although these incidences are higher than ours, 2 factors must be considered. First, we diagnosed rheumatic tricuspid valve disease by 2-dimensional echocardiography, not morphologically. Gross pathologic disease was probably necessary since most patients had hemodynamically significant TS or TR; and, thus, 2-dimensional echocardiography may underestimate the actual incidence of anatomic rheumatic tricuspid valve involvement. Second, most previous studies were done in the preantibiotic era, when the incidence and severity of rheumatic fever was greater than it is now. Therefore, the actual incidence of tricuspid valve involvement may be lower today.

Recently, Guyer et al[3] suggested that 2-dimensional echocardiography is a sensitive and specific method of evaluating patients with suspected TS. They found the sensitivity of 2-dimensional echocardiography to be 100%, the specificity to be 91%, the predictive accuracy to be 70%, and the negative predictive value to be 100% in diagnosing hemodynamically significant TS. Although our figures for sensitivity, specificity, and negative predictive value are similar, we do not find the predictive accuracy of 2-dimensional echocardiography to be as high (70 versus 21%). When 2-dimensional echocardiography showed rheumatic tricuspid valve disease, hemodynamically significant TS occurred in

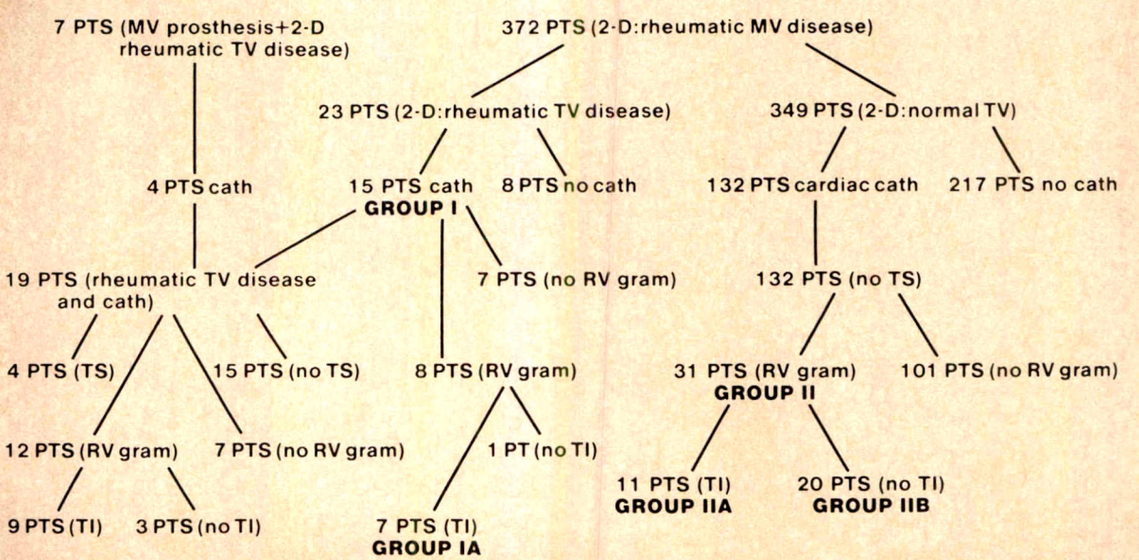

**FIGURE 5.** Flow diagram of the echocardiographic, hemodynamic, and angiographic analysis in this study. Cath = catheterization; MV = mitral valve; PTS = patients; RV = right ventricle; TI = tricuspid insufficiency; TS = tricuspid stenosis; TV = tricuspid valve; 2-D = 2-dimensional.

only a small proportion of our patients. Significant TR was more common.

Braunwald[12] suggested that in patients with rheumatic TR, pulmonary artery systolic pressures >60 mm Hg favor secondary or functional TR while pulmonary arterial systolic pressures <40 mm Hg favor organic tricuspid disease.

We compared patients with TR and rheumatic tricuspid involvement to patients with functional TR (Table II). There were no significant differences in the hemodynamic parameters studied. Pulmonary arterial systolic pressure, mean pulmonary arterial pressure, and pulmonary vascular resistance did not distinguish organic TR from functional TR. A high percentage of patients with significant organic rheumatic tricuspid valve disease have elevated pulmonary arterial pressures. In this population, the elevated pressures merely reflect the severity of the mitral valvular disease. In fact, 5 of 7 patients with rheumatic tricuspid valve disease with TR had pulmonary arterial systolic pressures >40 mm Hg, while 7 of 11 patients with "secondary" TR had pulmonary arterial systolic pressures <60 mm Hg. In patients with rheumatic tricuspid valve disease and pulmonary hypertension, TR may be partly "primary" and partly "secondary." Previous studies have examined the hemodynamics of secondary TR. Lichtlen[13] found higher right ventricular pressures, Schwartz[14] found higher right atrial and right ventricular end-diastolic pressures, and Sepulveda[15] found higher pulmonary vascular resistance, mean right atrial pressure, and right ventricular pressures in patients with rheumatic mitral valvular disease and secondary TR compared with patients with rheumatic mitral valvular disease and no TS or TR. We found no significant difference in any hemodynamic variable when we examined these 2 groups (Table III). The pathophysiology of secondary TR may be more complex and not merely secondary to pulmonary hypertension.

Thus, 2-dimensional echocardiography and cardiac catheterization provide complementary information in evaluating tricuspid valve involvement and function in patients with rheumatic mitral valvular disease. Two-dimensional echocardiographic findings of thickened tricuspid leaflets with restriction in motion and diastolic doming are not predictive of finding a tricuspid valve gradient. Hemodynamic variables do not appear to differentiate organic from functional TR in patients with rheumatic mitral valve disease. Two-dimensional echocardiography is useful in deciding whether the tricuspid valve is structurally involved by the rheumatic process. This becomes clinically important when mitral valve replacement is being considered. Patients with organic tricuspid valve disease require tricuspid valve replacement if the TR is severe, whereas patients with secondary TR may require only tricuspid anuloplasty or may not need any repair if the mitral valve lesion is corrected.

# Calcium Phosphorus Metabolism in Dialysis Patients With and Without Mitral Anular Calcium

## Analysis of 30 Patients

PASQUALE F. NESTICO, MD, NICHOLAS L. DePACE, MD, MORRIS N. KOTLER, MD, LESLIE I. ROSE, MD, JOSEPH H. BREZIN, MD, CHARLES SWARTZ, MD, GARY S. MINTZ, MD, and ALLAN B. SCHWARTZ, MD

**To test the hypothesis that accelerated metastatic calcification in the mitral anulus results from abnormalities in calcium phosphorus and parathyroid hormone, 10 patients with end-stage renal disease having echocardiographically proven mitral anular calcium (MAC) (Group I) and 20 patients without MAC (Group II) were evaluated over 12 consecutive months. Serum levels of total calcium, phosphorus, intact and carboxyl-terminal parathyroid hormone, serum ionized calcium, and total calcium-phosphorus product were compared for both groups. In addition, other variables such as sex, supine systolic and diastolic blood pressure, age, duration of hemodialysis, type of renal disease, and diabetes also were compared in both groups.**

**Although both groups had elevated intact and carboxyl-terminal parathyroid hormone levels. Group I did not differ significantly from Group II. Total serum calcium levels were within normal limits in both groups and were not significantly different. However, the serum ionized calcium level was significantly higher in Group I with MAC versus Group II without MAC ($p < 0.05$). The serum phosphorus level and calcium phosphorus product were significantly higher in the group with MAC compared to the group without MAC ($p < 0.01$ and $p < 0.001$, respectively). No significant differences were found in the other clinical variables analyzed.**

**It is concluded that MAC in patients with chronic renal failure occurs in the setting of secondary hyperparathyroidism. However, it is found more often in patients with increased ionized calcium and serum phosphorus levels and significantly higher calcium-phosphorus product levels. In chronic renal failure, MAC does not appear to be the result of a degenerative process and high ventricular systolic pressure as has been previously described.**

Mitral anular calcification (MAC), a known complication of progressive renal insufficiency, was detected in 9 to 26% of patients with chronic renal disease.[1,2] Degenerative processes associated with high ventricular systolic pressure are widely assumed to predispose to calcification of the anulus.[3] Recently, rapidly progressive acquired mitral anular and valvular calcification with resultant calcific mitral stenosis was described in a patient with chronic renal failure and elevated calcium-phosphorus product.[4] Roberts and Waller[5] recently emphasized the important role of metabolic factors, namely, hypercalcemia, in cardiac valvular anular calcific deposits in secondary hyperparathyroidism of renal origin.[5] This report evaluates the role of total calcium, ionized calcium, and phosphorus levels and calcium-phosphorus product in patients with end-stage renal disease with MAC.

### Methods

Thirty patients with chronic renal failure receiving maintenance hemodialysis (3 times/week) were evaluated. No patient was on vitamin D or calcium supplementation. The 10 consecutive patients of Group I with MAC and 20 patients of Group II without MAC were identified by echocardiographic technique. Echocardiographic recordings of all patients were obtained using standard techniques with an Irex System II ultrasonograph using a 1.27 cm, 2.25 MHz medium internally focused transducer with a repetition rate of 1,000 pulses/second. Calcium in the mitral anulus or submitral anulus was recognized echocardiographically as a uniform dense band of

echoes posterior to the posterior mitral leaflet and anterior to the left ventricular wall[6] (Fig. 1). Frequently, the band of echoes moved similarly to the left ventricular wall.

Both serum immunoactive intact parathyroid hormone[7] and serum carboxyl-terminal parathyroid hormone[8] were measured by radioimmunoassay. Ionized calcium levels were obtained using the ion specific electrode method.[9] These measurements were performed at the final month (12th) of the study for each patient. Total serum calcium levels were measured by atomic absorption spectrophotometry[10] and serum phosphorus levels were measured by semiautomated determination of phospholipids.[11] In addition, the outpatient monthly medical records were reviewed. The average supine systolic and diastolic predialysis blood pressure over the preceding 12-month period was recorded. In every patient, the total serum calcium and phosphorus values were determined each month before dialysis. The average phosphorus, calcium, and calcium-phosphorus product were calculated for each patient over the 12 months preceding the echocardiographic study. Length of time on hemodialysis, age, and presence of diabetes were recorded and the data subjected to statistical analysis. The Yates corrected chi-square test was used for comparison of differences in proportions, and differences in means were analyzed by Student's unpaired *t* test.[12]

## Results

**Clinical data:** The data are summarized in Tables I and II. The 10 patients with MAC (Group I, Table I) and 20 patients without MAC (Group II, Table II) did not differ in mean age (59.3 ± 9.5 and 53.5 ± 15.0 years, respectively), sex (70% male versus 50% female), length of time on hemodialysis (4.7 ± 2.8 and 4.5 ± 3.2 years), level of systolic blood pressure (147 ± 19 and 139 ± 20 mm Hg), level of diastolic pressure (81 ± 8.7 and 79 ± 8 mm Hg), or presence of diabetes (4 of 10 in Group I and 6 of 20 in Group II). Hypertensive nephrosclerosis accounted for 50% of patients in both groups followed by diabetic nephrosclerosis as the cause of chronic renal failure. None of the patients had a history or echocardiographic findings consistent with Marfan's syndrome, mitral and aortic valvular disease, or hypertrophic cardiomyopathy. Precordial systolic murmurs were heard in 13 patients (8 with and 5 without MAC).

**Laboratory data:** The data are summarized in Tables I and II. Mean intact parathyroid hormone (normal 163 to 347 pgEq/dl) was elevated in both groups but did not differ significantly between Group I (542 ± 438 pgEq/dl) and Group II (433 ± 306 pgEq/dl). Similarly, mean carboxyl-terminal parathyroid hormone levels (normal up to 375 pgEq/dl) were elevated in the MAC group (13,116 ± 19,730 pgEq/dl) versus the control group (6,233 ± 8,443 pgEq/dl), but this difference was not significant. The ionized calcium level was higher in Group I compared with Group II (3.77 ± 0.48 versus 3.36 ± 0.52 mg/dl, $p < 0.05$). Normal values for ionized calcium were 3.70 to 4.50 mg/dl.

The average serum phosphorus value (normal 2.5 to 4.5 mg/dl) measured monthly over a 12-month period was elevated at 5.4 ± 0.8 mg/dl in Group I and 4.1 ± 1.1 mg/dl in Group II ($p < 0.01$). The average total serum calcium (normal 8.5 to 10.5 mg/dl) over the same period was 9.1 ± 0.7 mg/dl in Group I and 8.7 ± 0.7 mg/dl in Group II (difference not significant [NS]). The average calcium-phosphorus product over 12 months was elevated at 50 ± 9 in Group I and normal at 35 ± 11 in Group II ($p < 0.001$). Analysis of laboratory data at the 12th month (when serum ionized calcium and parathyroid hormone were drawn) revealed no significant difference in total calcium (8.7 ± 0.8 in Group I and 8.4 ± 1.0 in Group II), but significant differences in phosphorus (5.7 ± 1.6 in Group I and 4.3 ± 1.7 in Group II, $p < 0.01$) and calcium-phosphorus product (49.6 ± 15.4 in Group I and 36.5 ± 15.0 in Group II, $p < 0.001$).

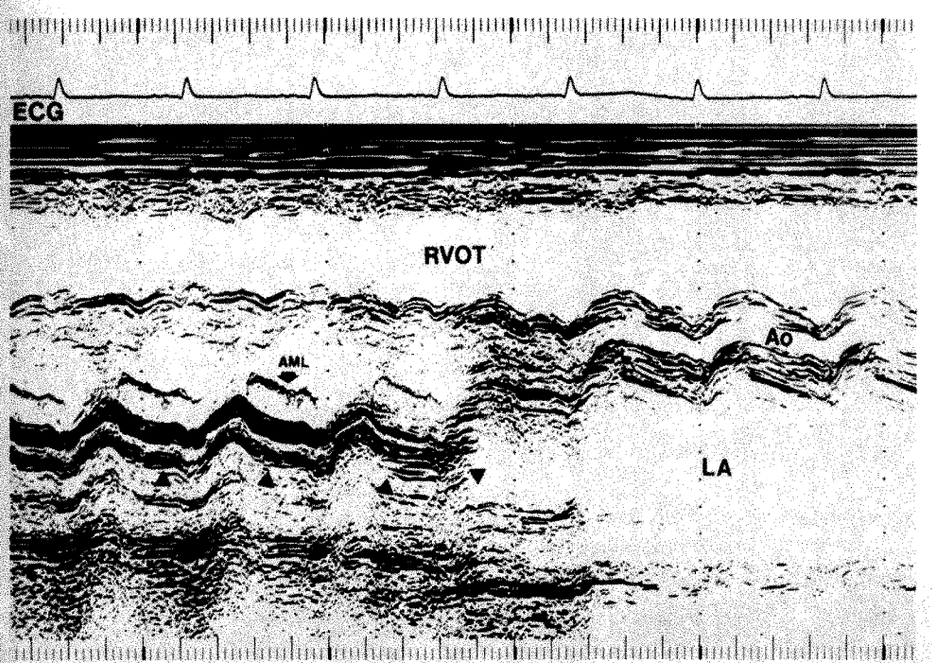

**FIGURE 1.** M-mode echocardiogram in a patient (Patient 5, Table I) with mitral anular calcification. Dense linear band of echoes (**lower triangular arrows**) starting at the atrioventricular groove and extending into the body of the left ventricle is seen. Marked mitral anular calcification is detected echocardiographically in a plane between the posterior mitral leaflet and the left ventricular posterior wall. AML = anterior mitral leaflet; Ao = aorta; ECG = electrocardiogram; LA = left atrium; RVOT = right ventricular outflow tract.

## Discussion

The pathogenesis of MAC in patients with chronic renal failure is probably multifactorial. Systemic hypertension is often found in this subset of patients. Disturbed calcium-phosphorus metabolism was proposed by Jain et al[13] as another possible predisposing factor. However, patients with MAC in that study underwent hemodialysis for a longer time than did the control group.[13] Our patients showed no differences in length of time on hemodialysis, blood pressure levels, age, and associated disorders such as aortic or mitral valvular disease. We found no significant difference in intact and carboxyl-terminal parathyroid hormone levels between the group with MAC and the control group, although both groups did have elevated intact and carboxyl-terminal parathyroid hormone levels. Values for ionized calcium were statistically higher in the group with MAC than in the control group. Values for mean serum phosphorus level and mean calcium-phosphorus product over a 1 year period and for the final month were statistically higher in the group with MAC than in those without MAC.

Because only a single parathyroid hormone level was obtained, it would be inappropriate to assume that parathyroid hormone did not play an important role in the MAC group, as it is known that parathyroid hormone levels change with dialysis over time.[14] Similarly, although ionized calcium was statistically significantly higher in the MAC group, differences in protein con-

centration or acid-base status (which were not determined) may have played a role. However, the data suggest that in patients with chronic renal failure accelerated MAC may be a complication of a disordered calcium-phosphorus balance. The significant feature of this imbalance is the elevated serum calcium-phosphorus product dependent on an elevated serum phosphorus in the presence of a background of secondary hyperparathyroidism. These coincident circumstances may result in the precipitation of calcium in the vulnerable tissue of the mitral anulus.

A prospective study in a group of patients with end-stage renal disease early in their dialysis program and before MAC has occurred would be helpful in clarifying the relations between parathormone, phosphorus, and calcium in the pathogenesis of MAC. However, the observation of an association between high serum phosphorus levels and MAC as well as other detrimental effects of hyperphosphatemia would prohibit performance of such a study, as therapy would have to be initiated for the elevated phosphorus level.

Biochemical factors are associated with accelerated deposition of calcium not only in the cardiac anuli but also in the valvular cusps, media, and intima of coronary arteries and individual myocardial fibers.[5] Therefore, acquired valvular heart disease[4] and accelerated coronary atherosclerosis are potential problems in patients with chronic renal failure. MAC is no longer considered a benign entity. Complications include mitral regurgitation, arterial emboli, atrioventricular block, and infective endocarditis.[3] In chronic hemodialysis patients, infective endocarditis has been reported in those with MAC.[15] Nonvisceral calcification can be prevented by reducing serum phosphorus concentration and, accordingly, the calcium-phosphorus product using dialysis and phosphate binding gels.[16] Therefore, aggressive phosphorus control may decrease the incidence of MAC in patients with end-stage renal disease. Serial echocardiograms may be useful in following up these patients to identify early MAC.

# Quantitative Morphologic Findings of the Myocardium in Idiopathic Dilated Cardiomyopathy

FRANZ SCHWARZ, MD, GERHARD MALL, MD, HORST ZEBE, MD, JOHANNES BLICKLE, MD, HARALD DERKS, JOACHIM MANTHEY, MD, and WOLFGANG KÜBLER, MD

**This study assesses the relation between quantitative morphologic findings and left ventricular contractile function in patients with idiopathic dilated cardiomyopathy. Left ventricular endomyocardial catheter biopsy specimens were obtained from 73 patients during diagnostic heart catheterization. All patients had normal coronary arteriograms but abnormal electrocardiograms. Twenty-six patients had normal left ventricular function (ejection fraction ≥55%), whereas 47 patients had contractile dysfunction (ejection fraction ≤54%). Myocardial fiber diameter, volume fraction of interstitial fibrosis, and intracellular volume fraction of myofibrils were determined by light microscopic morphometry. Results of light microscopic morphometry were confirmed by electron microscopic morphometry in 12 patients. The coefficient of variation (analysis of several biopsies from the same patient) was 6% for determination of fiber diameter, 43% for interstitial fibrosis, and 3% for volume fraction of myofibrils. Fiber diameter ($r = -0.32$, $p < 0.01$) and fibrosis ($r = -0.47$, $p < 0.001$) showed a negative correlation, the volume fraction of myofibrils ($r = 0.55$, $p < 0.001$) and calculated myofibrillar mass per 100 g of myocardium ($r = 0.64$, $p < 0.001$) a positive correlation with the ejection fraction. Thus, (1) sampling error is low for determination of fiber diameter and myofibrils but high for evaluation of fibrosis, and (2) a reduction in the volume fraction of myofibrils and an increase in fibrosis are morphologic correlates of left ventricular dysfunction in patients with idiopathic dilated cardiomyopathy.**

Right and left ventricular biopsy techniques have extended our knowledge of the relation between morphologic findings and clinical aspects in various types of heart disease.[1-7] Several features of the myocardium in patients with idiopathic dilated cardiomyopathy have been described.[1-3] However, quantitative morphometric data have not been reported. Furthermore, the sampling error of data obtained from endomyocardial biopsy specimens is not well defined. This study aims to (1) determine the sampling error of morphometric data obtained from left ventricular endomyocardial biopsy in patients with idiopathic dilated cardiomyopathy, and (2) correlate the quantitative morphometric data with the contractile function of the left ventricle.

From the Abteilung Innere Medizin III der Medizinischen Universitätsklinik und Pathologisches Institut der Universität, Heidelberg, West Germany. This study was supported by the Deutsch Forschungsgemeinschaft within the SFB 90, Kardiovaskuläres System, Universität Heidelberg, Heidelberg, West Germany. Manuscript received June 7, 1982; revised manuscript received August 31, 1982, accepted September 2, 1982.

## Methods

**Patients:** The study group consisted of 73 patients (61 men and 12 women) aged 23 to 55 years with idiopathic myocardial disease studied invasively between July 1978 and July 1980. At catheterization, each patient had 2 or more of the following clinical features: (1) symptoms of heart failure; (2) episodes of chest discomfort; (3) roentgenographic evidence of cardiomegaly (cardiothoracic ratio >0.5); (4) an electrocardiographic abnormality in the form of an intraventricular conduction defect (with a wide QRS complex >0.11 second), atrial arrhythmias, left ventricular hypertrophy (S wave in $V_1$ or $V_2$ plus R wave in $V_5$ or $V_6$ >35 mm), or S-T segment and T wave abnormalities. Table I lists the proportion of each clinical feature in the study population. Patients with coronary artery disease (diameter reduction of major coronary vessel of ≥25%), systemic hypertension, valvular heart disease, cor pulmonale, or systemic disease involving the heart muscle were excluded from the study.

**Catheterization:** All patients underwent left ventricular catheterization including selective coronary arteriography and left ventricular cineangiography. At catheterization, 52% of patients were taking digitalis or diuretics, or both. Single plane cineangiography was performed in the 30° right anterior

**TABLE 1 Clinical Features of the Study Population**

| Electrocardiographic abnormalities | |
| Intraventricular conduction defect | 29 |
| Atrial arrhythmias | 15 |
| Left ventricular hypertrophy | 23 |
| S-T segment and T wave abnormalities | 38 |

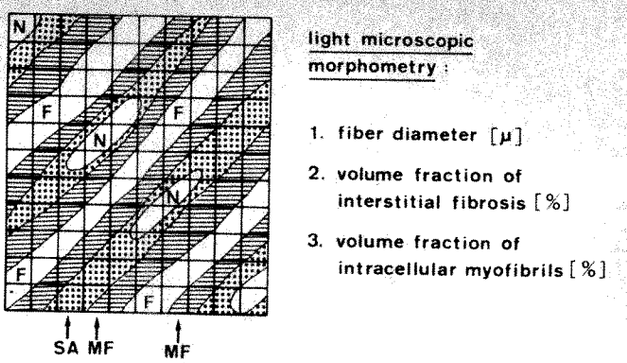

**FIGURE 1.** Schematic drawing illustrating the technique of light microscopic morphometry. The fiber diameter is determined from cross and oblique sections. The volume fraction of interstitial fibrosis and of intracellular myofibrils is determined from longitudinal sections by point counting technique, that is, intersections of the grid falling on fibrosis (F) or myofibrils (MF) are counted and expressed as a percentage of total points or points falling on myocardial cells. SA = sarcoplasm; N = nucleus.

oblique projection (50 to 60 ml of Urografin®-76, 35 mm cinefilm, 50 frames/s, Philips dual field 9-5 inch image intensifier system). Selective coronary arteriography was performed using the Judkins technique. Left ventricular volumes and ejection fraction were determined by the area length method.[8]

**Diagnosis:** Forty-seven patients had depressed left ventricular function as evaluated by a left ventricular ejection fraction of ≤54%. These patients were classified as having idiopathic dilated cardiomyopathy. Among these patients the following etiologic "risk factors" could be encountered: peripartal cardiomyopathy in 1 patient and increased alcohol intake (>2,000 ml of beer or an equivalent dose of wine per day for more than 10 years in 12 patients).[9] The remaining 26 patients had a normal ejection fraction (≥55%). Clinical features in most patients were episodes of chest pain and electrocardiographic abnormalities, and the patients were classified as having chronic myocarditis or latent cardiomyopathy.[4]

**Endomyocardial biopsy:** Endomyocardial biopsy specimens were taken with the King's College Bioptome using the retrograde transarterial route and a polyvinyl chloride (PVC) sheath.[10] At least 2 biopsy samples were obtained from the left ventricular anterior free wall. Biopsy from the left ventricular apex was carefully avoided. There were no serious complications in the 73 patients during and after biopsy. Immediately after biopsy, tissues were fixed in a mixture of 1.5% glutaraldehyde and 1.5% formaldehyde in 0.2 *M* phosphate buffer. The biopsy specimens were embedded in Araldit®, and thin sections (0.5 μm) were prepared and stained with alkaline toluidine blue and 3% paraphenylendiamine (combined staining) for light microscopic morphometry (magnification 160× for determination of fibrous tissue and 1,000× for determination of myofibrils). The area of tissue analyzed ranged from 1.2 to 6.5 $mm^2$ (mean 2.8 ± 1.7). Fiber diameter of myocardial cells was measured from 80 to 300 cross and oblique sections of myocardial cells using the light microscope (magnification 400×). When oblique sections were counted, the short diameter of the section profile was determined. The volume fraction of fibrous interstitial tissue[11] was measured by light microscopic morphometry. The volume fraction of fibrous interstitial tissue and of myofibrils was measured in randomly selected sections without respect for the direction of sectioning. Random test areas were evaluated to determine volume fractions, and we did not use different planes of the same biopsy. If cross-sections were unavailable for measurement of fiber diameter, we changed the direction of sectioning. The point counting method was performed with a Zeiss eyepiece containing a test grid with 36 intersections (test points). From each biopsy 5 to 20 areas were counted (each containing 36 points). Volume fraction of fibrous tissue is the number of points falling on fibrosis divided by the points falling on total tissue (Fig. 1). We carefully avoided counting the endocardium as fibrous tissue. The collagen-containing tissue component was counted without edema, blood vessels, and interstitial tissue cells. At the edge of the biopsy specimens a rim of about 100 μm was excluded from analysis to avoid areas with marked hypercontraction. Myofibrils were counted in 12 areas. Intracellular volume fraction of myofibrils is the number of points falling on myofibrils divided by points falling on total myocardial cells (Fig. 1). Analysis of biopsies was performed without knowledge of clinical data.

**Comparison of light and electron microscopic morphometry:** Because light microscopic morphometry was used to measure the volume fraction of myofibrils in the present study and all previous studies used electron micrographs as the source of data, it was necessary to compare light and electron microscopic morphometry. To get formal validation of the light microscopic method, we chose randomly 12 tissues out of the series studied (12 patients). Ultra- and semithin sections were cut from the same tissue block. Electron microscopic point counting was performed on 40 random test areas using a total number of about 3,200 test points (magnification 10,000). Total test area mounted to 12,000 $\mu m^2$. A monitor with a television camera connected to a Zeiss EM 10 was used for the counting procedure. Details of this method were described elsewhere.[12] Light microscopic morphometry was performed with the method just described herein (test area 15,000 $\mu m^2$).

**Sampling variability of endomyocardial biopsies:** To determine what changes in the measurement of different biopsy samples from the same heart should be considered significant, we estimated reproducibility in terms of sampling variability of endomyocardial biopsies (that is, how much each measurement varied when made from separate biopsy specimens in the same patient). The sampling variability was determined in 26 patients in whom 2 (n = 14) or 3 (n = 12) separate biopsy specimens were obtained. Variability was determined by the coefficient of variation, defined as the standard deviation of all repeated measurements in a given case divided by the mean of those measurements. Two standard deviations on either side of the mean were calculated from estimates of reproducibility and the 95% confidence interval was determined for each variable; the actual value by which each measurement can vary was then calculated. All biopsy samples were encoded and analyzed without knowing which biopsies were from the same patient.

**Statistical analysis:** The linear regression analysis and Student's $t$ test for paired and unpaired data were used.[13] Significance was accepted at the 5% probability level. Data are mean ± standard deviation. A combined index of myofibrils and fibrosis was calculated: myofibrillar mass/100 g of myocardium (that is, [100 minus volume fraction of fibrosis in %] multiplied by volume fraction of myofibrils in % divided by 100).

## Results

**Comparison of light and electron microscopic morphometry:** Figure 2 illustrates sections of myocardium of biopsy specimens obtained from a patient with idiopathic dilated cardiomyopathy using light (upper panel) and electron microscopy (lower panel). Myofibrils can easily be identified by light microscopy. Data obtained by light and electron microscopic morphometry were correlated using linear regression analysis, and the following equation was obtained: myofibrils (determined by light microscopy) = 1.01 myofibrils (determined by electron microscopy) + 2.26, r = 0.96. To test whether both methods are equivalent when normal and abnormal muscle cells are analyzed, we divided the data into 2 subgroups with a volume fraction of myofibrils ≥50% (normal myocardial cells) and ≤50% (abnormal myocardial cells). Table II lists the individual and mean data obtained by both methods. Light microscopic morphometry revealed similar values of volume fraction of myofibrils as compared with electron microscopic morphometry, although there was a slight overestimation of the myofibrillar volume fraction when using light microscopic morphometry. Nevertheless, both methods produced similar results on normal as well as abnormal myocardial tissue.

**Sampling variability of morphologic findings:** Data analyzing sampling variability of morphometric analysis are presented in Table III. The greatest scatter

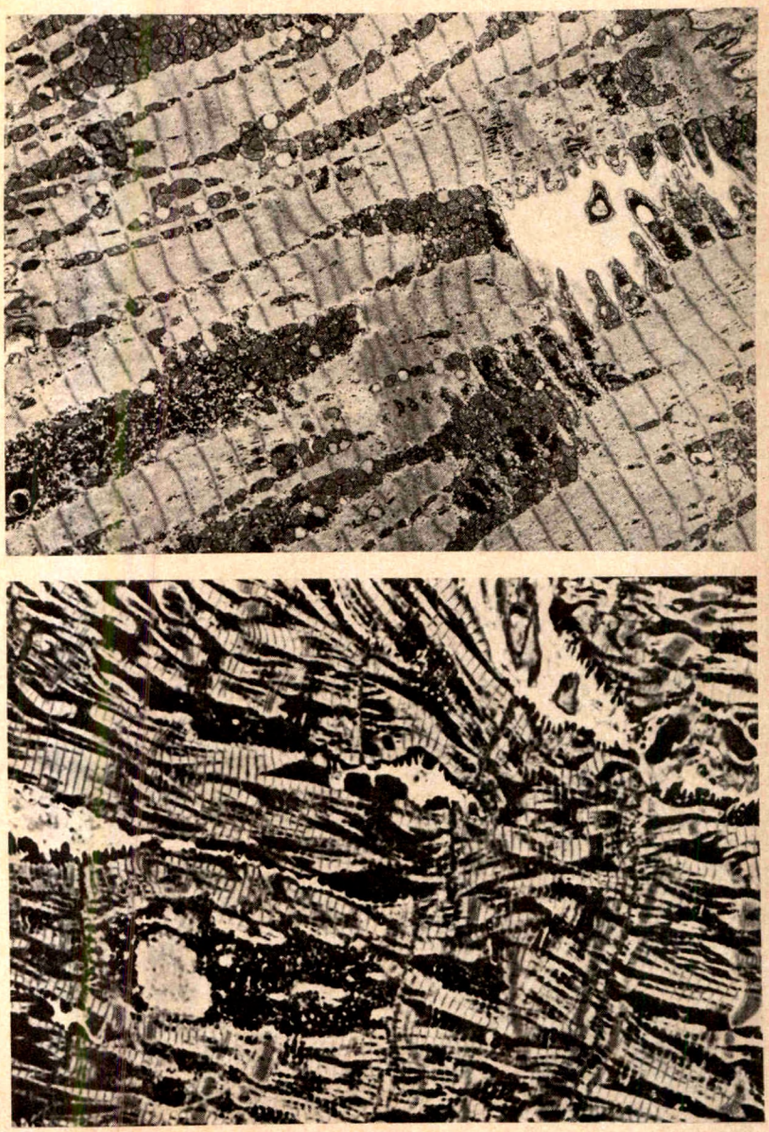

**FIGURE 2.** Endomyocardial biopsy obtained from a patient with idiopathic dilated cardiomyopathy. **Upper panel,** electron micrograph, magnification ×5,000. **Lower panel,** light micrograph, magnification ×1,000 for comparison. Both panels reduced 36%. Myofibrils are seen with the light microscope.

of data is found for the determination of interstitial fibrosis, whereas evaluation of fiber diameter and volume fraction of myofibrils reveals less variability.

**Reduced volume fraction of myofibrils in the failing heart:** Figure 3 represents inverse correlations between left ventricular ejection fraction and fiber diameter (upper panel) and the volume fraction of fibrosis (lower panel). Both correlations reveal considerable scatter of data points. Figure 4 displays the correlations between left ventricular ejection fraction and volume fraction of myofibrils (upper panel) and myofibrillar mass (lower panel). The latter correlation revealed the highest correlation coefficient ($r = 0.64$).

## Discussion

**Light versus electron microscopic morphometry:** In the present study morphologic changes of the left ventricular myocardium were quantitated by light microscopic morphometry. With this technique we assessed (1) hypertrophy of myocardial fibers, (2) interstitial fibrosis, and (3) intracellular volume fraction of myofibrils. The volume fraction of myofibrils was not previously measured by light microscopy. This technique was equivalent to electron microscopic morphometry provided 3 prerequisites are fulfilled: (1) use of thin sections (0.5 $\mu$m), (2) combined staining with toluidine blue and paraphenylendiamine, and (3) use of phase contrast microscopy with oil immersion. The staining technique was found superior to standard toluidine blue staining, because paraphenylendiamine enhances the contrast between myofibrillar and nonmyofibrillar components of myocardial cells. As shown in Figure 2 myofibrils can easily be identified with this technique. Furthermore, as shown in Table II, light and electron microscopic morphometry revealed similar results on normal as well as abnormal myocardium. Light microscopy was preferred for quantification of myofibrils, because large test areas could be analyzed (about 30,000 $\mu m^2$ per biopsy).

**Sampling error in endomyocardial biopsy technique:** In previous studies using various grading systems to evaluate intracellular degenerative changes in left ventricular biopsies taken from patients with idiopathic dilated cardiomyopathy, the sampling error was not defined and hence not taken into account in the interpretation of results.[4–6] Table III illustrates that a considerable scatter of data was found when quantitative data obtained from 2 different myocardial biopsy specimens taken from the same heart were compared. The sampling error was greatest for quantification of interstitial fibrosis. Determination of fiber diameter and volume fraction of myofibrils revealed a significantly smaller sampling error. Thus, the degree of fibrosis can only be approximated in idiopathic dilated cardiomyopathy, but cannot be determined with accuracy when endomyocardial biopsy technique is used.

**Reduced volume fraction of myofibrils in the failing heart:** In the failing heart with idiopathic dilated cardiomyopathy, a slight increase in fiber diameter as well as an increase in fibrosis and a reduction in myofibrils and myofibrillar mass was observed when the ejection fraction declined. These findings document that quantitative data of morphologic evaluation correlate with left ventricular dysfunction. The inverse relation between ejection fraction and fibrosis may suggest that fibrosis determines contractile dysfunction in idiopathic dilated cardiomyopathy. However, because the degree of fibrosis can only be approximated by the technique used, this relation remains uncertain. In contrast, determination of myofibrils shows high accuracy and the relation incorporating volume fraction of myofibrils was close and therefore shows that a reduction in myofibrils reflects myocardial dysfunction. What causes the decrease in the volume fraction of

**TABLE III Sampling Variability of Endomyocardial Biopsies (Reproducibility of Morphometric Evaluation)**

| | Patients (n) | Measured Data H (Mean ± SD) | Coefficient of Variation (%) | 95% Confidence Interval (±2 SD) of Each Measurement |
|---|---|---|---|---|
| Fiber diameter ($\mu$m) | 26 | 24.5 ± 4.0 | 6 | ±2.9 |
| Volume fraction of interstitial fibrosis (%) | 25 | 10.7 ± 9.7 | 43 | ±9.2 |
| Volume fraction of intracellular myofibrils (%) | 26 | 55.9 ± 4.7 | 3 | ±3.4 |

SD = standard deviation.

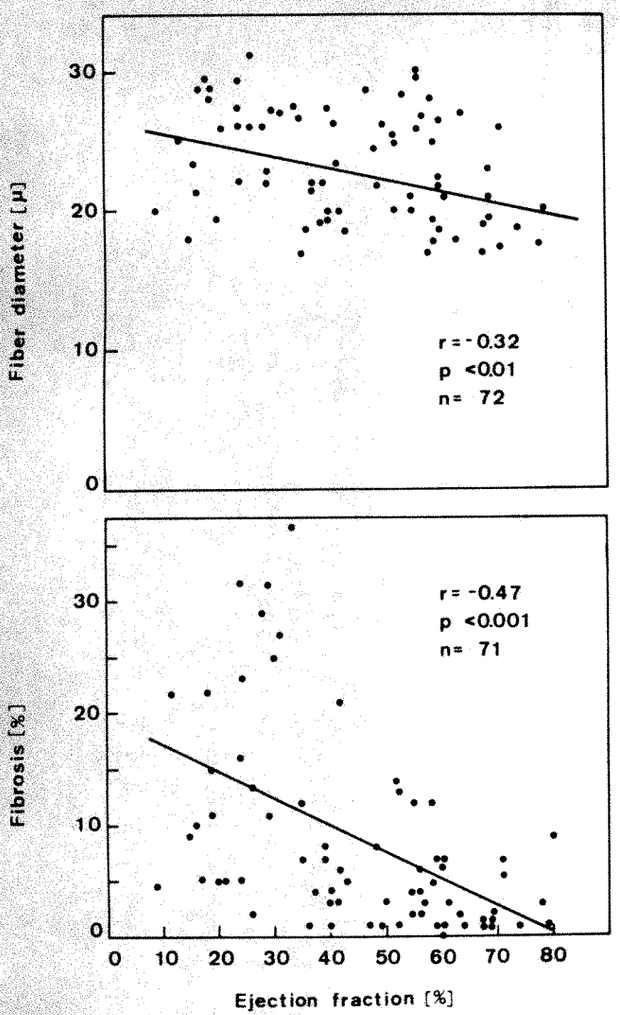

**FIGURE 3.** Inverse correlation between left ventricular ejection fraction and fiber diameter of myocardial cells (**upper panel**) and interstitial fibrosis (**lower panel**).

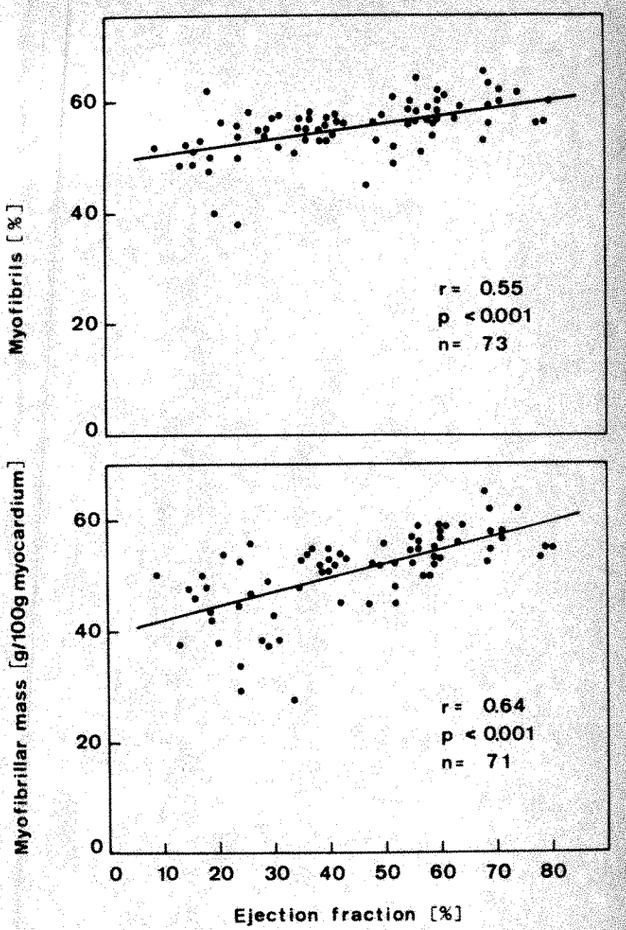

**FIGURE 4.** Correlation between left ventricular ejection fraction and intracellular volume fraction of myofibrils (**upper panel**) and myofibrillar mass (**lower panel**).

myofibrils? Is it a reflection of intracellular edema, proliferation of nonmyofibrillar components (mitochondria), or an absolute decrease in the number of myofibrils? Obviously, it is impossible to answer conclusively on the basis of morphometric data. Because we studied the biopsies by electron microscopy also (qualitatively), we believed that the decrease in the volume fraction of myofibrils is caused by a loss in myofibrils (myofibrillar lysis) or an impaired resynthesis of contractile proteins, or both. We interprete the reduction in volume fraction of myofibrils as a quantitative measure of the degeneration of myocardial fibers. Myofibrillar lysis was previously described by our group in patients with coronary artery disease.[14] An intracellular reduction in volume fraction of myofibrils (with or without an associated increase in interstitial fibrosis) is not pathognomonic for patients with idiopathic dilated cardiomyopathy, because similar findings were observed in patients with chronic aortic valve disease and in those with coronary artery disease.[7,14] Obviously, a uniform cellular response to various cardiac stresses occurs.

**Clinical implications:** From the data it can be concluded that the reduction in myofibrils is a consistent finding in myocardium in patients with idiopathic dilated cardiomyopathy. The degree of fibrosis cannot accurately be assessed by endomyocardial biopsy technique, although fibrosis seems to be augmented in cases with severe impairment of contractile function. Whether changes of myocardial structure are the cause or the effect of contractile dysfunction remains to be clarified.

# Significance of Ventricular Tachycardia in Idiopathic Dilated Cardiomyopathy: Observations in 35 Patients

SHOEI K. HUANG, MD, JOSEPH V. MESSER, MD, and PABLO DENES, MD

**To evaluate the significance of ventricular tachycardia (VT) in idiopathic dilated cardiomyopathy (IDC), 35 consecutive patients seen between 1976 and 1980 were studied. The criteria for diagnosis of IDC were based on clinical, laboratory, and cardiac catheterization findings. All patients had right and left heart catheterization, left ventriculography, and coronary cineangiography. Long-term ambulatory electrocardiograms (Holter) were obtained in all patients at the time of diagnosis. There were 24 male and 11 female patients aged 22 to 72 years (mean ± standard deviation [SD] 51 ± 12). Frequent ventricular premature beats (VPB) (30/h) were observed in 29 patients (83%): complex VPB (Lown grades 3, 4, and 5) in 93% and simple VPB in 7%. Twenty-one patients (60%) had nonsustained VT consisting of 3 to 46 beats (8 ± 5) with rates from 75 to 210/min. No difference between patients with and those without VT was observed in regard to the presenting symptoms, functional classification, electrocardiographic findings, heart size on chest X-ray, and the hemodynamic measurements including cardiac index, left ventricular end-diastolic pressure, and ejection fraction. Patients with VT were older ($p < 0.05$). Follow-up observation from 4 to 74 months (34 ± 17) showed that 2 patients died suddenly (1 with and 1 without previous VT), a third patient died from intractable congestive heart failure, and the fourth from sepsis. It is concluded that (1) the incidence of ventricular arrhythmias in IDC is high, (2) VT is frequent and tends to occur in the nonsustained form, and (3) there is no correlation between VT and the clinical and hemodynamic findings. VT does not appear to predict prognosis during a relatively short follow-up period in patients with IDC.**

Cardiomyopathy is a disease of the heart muscle caused by a spectrum of known (secondary) or unknown (primary or idiopathic) factors.[1] A variety of schemes for classifying the cardiomyopathy have been proposed. Goodwin's classification into congestive, hypertrophic, and restrictive cardiomyopathy has been widely accepted.[2] More recently, the term *dilated* has been substituted for *congestive* as the preferred terminology, that is, idiopathic dilated cardiomyopathy (IDC).[1,3,4] Several studies have correlated clinical features and hemodynamic findings with prognosis of IDC.[4–14] The design of these studies had several limitations because (1) some studies included patients with secondary cardiomyopathy,[4,6,10–14] (2) in others, the patients did not undergo cardiac catheterization and coronary angiography to confirm the diagnosis,[5,6,10] and (3) the prevalence of cardiac arrhythmias was evaluated only with standard electrocardiographic tracings taken at random intervals.[4,5,9,10,12,13]

Long-term dynamic electrocardiographic (Holter) monitoring has been useful in detecting and evaluating the significance of cardiac arrhythmias in different diseases.[15–22] With this diagnostic tool, many studies have focused on the prognostic significance of VPB and VT in patients with coronary artery disease and hypertrophic cardiomyopathy.[19–22] However, little is known about the prevalence of ventricular arrhythmias evaluated by long-term (≥24 hours) Holter monitoring and their clinical significance in patients with IDC. In the present study, we assess 35 consecutive patients with IDC. All patients had cardiac catheterization, angiography, and 24-hour Holter monitoring. We compared various clinical features and hemodynamic findings in patients with and those without VT and evaluated the prognostic significance of VT in patients with IDC.

## Methods

**Patient selection:** Of 118 consecutive patients with an initial diagnosis of cardiomyopathy screened between January 1976 and December 1980, 47 fulfilled the selection criteria for IDC. Of them, 35 had long-term ambulatory electrocardiograms taken during admission when the diagnosis was made. These 35 patients, 24 male and 11 female patients aged 22 to 72 years (51 ± 11), are our study population.

Diagnostic criteria of IDC included (1) the presence of 2 or more of the following clinical features[4]: (a) symptoms or signs of left or right heart failure, or both, (b) chest x-ray evidence of cardiomegaly, (c) abnormal electrocardiogram, and (d) history of embolization; (2) the presence of all of the following hemodynamic features[4]: (a) dilated left ventricular chamber with global or >3 segment hypokinesia on a single plane (right anterior oblique) left ventriculogram and an abnormal ejection fraction (<55%), (b) absence of significant coronary artery disease, that is, occlusion of >50% in any 1 of the major coronary arteries or their branches; (3) exclusion of all patients with specific heart muscle disease (infective or metabolic), general systemic disease (connective tissue disorders or infiltrative disease), heredofamilial disorders, and sensitivity or toxic reactions.[1]

**Clinical evaluation:** History and physical examinations in all patients were performed by 2 physicians. Interpretation of the electrocardiogram, chest X-ray, angiogram, and the like was performed by at least 2 observers. Functional status was classified according to the criteria of the New York State Heart Association.[23] All patients had standard posteroanterior and lateral chest X-ray films during initial admission. A cardiothoracic ratio of >0.50 was considered evidence of cardiomegaly on chest X-ray. During admission, 12-lead electrocardiograms were taken with simultaneous 3-channel recordings. The diagnosis of left ventricular hypertrophy was made according to the criteria of Romhilt and Estes.[24] Follow-up information was obtained in all patients by reviewing the patient's clinical records, contacting the primary physician, and contacting the patient or relatives by telephone.

**Cardiac catheterization and angiography:** All 35 patients underwent left and right cardiac catheterization, left ventriculography, and coronary cinearteriography. Resting intracardiac pressures were recorded. The cardiac index was determined by the Fick method. Twenty-four patients had single plane (45° right anterior oblique projection) left ventriculography; the other 11 had biplane projections. Left ventricular ejection fraction was obtained by planimetric volume calculation from either single or biplane left ventriculograms.[25,26] Coronary cineangiograms were taken in multiple projections.

**Dynamic electrocardiographic monitoring (Holter):** All patients underwent monitoring for a minimum of 24-hours during admission. All records were analyzed by a trained technician and reviewed by a cardiologist. For classifying ventricular arrhythmias, a modification of Lown's grading system was used[17]: grade 1, ≤30 uniform VPB in any hour of monitoring; grade 2, >30 uniform VPB in any hour of monitoring; grade 3, multiform VPB; grade 4, couplets; grade 5, R on T, defined as having a prematurity index RR′/QT <1. We defined nonsustained VT as having ≥3 consecutive VPB that lasted <1 minute and were self-terminating without specific therapeutic intervention. Each patient's Holter monitor finding with VT was analyzed to determine the number of episodes of VT per 24 hours, the number of VPB per episode, the rate of VT, and the prematurity index of the initiating beat of each episode. Supraventricular arrhythmias, which were analyzed, included the presence of >30 atrial premature beats in any hour of monitoring and the presence of supraventricular tachycardia defined as having ≥3 consecutive atrial premature beats. The corresponding entries in the patient's diary were received in only 12 patients.

**Statistical analysis:** Patients were divided into 2 groups: the VT group consisting of patients who had VT during Holter monitoring and the non-VT group consisting of patients who did not have VT. The VT and non-VT groups were compared with regard to age, sex, presenting symptoms, functional class, cardiomegaly on chest X-ray, electrocardiographic findings, and hemodynamic measurements by either the Student's *t* test or the chi-square test.

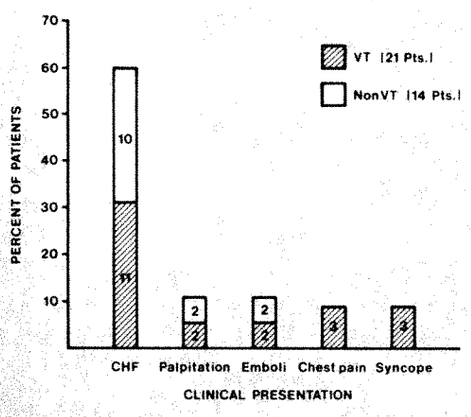

**FIGURE 1.** Clinical presentation of 35 patients with IDC. The numbers inside each bar represent the number of patients with each presenting symptom in the VT (**hatched bars**) and the non-VT (**open bars**) group. Comparison of clinical presentation in the 2 groups was not significantly different.

## Results

**Clinical and electrocardiographic findings:** Twenty-one patients (60%) had nonsustained VT and the remaining 14 patients (40%) had no VT during the initial Holter monitoring. The mean age of the VT group was 55 ± 10 years, which was significantly greater than that of the non-VT group (47 ± 12 years) ($p < 0.05$). There were 16 male and 5 female patients in the VT group and 8 male and 6 female patients in the non-VT group (chi-square = 0.67; p = not significant [NS]).

The presenting symptom was identified for each patient. Congestive heart failure was the most common clinical manifestation, occurring in 21 (60%) of the 35 patients. Three patients presented with cerebrovascular accidents due to systemic emboli and 1 with pulmonary emboli (11%). Three patients were hospitalized for chest pain (9%), 4 for palpitation (11%), and 3 for syncope

**TABLE I New York Heart Association Functional Class at the Time of Diagnosis**

| Functional Class | VT Group | | Non-VT Group | |
|---|---|---|---|---|
| | n | % | n | % |
| I | 2 | 9 | 0 | 0 |
| II | 6 | 29 | 2 | 14 |
| III | 9 | 43 | 10 | 72 |
| IV | 4 | 19 | 2 | 14 |

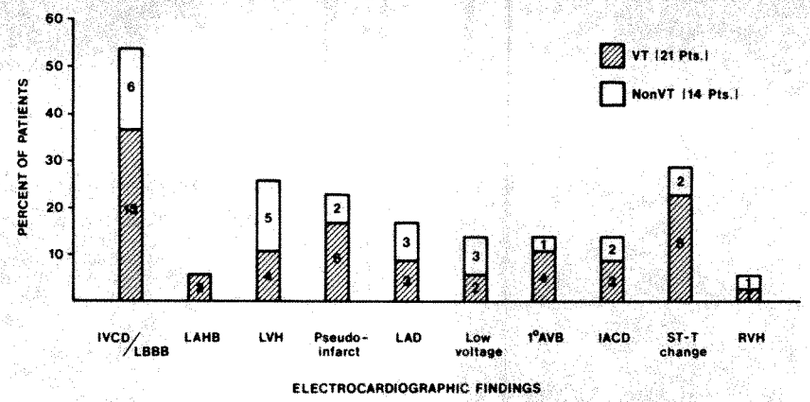

**FIGURE 2.** Electrocardiographic findings in patients with IDC. The numbers inside each bar represent the number of patients with different electrocardiographic findings in the VT and the non-VT group. Left bundle branch block (LBBB) or intraventricular conduction delay (IVCD) was the most common finding (54%). There were no significant differences in electrocardiographic findings in 2 groups. 1° AVB = first degree AV block; IACD = intraarterial conduction defect; LAD = left axis deviation; LAHB = left anterior hemiblock; LVH = left ventricular hypertrophy; RVH = right ventricular hypertrophy.

(9%) (Fig. 1). No significant differences in clinical presentation existed between the VT and the non-VT groups (chi-square = 5.44; p = NS). Most patients were New York Heart Association functional class III when the diagnosis of IDC was made. There were no significant differences between the VT and the non-VT group in functional classification (chi-square = 3.46; p = NS) (Table I).

Electrocardiographic abnormalities, present in all 35 patients, included left bundle branch block or intraventricular conduction delay in 19 patients (54%), nonspecific ST-T wave changes in 10 (29%), left ventricular hypertrophy in 9 (26%), and pseudoinfarct Q waves in 9 (23%) (Fig. 2). Other electrocardiographic findings included left axis deviation (17%), low QRS voltage (14%), right ventricular hypertrophy (6%), intraatrial conduction defect (14%), and first degree atrioventricular (AV) block (14%) (Fig. 2). There were no significant differences in electrocardiographic findings between the 2 groups. Cardiomegaly on chest X-ray was noted in 18 (86%) VT patients and 13 (93%) non-VT patients (chi-square = 0.01; p = NS).

**Hemodynamic findings:** The mean cardiac index, which did not differ significantly between the VT and the non-VT groups, was 2.7 ± 0.7 (range 1.6 to 4.0) versus 2.6 ± 0.6 liters/min/m (range 1.7 to 4.0). Similarly, no significant differences between the 2 groups were found regarding left ventricular end-diastolic pressure (17 ± 8 versus 19 ± 11 mm Hg) and left ventricular ejection fraction (33 ± 11 versus 32 ± 7%).

**Dynamic electrocardiographic (Holter) findings:** Table II outlines the Holter monitor findings in 35 patients. Basic sinus rhythm was found in 80% of patients and atrial fibrillation in 20%. Significant atrial premature beats (>30 beats/h) occurred in 15 patients (54%). In 7 patients (25%), 1 to 8 episodes of supraventricular tachycardia developed with a duration of 3 to 40 beats and rates of 105 to 175 beats/min. Frequent VPB (>30 beats/h) were noted in 29 patients (83%), of whom 27 patients (93%) had complex VPB (Lown grades 3, 4, and 5) and 2 (7%) had simple VPB (uniform). The prevalence of ventricular arrhythmias by modified Lown grades in 35 patients is shown in Figure 3.

The prevalence of VPB in patients with and those without VT according to frequency and complexity is shown in Table III. All patients in the VT group had multiform VPB and 90% of them had paired VPB. Thus, the occurrence of multiform and paired VPB was

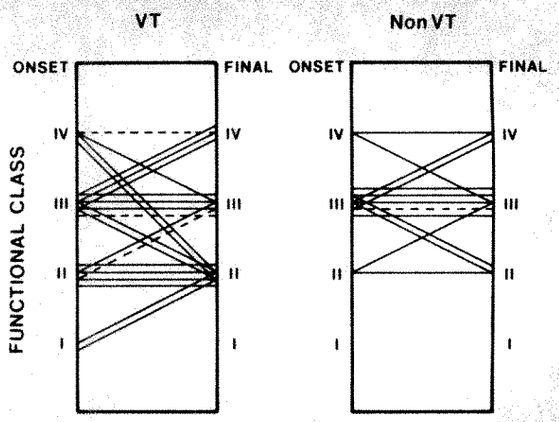

**FIGURE 4.** Change in functional class (New York Heart Association) in patients with IDC. The **dotted lines** indicate the patients who died. **Left,** the VT group; **right,** the non-VT group. No significant differences in the changes in functional classification were noted between the 2 groups.

significantly higher in the VT group (chi-square = 4.25 and 5.24; $p < 0.05$).

Eighty-five episodes of nonsustained VT were recorded in the 21 patients (mean 4.0 episodes/patient; range 1 to 16). No sustained VT was found during monitoring. The duration of VT ranged from 3 to 46 beats (mean ± SD 8 ± 4.7). Forty-six episodes (54%) were 3 beats in duration, 11 episodes (13%) had 4 beats, 7 episodes (8%) had 5 beats, and 21 episodes (25%) had >5 beats. The mean rate of VT was 155 ± 42 beats/min (range 75 to 210) with 58% of episodes at a rate >150 beats/min. Twelve (14%) of the 85 episodes of VT had a prematurity index (RR'/QT) <1.0 for the initiating beat. Only 2 patients recorded complaints of palpitation and dyspnea in the diary that corresponded in real time to the occurrence of VT.

**Follow-up data:** Follow-up data were obtained in all patients, and follow-up ranged from 4 to 74 months (mean ± SD 34 ± 17). Figure 4 shows changes in functional class during the last follow-up observation. Functional status in the 31 surviving patients improved in 8 (26%), deteriorated in 11 (35%), and was unchanged in 12 (39%). The number of patients who improved, were unchanged, or deteriorated in functional class between the 2 groups was not significantly different. A total of 27 patients had repeated 24-hour Holter recordings taken from 1 to 42 months during the follow-up period. Nineteen patients were in the VT group and 8 in the non-VT group. Twelve (44%) of 27 patients had nonsustained VT; 9 had previous VT and 3 patients did not. However, the latter 3 patients had previous complex VPB. The remaining 15 patients had complex ventricular arrhythmias (≥ grade 3). Of these 15 patients, 10 had previous VT and 5 did not. In summary, during follow-up study, 9 patients had VT, 3 had new VT, 10 no longer had VT, and 5 continued to have complex ventricular arrhythmias without VT.

Four patients died during the follow-up period from 4 to 39 months. Two died suddenly, 1 in the VT group and the other in the non-VT group. A third patient died from intractable congestive heart failure and the fourth from sepsis; both were in the VT group. Two of the 4 patients who died had follow-up Holter recordings before death. Both patients showed frequent complex ventricular ectopy without the recurrence of VT.

**Antiarrhythmic drugs:** On entry into the study 5 patients were receiving antiarrhythmic medication, 3 quinidine and 2 procainamide. Four patients were in the VT group and 1 in the non-VT group. At the time of discharge all patients who showed VT on admission and 8 patients in the non-VT group were receiving antiarrhythmic drugs (Table VI). Decision regarding the use of antiarrhythmic drugs was made by the attending physician. During follow-up study, while on antiarrhythmic therapy, 10 patients no longer had VT and 9 continued to show VT on Holter monitoring. Of the 8 patients receiving antiarrhythmic drugs for the treatment of complex ventricular arrhythmias, 3 demonstrated new VT on monitoring and 5 continued to show complex ventricular arrhythmias. All 4 patients who died were receiving antiarrhythmic drugs (Table IV).

## Discussion

**Arrhythmias in idiopathic cardiomyopathy:** Our study demonstrates that VPB are frequent in patients with IDC. Frequent VPB (30/hour) occurred in 83% of patients, with a remarkably high percentage (93%) showing complex forms (Lown grades 3, 4, and 5). These findings resemble those in patients with hypertrophic cardiomyopathy.[20-22] McKenna et al[20] reported that 62% of 86 patients with hypertrophic cardiomyopathy had frequent, complex VPB and 74% of 150 patients studied by Savage et al[22] had similar findings. Interestingly, our study demonstrates a considerably higher prevalence of VT than did those of Savage et al[21,22] and McKenna et al[20] in patients with hypertrophic cardiomyopathy. We found that 21 (60%) of 35 patients studied had 1 to 16 episodes (mean 4 episodes/patient) of nonsustained VT during 24 hours of Holter monitoring. Most (86%) VT was initiated by late-coupled ventricular ectopic beats (prematurity index >1.0). This observation is consistent with those of other studies showing that the prematurity index is not an important predictor of subsequent VT.[19] The present study also confirms the previous observation that atrial fibrillation, atrial premature beats, and supraventricular tachycardia were relatively common in patients with IDC.[2,4,5,9]

**Role of clinical findings in VT:** Previous studies showed that several clinical characteristics have prognostic value in patients with IDC. Besides ventricular arrhythmias, Segal et al[5] emphasized that initial heart size, functional class, and presence of atrial fibrillation were indicators of prognosis. A recent study by Fuster et al[4] showed that age and cardiothoracic ratio on chest roentgenography were highly predictive of the clinical course. Nonetheless, the question of whether these clinical characteristics are related to VT has not previously been answered. Our findings indicate that the sex, presenting symptoms, initial functional class, heart size on chest X-ray, and various electrocardiographic findings in patients with VT were no different from those in patients without VT.

**Role of hemodynamic measurements in VT:** Previous reports commented on the high mortality and sudden death associated with reduced cardiac index, elevated left ventricular end-diastolic pressure, and diminished ejection fraction.[2,4,10,11] Our results demonstrate that hemodynamic measurements in patients with VT are no different from those in patients without VT, suggesting that low cardiac index, high left ventricular end-diastolic pressure, or low left ventricular ejection fraction are not determinants of VT in IDC.

**Prognostic value of VT:** Some investigators espouse the predictive value of VT in sudden death in patients with hypertrophic cardiomyopathy.[20,21] Segal and his associates[5] found a 50% mortality rate within 3 years among patients with a diagnosis of IDC who had VT on the electrocardiogram. Follansbee et al[16] demonstrated that patients with congestive cardiomyopathy or congestive heart failure and nonsustained VT detected by ambulatory electrocardiographic monitoring are at high risk for sudden death. In our study of 21 patients with nonsustained VT we had 3 deaths. Only 1 was sudden, whereas the other 2 patients died from intractable congestive heart failure and sepsis, respectively. VT was not demonstrated on subsequent Holter recording during antiarrhythmic therapy in 2 of these 3 patients. Of the 14 patients who did not have VT, 1 died suddenly. No survivor had sustained VT or ventricular fibrillation requiring cardioversion or defibrillation during follow-up study. These findings argue against the role of nonsustained VT as a predictor of prognosis in IDC.

**Limitations of the present study:** The major limitations include (1) the retrospective nature of the study design, (2) the lack of systematic evaluation of antiarrhythmic drug therapy (due to the retrospective nature of the study, where information regarding drug dosage, drug blood levels, and compliance with therapy were usually incomplete, and (3) the relatively small number of patients and a short follow-up period. Although other studies include a larger number of patients, our strict selection criteria limited the number of cases.

**Clinical implications:** This report is the first to investigate the incidence and clinical significance of VT in patients with IDC by long-term ambulatory electrocardiographic recordings. Our study demonstrated no significant differences between patients with and those without nonsustained VT in those clinical characteristics and hemodynamic findings that have been shown to be of prognostic value in IDC. Furthermore, we found no differences in mortality between the VT and the non-VT groups, suggesting that VT is not an independent predictor of prognosis. The relatively low mortality in our study compared with those in other studies is intriguing.[5,16] Antiarrhythmic therapy may have prevented sudden death in some patients in the VT group. However, all 4 patients who died were receiving antiarrhythmic therapy and 2 of them no longer had VT on repeat Holter recording.

**Acknowledgment:** We gratefully acknowledge the invaluable photographic assistance of Gary Cummens, the statistical assistance of Jerry Jones, and the secretarial help of Lillian Linares in the preparation of this manuscript.

# Transesophageal Pacing for Prognostic Evaluation of Preexcitation Syndrome and Assessment of Protective Therapy

GIUSEPPE CRITELLI, MD, GINO GRASSI, PhD, FRANCESCO PERTICONE, MD, FERNANDO COLTORTI, MD, VITTORIO MONDA, MD, and MARIO CONDORELLI, MD

**An esophageal lead was used to perform decremental atrial pacing and elective induction of atrial fibrillation (AF) in 5 patients with the Wolff-Parkinson-White (W-P-W) syndrome before and after amiodarone therapy. In the control state, 1:1 atrioventricular (AV) conduction over the accessory pathway ranged from 220 to 260 ms (mean 232). The shortest R-R interval during AF ranged from 190 to 210 ms (mean 198). The ventricular rate ranged from 175 to 212 beats/min (mean 196). After amiodarone therapy, the shortest cycle length with 1:1 AV conduction increased in all patients, ranging from 290 to 540 ms (mean 370); during AF, no preexcited beat was present in 2 patients, whereas the minimal preexcited R-R interval in the remaining 3 was 290, 240, and 370 ms, respectively. The ventricular response during AF decreased in all patients. Thus, esophageal pacing is a useful method for identifying patients at risk with the W-P-W syndrome and for assessing appropriate management in individual patients. Amiodarone provides protection against life-threatening arrhythmias in these patients.**

The prognosis of preexcitation syndrome due to an accessory AV pathway (W-P-W syndrome) is considered with less optimism than it was in the past, because life-threatening arrhythmias and sudden death have been reported with it.[1-6] The determinant of risk in the preexcitation syndrome is a very short anterograde effective refractory period of the accessory pathway, which can be responsible for a rapid ventricular response when atrial flutter or AF develops.[5,7-10] In fact, previous studies found a correlation between the duration of the anterograde effective refractory period of the accessory pathway and the ventricular response during AF.[11-13] To evaluate the ventricular response during faster atrial rates and to assess protective drug regimen in patients with the W-P-W syndrome at risk, an esophageal lead was used to perform decremental atrial pacing and elective induction of AF.

## Methods

**Patients:** The study group consisted of 4 male patients and 1 female patient, aged 18 to 38 years (mean 27), selected from 52 consecutive patients with the W-P-W syndrome. One patient had been resuscitated from VF, 1 had a history of tachycardia, and 3 had familial W-P-W syndrome with a history of sudden death in 2 other family members. All patients had previously undergone endocavitary electrode catheter study for electrophysiologic evaluation of the W-P-W syndrome. Four patients had multiple accessory pathways; in addition, enhanced conduction of the AV node was present in 3 and a Mahaim fiber of the fasciculoventricular variety in 1.

**Procedure:** Studies were performed in the postabsorptive, nonsedated state. A bipolar permanent transvenous pacing lead with a 29 mm interelectrode distance (Medtronic Coronary Sinus Permanent Pacing Lead model 6992) was passed through the nares into the distal esophagus with the patient supine. The lead was secured where unipolar atrial electrograms showed the greatest amplitude and the most rapid deflection on the proximal electrode; this electrode was then designated as the cathodal (negative) pacing terminal. The unipolar tracings were filtered at 0.1 to 1 kHz. The pulse duration of the external generator ranged from 7 to 10 ms, and the current strength required for a stable capture ranged from

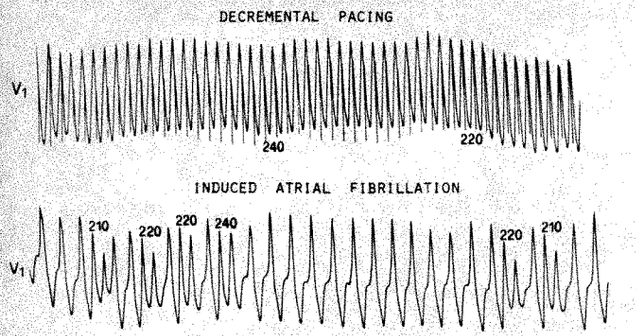

**FIGURE 1.** Transesophageal pacing in a patient with the W-P-W syndrome at risk. Decremental pacing shows 1:1 conduction at a cycle length of 220 ms; during induced AF, the shortest R-R interval measures 210 ms. Numbers are in ms. The tracings are taken from Case 3, Table I.

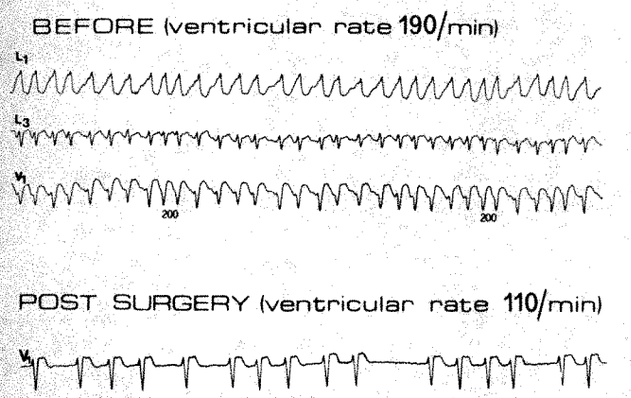

**FIGURE 2.** Case 5. Transesophageal pacing before and after surgery in a patient with the W-P-W syndrome and multiple accessory pathways at risk for sudden death. Note the absence after surgery of preexcited beats with a slow ventricular response during induced AF.

20 to 30 mA. All studies were performed with an intravenous line in place and with resuscitative equipment immediately available. To be certain the ventricle was not paced, pacing was first performed at a slow rate. Decremental pacing was then performed initially at a cycle length just below the sinus cycle length, with progressive reduction in the cycle length until block appeared in the accessory pathway. Finally, AF was induced by pacing at cycle lengths ranging from 60 to 120 ms.

The following variables were defined in the control state and after chronic amiodarone therapy: (1) the shortest cycle length with 1:1 AV conduction over the accessory pathway during decremental atrial pacing; (2) the ventricular response during induced AF as assessed by the minimal R-R interval between preexcited beats, percentage of preexcited beats observed, and the ventricular rate. The first evaluation of drug effect was performed after a 4-week period of treatment with 2,000 mg of amiodarone weekly (administered as 200 mg every 12 hours for 5 consecutive days). Serial esophageal pacing was then

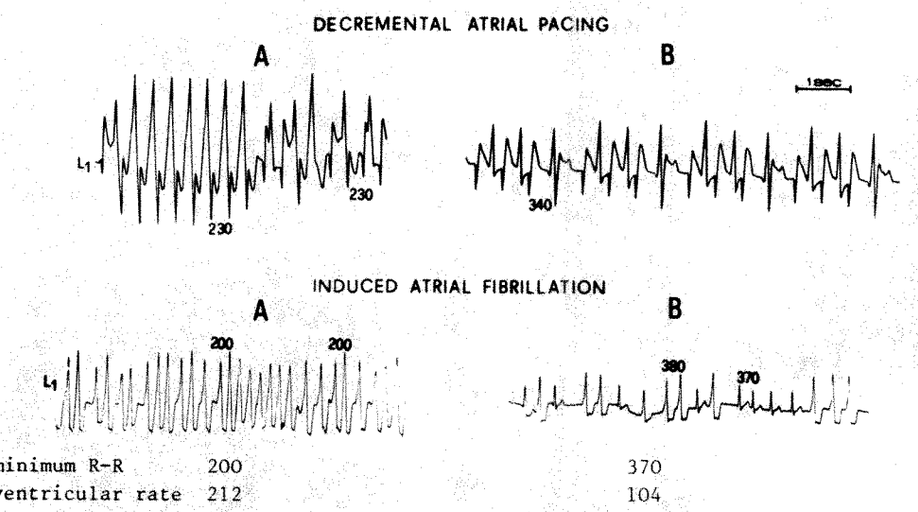

**FIGURE 3.** Case 1. Unsuccessful surgery in the W-P-W syndrome (multiple accessory pathways and enhanced AV node conduction) at risk, documented by transesophageal pacing. The protective drug regimen is assessed using transesophageal pacing. **A**, before amiodarone; **B**, after amiodarone. See text for further details.

performed to check the response to pharmacologic therapy. Figure 1 is an example of the usefulness of the method; in this case, 1:1 AV conduction over the accessory pathway was present at a cycle length of 220 ms; the shortest R-R interval during induced AF was 210 ms.

## Results

Decremental atrial pacing and AF were successfully obtained by esophageal pacing in all patients. During the procedure, all patients experienced discomfort described as a burning chest sensation, but this discomfort was easily tolerated. External direct current shock was not required in any patient, AF terminating at about 10 minutes spontaneously or after intramuscular quinidine administration.

Results are summarized in Table I. In the control state, 1:1 AV conduction over the accessory pathway ranged from 220 to 260 ms (mean 232). The shortest preexcited R-R interval during AF ranged from 190 to 210 ms (mean 198), the ventricular rate ranging from 175 to 212 beats/min (mean 196). During amiodarone therapy, the shortest cycle length with 1:1 AV conduction over the accessory pathway was prolonged in all patients, ranging from 290 to 540 ms (mean 370); during AF, no preexcited beat was present in 2 patients, whereas the minimal preexcited interval in the remaining 3 patients was 370, 240, and 290 ms, respectively. The ventricular response during AF decreased in all patients. No consistent difference in the cycle length required to induce AF or the duration of AF was observed after amiodarone therapy.

Two patients underwent surgical dissection of accessory pathways, and transesophageal pacing permitted repeated assessment of surgical results during

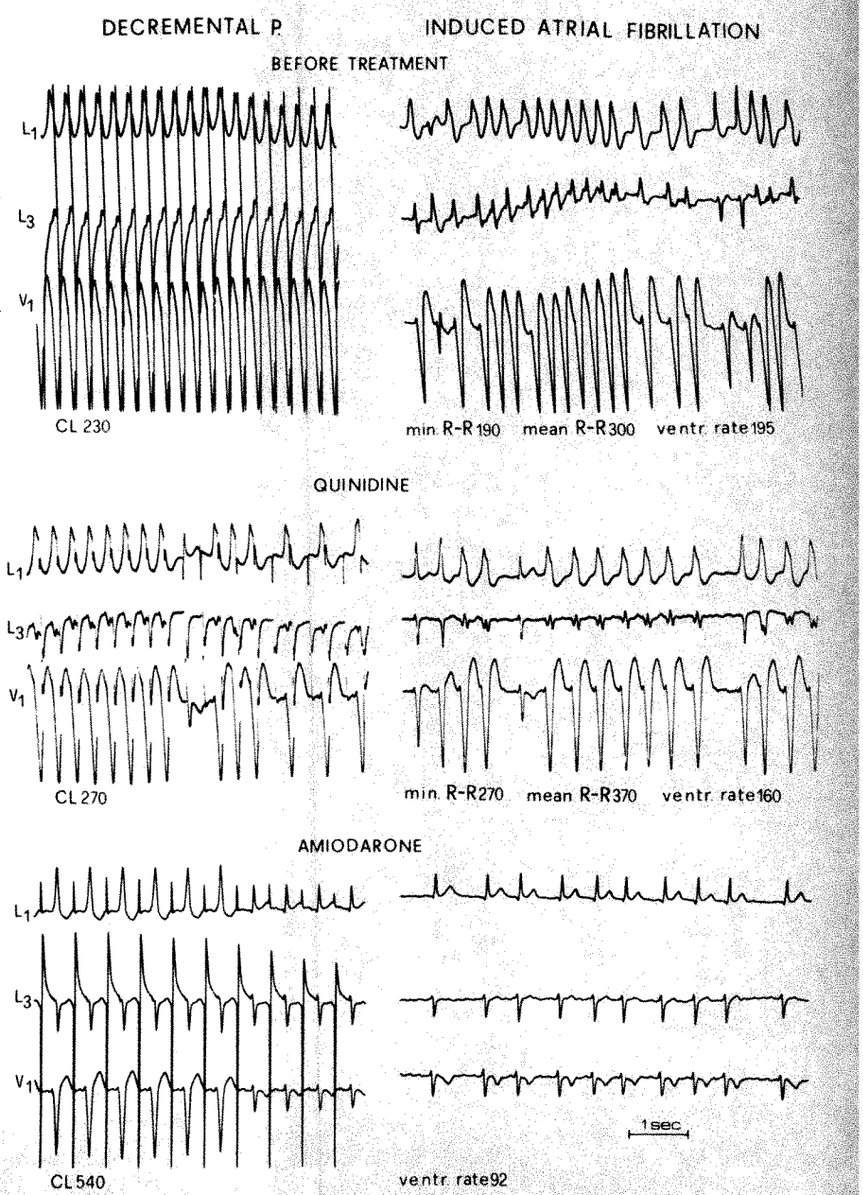

**FIGURE 4.** Case 4. Transesophageal pacing (P.) to assess the pharmacologic regimen in a patient with the W-P-W syndrome at risk. Before treatment, 1:1 conduction at a cycle length (CL) of 230 ms is present; minimal R-R interval of preexcited beats measures 190 ms and ventricular rate is 195 beats/min. Results from quinidine treatment are inconsistent. Amiodarone therapy has a better protective effect on ventricular response during faster atrial rates: block in accessory pathway appears at a cycle length of 540 ms and no preexcited beat is present during AF, the ventricular rate being moderate.

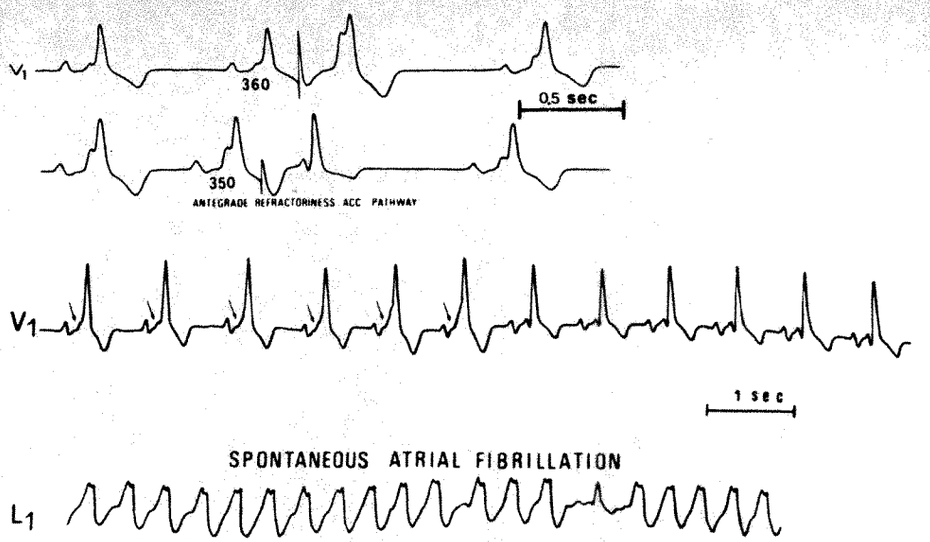

**FIGURE 5.** W-P-W syndrome with a long (350 ms) anterograde effective refractory period of accessory pathway and intermittent preexcitation (**arrows**). A QRS preexcitation morphology is present during AF. Right bundle branch block is evident during sinus rhythm, when preexcitation disappears. (See text for further details.) This illustration is taken from a patient not included in the present study.

long-term follow-up study. In the first patient, the method allowed demonstration of the beneficial effects of the intervention (Fig. 2). Before surgery, induced AF resulted in a minimal preexcited interval of 200 ms, the ventricular response being 190 beats/min; after surgery, no preexcited beat was present during AF, with a ventricular response to 110 beats/min.

In the second patient, a surgical failure was uncovered 2 months later (Fig. 3). In addition to demonstrating preexcitation, decremental pacing resulted in 1:1 AV conduction over the accessory pathways at cycle length of 230 ms; the minimal R-R interval during induced AF was 200 ms with a ventricular response of 212 beats/min. Repeated transesophageal pacing allowed assessment of a protective drug regimen in this patient. Thus, after amiodarone treatment with 2,000 mg weekly for 4 weeks, the Wenckebach phenomenon in AV conduction appeared at a cycle length of 340 ms. During induced AF, the minimal R-R preexcited interval was 370 ms with a moderate ventricular response. A second successful intervention was performed in this patient. In the patients in whom amiodarone therapy was used instead of surgery, the follow-up period was 11 months.

The possibility of using the method repeatedly during chronic drug therapy permitted the comparative evaluation of different antiarrhythmic agents. In 2 patients the effects of quinidine versus amiodarone therapy were evaluated, and amiodarone showed better effectiveness. In the example shown in Figure 4, no consistent modification of the ventricular response to either decremental pacing or induced AF was evident with quinidine therapy; on the contrary, after amiodarone therapy, block in the accessory pathway appeared at a cycle length of 540 ms and the ventricular rate during induced AF was slow, with no preexcited QRS complex.

## Discussion

The use of atrial pacing from the esophagus for diagnosis or therapy is well known,[14,15] but its application has been limited because of either patient discomfort due to high current requirements or the lack of consistent capture. Gallagher and co-workers[16] demonstrated that lower pacing thresholds can be obtained by using a wider pulse duration and a bipolar electrode with a wide interelectrode distance. These investigators pointed out the usefulness of this method as a diagnostic and therapeutic tool for the investigation and treatment of supraventricular tachycardia.[16]

Our study demonstrates that esophageal pacing provides a noninvasive method for identifying patients at risk with the W-P-W syndrome and for assessing appropriate management in individual cases.

A patient with the W-P-W syndrome at risk of sudden death can be identified if an electrocardiographic tracing during atrial flutter/AF is available.[10] In patients not exhibiting this particular tachyarrhythmia, an invasive procedure is required to define the anterograde effective refractory period of the accessory pathway at different cycle lengths and the ventricular response to either decremental atrial pacing or induced AF.[12–14] In addition, because sudden death may be the first manifestation of the W-P-W syndrome,[6,17,18] a similar approach might reasonably be considered in asymptomatic patients. Because an endocavitary study would be impossible in all patients with electrocardiographic evidence of preexcitation, certain criteria have been suggested to noninvasively exclude a short anterograde effective refractory period of the accessory pathway. The findings considered to indicate a relatively long refractory period include (1) intermittent preexcitation,[5] (2) block in the accessory pathway after

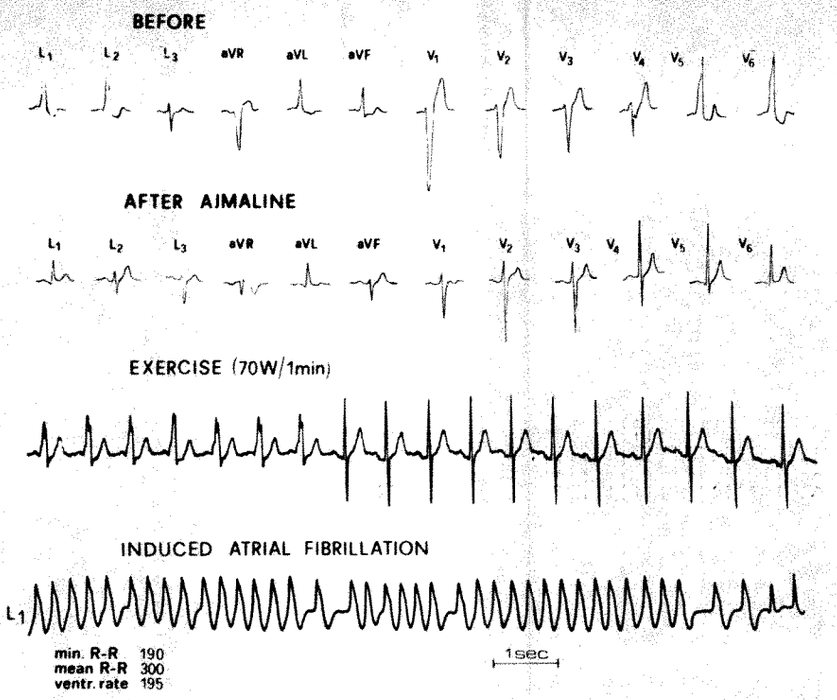

**FIGURE 6.** Case 4. Inability of noninvasive tests to exclude a short anterograde effective refractory period of accessory pathway in the W-P-W syndrome. Both ajmaline administration and exercise testing induce block in accessory pathway, but the ventricular response during AF is rapid with almost all beats preexcited and minimal R-R interval measures 190 ms.

intravenously administered ajmaline,[19] and (3) block in the accessory pathway during exercise testing.[20] All are limited because the assessment takes place during sinus rhythm. In fact, these criteria provide no information on the anterograde effective refractory period of the accessory pathway during fast atrial rates. Because AV bypass tracts in the W-P-W syndrome are usually composed of working myocardium,[21–26] it should not be surprising that in some patients an accessory pathway with a long anterograde effective refractory period during sinus rhythm can increase its conduction capacity when a rapid atrial rhythm develops. Figure 5 shows that despite a long anterograde effective refractory period, that is, 350 ms, of the accessory pathway and a pattern of intermittent W-P-W electrocardiogram during sinus rhythm, maximal preexcitation with a fast ventricular response can occur with the development of AF.

Other noninvasive tests are unable to exclude a very short anterograde effective refractory period of an accessory pathway in some patients. In the patient in Figure 6, although the accessory pathway is blocked both after ajmaline and during exercise, AF induces a rapid ventricular response with preexcited QRS complexes. Thus, the standard electrocardiogram in the W-P-W syndrome, even with exercise and drug testing, lacks sufficient prognostic sensitivity. Atrial pacing, including elective induction of AF, is the most reliable means of evaluating the potential for rapid ventricular response during AF and thus of identifying subjects at risk.

Our study demonstrates that this goal can be achieved using esophageal pacing, thus avoiding several problems that arise from endocavitary studies. In addition, our preliminary study indicates that amiodarone therapy can protect against life-threatening arrhythmias in patients with the W-P-W syndrome at risk.

# Electrophysiologic Studies Before and After Myocardial Revascularization in Patients With Life-Threatening Ventricular Arrhythmias

HASAN GARAN, MD, JEREMY N. RUSKIN, MD, JOHN P. DiMARCO, MD, PhD, WAYNE M. DERKAC, MD, CARY W. AKINS, MD, WILLARD M. DAGGETT, MD, W. GERALD AUSTEN, MD, and MORTIMER J. BUCKLEY, MD

**Electrophysiologic studies with programmed cardiac stimulation were performed in a selected group of 17 patients with severe proximal coronary artery disease involving at least 2 major vessels and left ventricular ejection fractions >30% who were undergoing coronary artery bypass graft surgery after prehospital cardiac arrest or ventricular tachycardia (VT) unassociated with acute myocardial infarction. Before surgery and without antiarrhythmic drug therapy, programmed cardiac stimulation induced ventricular fibrillation (VF) in 4 patients, and VT (≥5 beats) in 11 patients. Inducible VT or VF was suppressed by antiarrhythmic drugs in 7 of 13 patients in whom they were tried. Patients underwent coronary artery bypass graft surgery unassociated with perioperative myocardial infarction. When studied again an average of 19 days after surgery, 10 patients had no inducible VT or VF without antiarrhythmic drug therapy; 6 had induced VT. One patient had spontaneous VT. An effective antiarrhythmic regimen that suppressed inducible or spontaneous VT, or both, was defined by serial electrophysiologic studies in 4 patients, whereas 3 patients continued to manifest electrically inducible VT with all antiarrhythmic regimens tested. All but 1 patient, in whom postoperative VT could not be suppressed, are free of arrhythmias after a mean follow-up period of 23 months (range 6 to 53). It is concluded that myocardial revascularization alone may improve the abnormal electrophysiologic findings in certain patients; however, this effect of coronary artery bypass graft surgery is unpredictable, and pre- and postoperative electrophysiologic studies are recommended as part of the evaluation of these patients.**

The role of myocardial ischemia in the genesis of sudden, life-threatening ventricular tachyarrhythmias is a complex and poorly understood topic. Consequently, the role of surgical myocardial revascularization in the management of patients with ventricular arrhythmias resulting from ischemic heart disease has not been well established. Although there have been several reports on this topic,[1–3] no study to date has examined systematically the efficacy of coronary artery bypass graft surgery in suppressing the ventricular arrhythmias that are inducible by programmed ventricular stimulation.[4–6] Although the majority of patients with lethal ventricular arrhythmias have severely depressed left ventricular function,[4,6,7] a selected subgroup of them have, in addition to severe proximal coronary artery disease, left ventricular function not depressed enough to preclude cardiac surgery with myocardial revascularization. We investigated the effect of myocardial revascularization on inducible ventricular arrhythmias by performing programmed cardiac stimulation before and after coronary artery bypass surgery in such a selected group of 17 patients.

## Methods

The patient population included 11 men and 6 women, ranging in age from 51 to 74 years, who satisfied the following criteria: proximal coronary artery disease with ≥70% reduction in diameter, involving at least 2 of the major coronary arteries (Table I), and left ventricular ejection fraction >30%, calculated from biplane angiography.[8] Thirteen of the 17 patients collapsed unexpectedly and VF was documented at the time of resuscitation. In no patient was the episode of VF associated with the evolution of a new myocardial infarction. The remaining 4 patients had a history of syncope with documented VT. Eight patients had a history of remote myocardial infarction. Only 2 patients had been having stable

* This patient was not tested without drugs after surgery. AK = akinesia; CABG = coronary artery bypass graft; HK = hypokinesia; LAD = left anterior descending coronary artery; LC = left circumflex coronary artery; LM = left main coronary artery; LV = left ventricle; NS = nonsuppression

angina pectoris. Two other patients were receiving antiarrhythmic therapy with quinidine at the time of ventricular arrhythmia. None of the other patients were receiving any antiarrhythmic drugs when VF or VT occurred. One patient had already undergone coronary artery bypass graft surgery once, with successful relief of angina, 10 months before prehospital cardiac arrest. The cardiac catheterization and the presurgical electrophysiologic studies were performed 1 to 14 days apart. The electrophysiologic studies were carried out an average of 2.5 weeks after resuscitation from cardiac arrest without any complications. All antiarrhythmic drugs were discontinued under continuous electrocardiographic monitoring at least 48 hours before the initial electrophysiologic study. No patient had received amiodarone before the initial electrophysiologic study. Endocavitary recordings from the high right atrium, the bundle of His, and the right ventricular apex were obtained, and programmed cardiac stimulation was carried out using quadripolar electrode catheters inserted percutaneously by way of femoral or antecubital veins. The protocol for programmed cardiac stimulation included single, double, and triple programmed premature ventricular stimuli applied during sinus rhythm and fixed-rate ventricular pacing, and brief (3 to 5 beat) bursts of rapid ventricular pacing during normal sinus rhythm. VT (≥5 beats) or VF was considered an end point during the stimulation protocol. If no inducible ventricular tachyarrhythmia occurred in response to stimulation from the right ventricular apex, the stimulation protocol was repeated from the right ventricular outflow tract.

Serial drug trials with oral antiarrhythmic drug therapy were conducted in an attempt to suppress the inducible ventricular arrhythmias during the period before the coronary artery bypass graft surgery in all but 2 patients who had inducible ventricular arrhythmias (Table I). One of these 2 patients had a stenosis with 70% reduction in diameter involving the left main coronary artery. Both patients were kept under continuous cardiac monitoring without any antiarrhythmic drug therapy and without serial drug trials until surgery. Coronary artery bypass graft surgery was performed an average of 2.8 months after out-of-hospital cardiac arrest (range 1 to 6 months). Two patients continued to have angina pectoris during the iterim period, but no patient had myocardial infarction during this period. There were no surgical complications and no enzymatic or electrocardiographic evidence of acute myocardial infarction associated with coronary

artery bypass graft surgery in any of the 17 patients. Every patient had continuous electrocardiographic monitoring for at least 10 days after surgery. All 17 patients underwent repeat electrophysiologic studies using the same stimulation protocol an average of 19 days (range 12 to 47) after cardiac surgery. The mean interval between the pre- and postoperative electrophysiologic study was 2.5 ± 0.8 months (mean ± standard deviation of the mean). In all but 3 patients this period was <3 months long; in these 3 patients, the periods were 4, 5, and 6 months long. The patients in whom programmed cardiac stimulation induced VT after revascularization surgery underwent serial antiarrhythmic drug tests with programmed cardiac stimulation in an attempt to define a regimen that suppressed inducible ventricular arrhythmia.

## Results

**Electrophysiologic and angiographic findings before coronary artery bypass graft surgery (Table I):** Before aortocoronary saphenous vein bypass graft surgery, 15 of the 17 patients had inducible ventricular arrhythmias in response to programmed cardiac stimulation: inducible VF in 4 (Fig. 1), and inducible VT in 11. In 3 of the 11 patients, the induced VT was sustained, whereas in 8 other patients the induced VT ended spontaneously after 6 to 27 beats. The remaining 2 patients manifested 1 to 3 repetitive ventricular responses with programmed cardiac stimulation from both the right ventricular apex and the right ventricular outflow tract. Programmed double premature ventricular stimuli during normal sinus rhythm did not initiate ventricular arrhythmias in any patient. VT and VF were initiated by double premature ventricular beats delivered during ventricular pacing in 13 patients (Fig. 1) and by bursts of 3 and 4 ventricular stimuli applied during normal sinus rhythm in 2 patients. The average rate of the induced VT was 265 beats/min. Of all the patients, only 1 had angina pectoris or manifested electrocardiographic signs of myocardial ischemia during programmed cardiac pacing.

In 14 of the 17 patients, biplane contrast left ventriculography revealed single or multiple segmental wall motion abnormalities of varying severity. Three patients

had normal left ventricular systolic function by angiographic criteria. No patient had a single, large, discrete, dyskinetic segment or aneurysm that was suitable for resection. The mean left ventricular ejection fraction calculated from biplane angiography[8] was 49 ± 7% (mean ± standard error of the mean) with a range of 32 to 76%. All patients had extensive proximal coronary artery disease, including 2 who had left main coronary artery stenosis of ≥60% reduction in diameter and, in addition, stenoses involving the right coronary artery. In general, there were no distinct patterns of coronary artery disease or left ventricular contraction abnormalities that predicted specific electrophysiologic responses to programmed ventricular stimulation.

Serial antiarrhythmic drug tests were carried out preoperatively in conjunction with programmed cardiac stimulation in 13 of the 15 patients with inducible VT or VF. A total of 39 drug trials (average 3/patient), were carried out without complications. In 8 of these 13 patients, complete suppression of electrically inducible ventricular arrhythmias (defined as a maximum of 3 repetitive ventricular responses during programmed ventricular stimulation) was achieved with the use of either conventional antiarrhythmic drugs or mexiletine. In the remaining 5 patients, programmed ventricular stimulation repeatedly resulted in VT or VF despite therapeutic trials with quinidine, procainamide, disopyramide, propranolol, mexiletine, tocainide, and amiodarone. The only patient who received amiodarone before surgery underwent programmed cardiac stimulation after 2 weeks of therapy with this drug.

**Electrophysiologic findings after coronary artery bypass graft surgery (Table I):** All 17 patients underwent electrophysiologic evaluation with programmed ventricular stimulation an average of 19 days after aortocoronary saphenous vein bypass graft surgery. Patients who were taking digoxin before surgery underwent postoperative electrophysiologic study while taking digoxin and were discharged on this drug therapy. All but 1 of the 17 patients were tested without antiarrhythmic therapy after surgery. The only patient who received amiodarone before surgery had not been

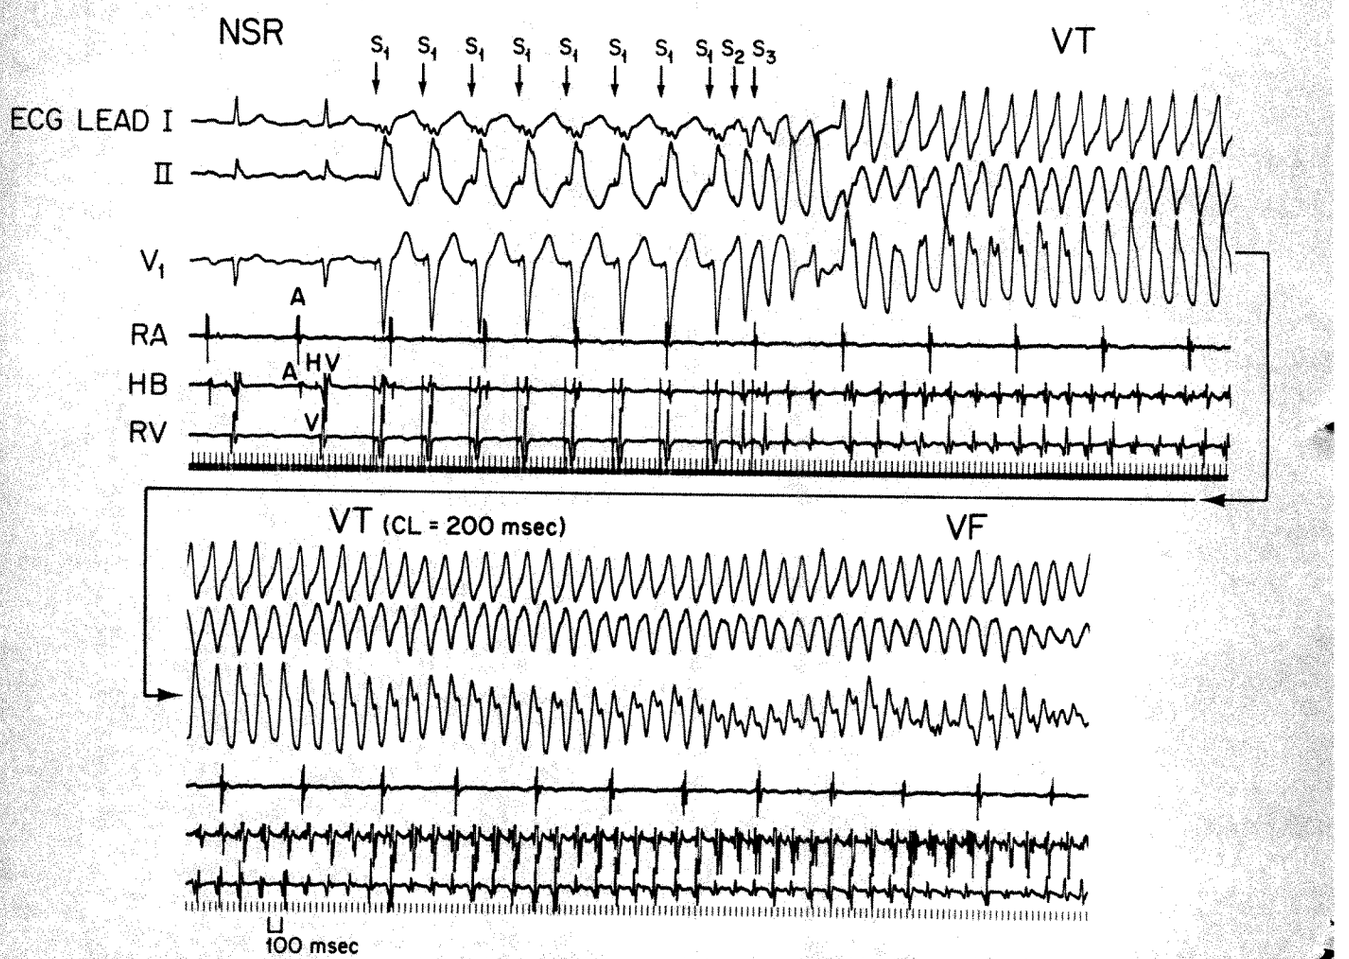

**FIGURE 1.** Response to programmed double premature ventricular depolarizations during ventricular pacing in 1 patient. The continuous tracing shows the initiation of VT with a cycle length (CL) of 200 ms and its gradual transformation into VF. Electrocardiographic (ECG) limb leads I and II and precordial lead $V_1$ are displayed simultaneously with right atrial (RA), His bundle (HB), and right ventricular (RV) electrograms. A = atrial depolarization; H = His electrogram; NSR = normal sinus rhythm; $S_1$, $S_2$, $S_3$ = stimulus artifacts; V = ventricular depolarization.

taking this drug for 35 days at the time of postoperative programmed cardiac stimulation. One patient had recurrent spontaneous VT which was suppressed with quinidine, mexiletine, and propranolol. This patient underwent a postoperative electrophysiologic evaluation while following this antiarrhythmic regimen, was found to have no inducible ventricular arrhythmia in response to programmed ventricular stimulation, and was discharged on this regimen. Ten patients manifested no VT or VF in response to any mode of programmed ventricular stimulation without any antiarrhythmic drug therapy after coronary artery bypass graft surgery. Included in this group of 10 were all 4 patients who had VF in response to programmed stimulation before coronary artery bypass graft surgery. Eight of these 10 patients were discharged without any antiarrhythmic drug therapy. The remaining 2 patients without inducible arrhythmias continued to have spontaneous symptomatic ventricular ectopic activity of a higher degree than before surgery, which was suppressed empirically with quinidine, mexiletine, and propranolol by the attending physicians. These 2 patients underwent repeat electrophysiologic testing while taking these antiarrhythmic drugs and, as observed in the absence of antiarrhythmic drugs, no ventricular arrhythmias could be initiated by programmed ventricular stimulation.

The remaining 6 patients manifested VT in response to programmed cardiac stimulation during postoperative electrophysiologic studies. The ventricular arrhythmias induced by programmed ventricular stimulation in these 6 patients before and after coronary artery bypass graft surgery were similar. Five patients manifested nonsustained (5 to 22 beats) and 1 had sustained VT in response to the same mode of programmed cardiac stimulation as before surgery. The average tachycardia rate was also comparable (265 beats/min before and 246 beats/min after surgery). Serial antiarrhythmic drug trials were carried out in conjunction with programmed cardiac stimulation in these 6 patients. In 3 patients, a drug regimen that prevented electrical induction of VT after coronary artery bypass graft surgery was defined, whereas the other 3 patients had inducible VT with all drug regimens tested. The latter 3 patients were discharged on antiarrhythmic drug regimens that were thought to modify the inducible ventricular arrhythmias favorably by decelerating or abbreviating them.

In summary, 2 patients who manifested no inducible ventricular arrhythmia before surgery also remained free of inducible ventricular arrhythmias after surgery. In 15 patients who had inducible VT or VF before surgery, these arrhythmias became noninducible through myocardial revascularization alone in 8 (53 %), and through surgery and antiarrhythmic drugs in another 4 (27 %); the remaining 3 patients (20 %) continued to have inducible arrhythmias.

**Clinical follow-up:** None of the 17 patients in this series died during a mean follow-up of 23 months (range 6 to 53). Only 1 had recurrent VT. This patient was 1 of 3 in whom inducible VT could not be suppressed completely by antiarrhythmic drugs even after myocardial revascularization. Twenty-four hour ambulatory electrocardiographic recordings obtained after discharge were either normal or showed low-grade ventricular ectopic activity with uniform, nonrepetitive, premature ventricular beats, but no VT. The patients have remained free of angina as well as of signs and symptoms of heart failure. Two patients underwent repeat electrophysiologic studies with programmed cardiac stimulation without any antiarrhythmic drug therapy 6 months after surgery. One of these patients who had no inducible ventricular arrhythmia 2 weeks after surgery also had no inducible arrhythmia 6 months later. The other patient had inducible VT 2 weeks as well as 6 months after surgery.

## Discussion

Recent studies have found that important electrophysiologic abnormalities can be demonstrated by programmed cardiac stimulation in patients with severe coronary artery disease who have been rescuscitated from an episode of prehospital cardiac arrest unassociated with acute myocardial infarction.[4–6] However, no study to date has examined systematically the effects of surgical revascularization on inducible ventricular arrhythmias and only limited data are available on the role of coronary artery bypass graft surgery, specifically in survivors of prehospital cardiac arrest.[1–3,4,6] These data suggest that recurrent VF remains a serious problem even after coronary artery bypass graft surgery.[1,3] Our study shows that inducibility of ventricular arrhythmias, which is an important prognostic factor, can be substantially influenced by surgical myocardial revascularization in a select group of patients.

By selection, our patients had relatively well-preserved left ventricular function and critical proximal coronary artery disease. The mean left ventricular ejection fraction of 49 ± 7% in this group of patients reflects better left ventricular function than the previously reported patients resuscitated from out-of-hospital cardiac arrest.[4,5,7] The stimulation study results seen in this selected group of patients were also different from those previously reported, with a greater incidence of VF and a smaller incidence of sustained VT.[4,5] Although the majority of inducible ventricular arrhythmias are observed in patients with infarcted left ventricles,[4,5,6,9,10] the presence of an angiographically detectable scar was neither necessary nor sufficient for the presence of an inducible ventricular arrhythmia in our patients. For example, VF was induced in a patient with normal left ventricular wall motion and VT in a patient with a single hypokinetic segment. On the other hand, in 2 patients with multiple wall motion abnormalities no VT could be induced by programmed cardiac stimulation. These differences are not likely to be due to differences in stimulation technique, since in patients with only repetitive ventricular responses the entire stimulation protocol was carried out. Thus, there could be a complex and poorly understood interaction of reversible ischemia with chronically fixed anatomic and electrophysiologic abnormalities underlying the genesis

of ventricular arrhythmias in this select group of patients. Despite the absence of subjective or objective criteria for reversible myocardial ischemia in the majority of the patients during the electrophysiologic studies, pacing-induced changes in myocardial perfusion could play a role in the genesis of induced ventricular arrhythmias, because in half of our patients myocardial revascularization alone prevented the induction of ventricular arrhythmias. This phenomenon was true especially in cases of induced VF but was also seen in patients with reproducible VT.

In our study, the comparison between electrophysiologic findings is made on studies performed no more than 3 months apart except for 3 cases; in 2 of these 3 cases, pre- and postoperative findings were the same. It is unlikely that the changes observed in electrophysiologic study results were related to the time intervals between the studies rather than the surgical intervention. More importantly, the reproducibility of the findings observed during the postoperative electrophysiologic studies may be questioned because of several factors, such as plasma catecholamine level, that may differ from baseline values due to recent surgery. This question can be resolved only by repeating the programmed stimulation several weeks or months after surgery—a difficult prospect since it involves invasive studies in asymptomatic patients. The repeat studies were done in only 2 patients in our study group and the results obviously cannot be generalized to the whole group. Nevertheless, in these 2 patients the responses to programmed cardiac stimulation 2 weeks and 6 months after surgery were the same.

Only 2 patients in our study group were receiving antiarrhythmic drugs at the time of their out-of-hospital cardiac arrest or VT. Since antiarrhythmic drugs can be proarrhythmic, their contribution to the mechanism producing ventricular arrhythmias cannot be ruled out. However, both of these patients also had inducible ventricular arrhythmias when studied without any antiarrhythmic drug therapy, thus manifesting at least their potential to have lethal ventricular arrhythmias even in the absence of antiarrhythmic drugs.

In most of the patients with spontaneous complex ventricular ectopic activity, these arrhythmias persist after coronary artery bypass surgery, and the frequency and severity of ventricular ectopic activity may even exceed that observed before surgery.[11-13] Our study showed that surgical myocardial revascularization may influence spontaneous ventricular ectopy and inducible ventricular arrhythmias differentially, thus presenting a therapeutic dilemma for the clinician concerning the use of antiarrhythmic agents. When symptomatic ventricular ectopic activity requires treatment even when VT is no longer inducible, our approach has been to select an antiarrhythmic drug regimen which suppresses electrically inducible ventricular arrhythmias as well as spontaneous ventricular ectopy.

In summary, our study shows that myocardial revascularization has a role in suppressing lethal ventricular arrhythmias, alone, or in conjunction with antiarrhythmic drugs in a selected group of patients even when scarred myocardium is left in situ. During the follow-up period, all patients in whom inducible ventricular arrhythmias were suppressed by surgery alone or in conjunction with antiarrhythmic drugs remained free of VT or VF. However, it is not possible to select these patients from preoperative angiographic data alone. The differences in the outcome of surgery may reflect the nonuniformity of the underlying disease process as well as our lack of understanding of the electrophysiologic mechanisms responsible for VT and VF in this patient population. As long as the efficacy of coronary artery bypass surgery in eliminating susceptibility to life-threatening ventricular arrhythmias remains unpredictable, pre- and postoperative electrophysiologic studies constitute an important part of the evaluation and treatment of patients who are known to be at high risk for sudden cardiac death.

**Acknowledgment:** We thank Ellen DiBiase for assistance in preparing the manuscript.

# QUANTUM: THE PROBLEM SOLVER

## Indication For Pacing: Intermittent Heartblock, Sinus Arrest.

ECG: *Loss of capture*

*This is the second in a series of case histories demonstrating the Quantum system's unique ability to help physicians diagnose the condition of a pacemaker patient.*

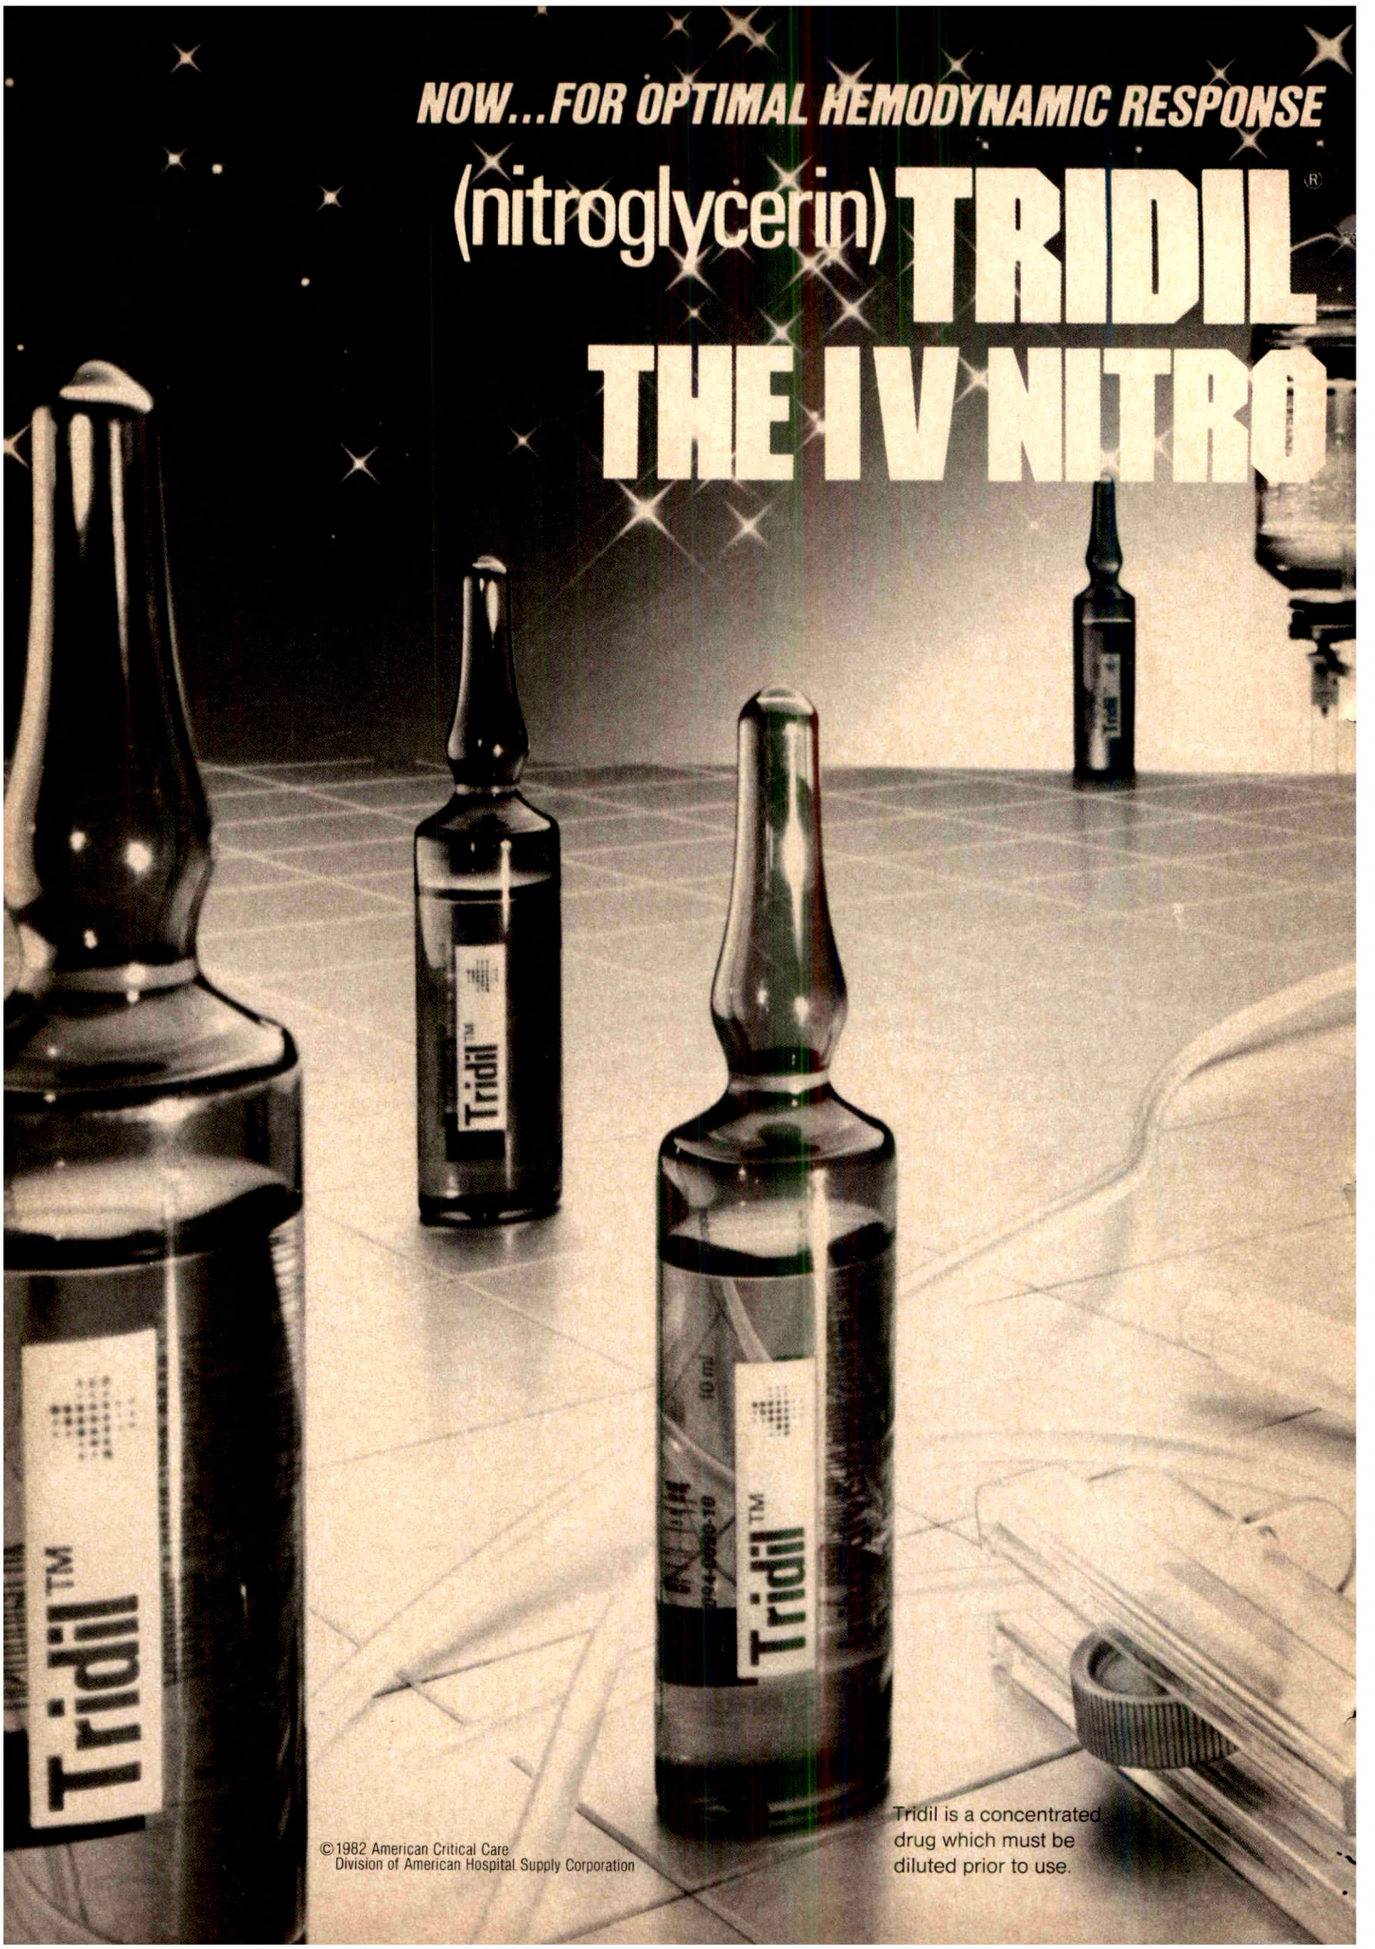
### An Actual Case History*

Patient: MALE
Age: 67 YEARS
Indication for Pacing: INTERMITTENT HEARTBLOCK, SINUS ARREST

The patient received a bipolar Quantum™ pulse generator with a transvenous bipolar lead. Intraoperative fluoroscopy and postoperative telemetry indicated satisfactory lead position.

Several months later, during routine telephone follow-up through Intermedics' Trace-A-Pace™ service, the patient's transtelephonic telemetry readout displayed abnormally low lead impedance values. A subsequent ECG strip indicated intermittent pacing, although the patient had experienced no discomfort.

Reexamination revealed insulation fractures of the lead that probably were causing intermittent shorting of the electrode. Access to the lead was gained via the pacer pocket and the repair was effected by medical adhesive and a suture sleeve tied in place. Postrepair pacing is normal with telemetry indicating acceptable lead impedance values.



*This is just one example of how Quantum helped pinpoint the exact source of a patient's problem. The complete Quantum pacing system, including a Decoder, Printer, Transmitter, Intermedics Programmer and three pacemaker models, represents the most sophisticated technology available today. By providing you with more information, Quantum helps you better manage your pacemaker patients.*

NOW...FOR OPTIMAL HEMODYNAMIC RESPONSE
(nitroglycerin) TRIDIL®
THE IV NITRO
Tridil™
Tridil™
Tridil™
10 ml
©1982 American Critical Care
Division of American Hospital Supply Corporation
Tridil is a concentrated
drug which must be
diluted prior to use.

IN CHF ASSOCIATED WITH ACUTE MI
SYSTEM
THAT DELIVERS
Efficacy:
• Quickly relieves pulmonary congestion with little effect on cardiac output[1]
• Helps redistribute blood flow to the infarcted myocardium[2,3]
Predictability:
• Produces dose-responsive venous and arterial dilation to help control both preload and afterload
• Tridilset,™ a special non-absorbing IV administration set, delivers Tridil with the greatest possible accuracy[4,5]
Safety:
• Metabolites have only minor activity and are rapidly excreted
• Highly concentrated Tridil (5 mg/ml) helps avoid the risk of fluid overload (especially helpful in the presence of oliguria)
TRIDIL SYSTEM—the preferred IV nitroglycerin in CHF associated with acute MI
• Highest concentration currently available—easy dilution, convenient administration, conserves fluid intake.
• Non-absorbing Tridilset IV set allows precise titration
• Comprehensive clinical/technical support
TRIDIL SYSTEM
delivers a new level of therapeutic precision to the treatment of CHF associated with acute MI

Please see the following page for a brief summary of prescribing information.
TRIDIL (nitroglycerin) SYSTEM
American Critical Care

# TRIDIL® (nitroglycerin)

**Brief Summary of Full Prescribing Information**

NOT FOR DIRECT INTRAVENOUS INJECTION. TRIDIL® MUST BE DILUTED IN DEXTROSE (5%) INJECTION, USP OR SODIUM CHLORIDE (0.9%) INJECTION, USP PRIOR TO ITS INFUSION (SEE DOSAGE AND ADMINISTRATION SECTION OF FULL PRESCRIBING INFORMATION). THE ADMINISTRATION SET USED FOR INFUSION WILL AFFECT THE AMOUNT OF TRIDIL DELIVERED TO THE PATIENT. (SEE WARNINGS, AND DOSAGE AND ADMINISTRATION SECTIONS.)

**CAUTION**

SEVERAL PREPARATIONS OF NITROGLYCERIN FOR INJECTION ARE AVAILABLE. THEY DIFFER IN CONCENTRATION AND/OR VOLUME PER VIAL. WHEN SWITCHING FROM ONE PRODUCT TO ANOTHER ATTENTION MUST BE PAID TO THE DILUTION AND DOSAGE AND ADMINISTRATION INSTRUCTIONS.

**CONTRAINDICATIONS**

TRIDIL should not be administered to individuals with:

1. A known hypersensitivity to nitroglycerin or a known idiosyncratic reaction to organic nitrates.
2. Hypotension or uncorrected hypovolemia, as the use of TRIDIL in such states could produce severe hypotension or shock.
3. Increased intracranial pressure (e.g., head trauma or cerebral hemorrhage).
4. Constrictive pericarditis and pericardial tamponade.

**WARNINGS**

1. Nitroglycerin readily migrates into many plastics. To avoid absorption of nitroglycerin into plastic parenteral solution containers, the dilution and storage of TRIDIL for intravenous infusion should be made only in *glass* parenteral solution bottles.
2. Some filters absorb nitroglycerin; they should be avoided.
3. Forty to 80% of the total amount of nitroglycerin in the final diluted solution for infusion is absorbed by the polyvinylchloride (PVC) tubing of the intravenous administration sets currently in general use. The higher rates of absorption occur when flow rates are low, nitroglycerin concentrations are high, and the administration set is long. Although the rate of loss is highest during the early phase of infusion (when flow rates are lowest) the loss is neither constant nor self-limiting; consequently no simple calculation or correction can be performed to convert the theoretical infusion rate (based on the concentration of the infusion solution) to the actual delivery rate.

Because of this problem, American Critical Care has developed TRIDILSET,™ an administration set in which loss of TRIDIL is minimal (less than 1%). TRIDILSET (or a similar administration set) is recommended for infusions of TRIDIL.

DOSING INSTRUCTIONS MUST BE FOLLOWED WITH CARE. IT SHOULD BE NOTED THAT WHEN TRIDILSET IS USED, THE CALCULATED DOSE WILL BE DELIVERED TO THE PATIENT BECAUSE THE LOSS OF TRIDIL DUE TO ABSORPTION IN STANDARD PVC TUBING WILL BE KEPT TO A MINIMUM. NOTE THAT THE DOSAGES COMMONLY USED IN PUBLISHED STUDIES UTILIZED GENERAL-USE PVC ADMINISTRATION SETS AND RECOMMENDED DOSES BASED ON THIS EXPERIENCE ARE TOO HIGH WHEN TRIDILSET IS USED.

**PRECAUTIONS**

TRIDIL (nitroglycerin) should be used with caution in patients with severe liver or renal disease.

Excessive hypotension, especially for prolonged periods of time, must be avoided because of possible deleterious effects on the brain, heart, liver, and kidney from poor perfusion and the attendant risk of ischemia, thrombosis, and altered function of these organs. Paradoxical bradycardia and increased angina pectoris may accompany nitroglycerin-induced hypotension. Patients with normal or low pulmonary capillary wedge pressure are especially sensitive to the hypotensive effects of TRIDIL. If pulmonary capillary wedge pressure is being monitored, it will be noted that a fall in wedge pressure precedes the onset of arterial hypotension, and the pulmonary capillary wedge pressure is thus a useful guide to safe titration of the drug.

**Carcinogenesis, mutagenesis, impairment of fertility**

No long-term studies in animals were performed to evaluate carcinogenic potential of TRIDIL.

**Pregnancy**

Category C. Animal reproduction studies have not been conducted with TRIDIL. It is also not known whether TRIDIL can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. TRIDIL should be given to a pregnant woman only if clearly needed.

**Nursing Mothers**

It is not known whether nitroglycerin is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when TRIDIL is administered to a nursing woman.

**Pediatric Use**

The safety and effectiveness of TRIDIL in children have not been established.

**ADVERSE REACTIONS**

The most frequent adverse reaction in patients treated with TRIDIL is headache, which occurs in approximately 2% of patients. Other adverse reactions occurring in less than 1% of patients are the following: tachycardia, nausea, vomiting, apprehension, restlessness, muscle twitching, retrosternal discomfort, palpitations, dizziness and abdominal pain.

The following additional adverse reactions have been reported with the oral and/or topical use of nitroglycerin: cutaneous flushing, weakness, and occasionally drug rash or exfoliative dermatitis.

**OVERDOSAGE**

Accidental overdosage of TRIDIL may result in severe hypotension and reflex tachycardia which can be treated by elevating the legs and decreasing or temporarily terminating the infusion until the patient's condition stabilizes. Since the duration of the hemodynamic effects following TRIDIL administration is quite short, additional corrective measures are usually not required. However, if further therapy is indicated, administration of an intravenous alpha adrenergic agonist (e.g., methoxamine or phenylephrine) should be considered.

**DOSAGE AND ADMINISTRATION**

(For complete information, please see Full Prescribing Information)

**NOT FOR DIRECT INTRAVENOUS INJECTION**

TRIDIL IS A CONCENTRATED, POTENT DRUG WHICH MUST BE DILUTED IN DEXTROSE (5%) INJECTION, USP OR SODIUM CHLORIDE (0.9%) INJECTION, USP PRIOR TO ITS INFUSION. TRIDIL SHOULD NOT BE ADMIXED WITH OTHER DRUGS.

Some patients with normal or low left ventricular filling pressures or pulmonary capillary wedge pressure (e.g., angina patients without other complications) may be hypersensitive to the effects of TRIDIL and may respond fully to doses as small as 5 mcg/min. These patients require especially careful titration and monitoring.

There is no fixed optimum dose of TRIDIL. Due to variations in the responsiveness of individual patients to the drug, each patient must be titrated to the desired level of hemodynamic function. Therefore, continuous monitoring of physiologic parameters (e.g., blood pressure and heart rate in all patients, other measurements such as pulmonary capillary wedge pressure, as appropriate), MUST BE PERFORMED to achieve the correct dose. Adequate systemic blood pressure and coronary perfusion pressure must be maintained.

**HOW SUPPLIED**

NDC 0094-0090-10, 50 mg-10 ml ampul. Each ml contains 5 mg nitroglycerin. Protect from freezing.

*Announcing the comprehensive study of...the most fascinating syndrome in Cardiology...*

# THE PRE-EXCITATION SYNDROME: FACTS AND THEORIES

**Libi Sherf, MD, FACC**

Assoc. Professor of Cardiology, Heart Institute, Chaim Sheba Medical Center, Tel Hashomer, University of Tel Aviv—Sackler School of Medicine, and Visiting Assoc. Professor, Dept. of Medicine, University of Alabama.

**Henry N. Neufeld, MD, FACC**

Professor of Medicine and Chaim Sheba Professor of Cardiology, Chief, Heart Institute, Chaim Sheba Medical Center, Tel Hashomer, University of Tel Aviv—Sackler School of Medicine.

Every cardiologist, internist, pediatrician, surgeon—indeed, *every physician*—should have a good basic knowledge of the Pre-excitation Syndrome. Here are just a few reasons why this is so essential:

- ☐ ⅓ of all pre-excitation cases are misdiagnosed.
- ☐ 5% to 10% of all tachycardias in adults are produced by pre-excitation.
- ☐ In ½ of all infants under 10 months of age with life-threatening tachycardias, the tachycardias are actually secondary to pre-excitation.
- ☐ ⅓ to ½ of all children with pre-excitation have an additional heart disease.

Starting with Wolff, Parkinson and White's classic paper, this book gives a comprehensive summary of all important facts of pre-excitation, plus the authors' personal experiences of follow-up studies of patients through many decades. It also brings a broad view of the literature and discusses the different structural and physiological aspects which form the pathomechanism of pre-excitation.

*"What is offered richly in this book is a methodical and comprehensive analysis of virtually all currently available knowledge on the subject. This is done with an admirable even-handedness, dealing objectively with all viewpoints but at the same time evaluating relative strengths and weaknesses of each observation and hypothesis. There is brought a wisdom here which only time and experience can provide. The encyclopedic references alone would make the book invaluable to anyone seriously interested in the Wolff-Parkinson-White syndrome. But when knowledgeable discussion and personal observations are added, it is genuinely a monumental contribution to clinical cardiology and cardiac electrophysiology."*

*Thomas N. James, MD*

# Finally.
# A computer fast enough to make dynamic cardiac quantitation a practical reality.

PROMPT
IMAGE
Panasonic

# The Franklin Quantic 1200.

Now, for the first time, Franklin makes it possible to digitize complete cardiac cycles in real time and quantitate the massive amounts of information captured by video echocardiographic studies.

In fact, the Quantic 1200 uses all the significant information on every frame of a cycle to guide and correct the information on every other frame of the same cycle.

This allows the computer to:

- Automatically recognize and track the borders of the endocardium. (The operator has the flexibility to interrupt the process, draw new borders, and edit at any time.)
- Perform comparative analyses of normal and abnormal beats using segmental wall motion displays.
- And provide repeatable calculations on perimeters, areas, volumes, and ejection fractions.

All within a few short minutes.

So, now you can make decisions based on more complete and more precise information about the region, extent, magnitude, and timing of heart abnormalities from non-invasive images.

Furthermore, because the entire process is repeatable, relatively inexpensive, and non-invasive, the Franklin Quantic 1200 provides you with the first practical way to monitor and evaluate heart performance before and after therapy.

**FRANKLIN**

We make it possible.

# The Franklin Quantic 1200.

## It can give you more useful information, *faster.*

It is, in fact, the first computer fast enough and powerful enough to capture and digitize the massive amounts of data present in real time ultrasound video signals.

In addition, the Quantic 1200 is the only echocardiographic computer on the market with enough power to apply the extraordinarily complex algorithms researchers are currently developing for future clinical use. These include automatic edge detection, tissue characterization, image processing, frame-to-frame averaging, motion detection, and noise reduction.

Yet, for all its sophistication, the Quantic 1200 is even simpler to operate than many home/office minicomputers.

Compare these features with any other system at any price:

### SOFTWARE

Operator-friendly, screen-prompted software programs provide faster access to information and greater flexibility than any other system currently available.

Furthermore, because all programs are designed for maximum simplicity and ease of operation, no prior knowledge of computers is necessary for full clinical use of the Quantic 1200.

### CLINICAL PROGRAMS

Five of the most widely accepted algorithms used to calculate 2D echocardiographic measurements of areas, volumes, ejection fractions, and other essential derived physiological data.

A full complement of M-mode programs for calculations from both video and hard copy.

Automatic Border Recognition Algorithm developed for Franklin under exclusive license by one of the nation's leading university research centers. (Clinical human validation studies ongoing.)

Full cycle analysis programs including three segmental wall motion algorithms and one area/perimeter change analysis algorithm.

### REAL TIME FRAME GRABBER

Capable of capturing and digitizing complete cardiac cycles in real time.

### DIGITAL STORAGE

Hard disk for efficient storage and retrieval of 1200 discreet frames of video information.

### COMPUTER

Special purpose, 16 bit computer.
Half-million byte RAM memory (expandable).
High speed, high resolution graphics system.

### TWO MONITORS

Two high resolution, 9-inch screens; one for prompting, one for imaging.

### KEYBOARD

Typewriter quality, full alphanumeric keyboard for convenient labeling and data entry.

### JOY STICK

Precision, strain gauge joy stick, custom-designed by Franklin for the specific task of tracing borders of the endocardium.

### DIGITIZING PAD

High resolution, convenient digitizing pad and pen.

### PRINTER

High resolution, dot matrix graphics printer.

### PRINT SPOOLER

Stores and prints up to eight pages of summary. Operator never waits to perform other computer functions.

### OTHER FEATURES

- Fully programmable with optional floppy disk drive and software.
- Modular software upgrades on floppy disks will be available.
- Off-line video and hard copy capability.
- On-line real time capability.
- Video archiving.
- Compatible with all video ultrasound systems.
- Portable and compact.
- Rugged, reliable, solid state components.

We make it possible.

# Electrophysiologic Mechanism of Exercise-Induced Sustained Ventricular Tachycardia

RUEY J. SUNG, MD, EDWARD N. SHEN, MD, FRED MORADY, MD,
MELVIN M. SCHEINMAN, MD, DAVID HESS, MD, and ELIAS H. BOTVINICK, MD

**To elucidate electrophysiologic mechanism of exercise-induced ventricular tachycardia (VT), electrophysiologic studies were performed in 12 patients in whom sustained VT had developed during treadmill exercise testing. Six patients had arteriosclerotic coronary heart disease, 3 had cardiomyopathy, and 3 had no clinical evidence of organic heart disease. All patients had had documented episodes of sustained VT related to exertion and had experienced dizziness, syncope, or both. In addition, 3 patients had had nonfatal cardiac arrest. Electrophysiologic studies provoked paroxysms of sustained VT identical to those observed during treadmill exercise testing in 10 patients and provoked ventricular flutter/fibrillation in 1. Seven patients had VT suggestive of a reentrant mechanism, as the VT could be readily initiated with programmed ventricular extrastimulation or terminated by ventricular overdrive pacing, or both. Three patients had VT suggestive of catecholamine-sensitive automaticity. The VT could not be initiated with programmed electrical stimulation, but it could be provoked by intravenous isoproterenol infusion; furthermore, the VT could not be terminated with ventricular overdrive pacing, but it could be abolished by discontinuing isoproterenol infusion. Reproduction of VT in these 10 patients allowed serial pharmacologic testing in selecting an effective antiarrhythmic regimen. Thus (1) exercise-induced VT can be caused by either reentry or cathecholamine-sensitive automaticity, and (2) electrophysiologic studies are of use in defining the underlying mechanism of exercise-induced sustained VT.**

In 1927, Bourne[1] suggested the use of exercise in exposing ventricular arrhythmias, particularly in patients with arteriosclerotic coronary heart disease. In 1932 Wilson et al[2] described a form of paroxysmal VT induced by exertion in patients without clinical evidence of organic heart disease. Several clinical investigators[3–11] subsequently demonstrated that exercise stress testing may provoke ventricular arrhythmias in normal subjects as well as in those with cardiac disease. Although changing heart rate, enhanced sympathetic nervous activity, increased catecholamine secretion, and development of myocardial ischemia have been implicated as contributing factors, the mechanism by which exercise-induced ventricular arrhythmias occur remains poorly understood. In the course of evaluating 12 patients in whom sustained VT developed during treadmill exercise testing, we performed electrophysiologic studies to delineate the underlying electrophysiologic mechanism. Our findings suggest that exercise-induced sustained VT can be caused either by reentry or by catecholamine-sensitive automaticity.

From the Division of Cardiology, Department of Medicine, and the Cardiovascular Research Institute, University of California at San Francisco, San Francisco, California. ## Methods

**Study patients:** The study population consisted of 12 patients who had sustained VT (lasting >30 seconds or requiring pharmacologic or electrical intervention, or both, because of circulatory collapse) during multistaged graded-treadmill stress testing using the Bruce protocol.[12] We selected these patients because electrophysiologic studies are more likely to reproduce the arrhythmia in patients with sustained than those with nonsustained VT.[13] Nine patients had complete cardiac catheterization and coronary angiography before admission.

**Electrophysiologic study:** Before the study, antiarrhythmic drugs were withheld for over 5 half-lives. The study was performed with patients in a postabsorptive, nonsedated state. With the conventional method,[14] a tetrapolar electrode catheter was introduced from the right femoral vein and, under fluoroscopy, placed in the right atrium across the tricuspid valve to record the His bundle potential. Another tetrapolar electrode catheter was also introduced from the right femoral vein and placed in the high right atrium for programmed atrial stimulation or placed in the right ventricle for programmed right ventricular stimulation. Electrocardio-

graphic leads $V_1$, I, and III were simultaneously displayed with intracardiac electrograms on a multichannel oscilloscope (Electronics for Medicine, VR-12, White Plains, New York), and recordings were made at a paper speed of 50 to 100 mm/s using filter frequency settings of 30 to 500 Hz.

A programmed digital stimulator (Bloom & Associates, Narberth, Pennsylvania) was used to deliver electrical impulses of 2.0 ms duration at approximately twice diastolic threshold. Programmed electrical stimulation consisted of incremental pacing and extrastimulation,[15] and was performed in the right atrium, right ventricle (apex and outflow tract), and, if necessary, in the left ventricle by way of a bipolar electrode catheter placed in the left ventricular apex through the right femoral artery. During programmed ventricular extrastimulation, the ventricle was paced at 2 cycle lengths (usually 500 and 400 ms). If a single ventricular extrastimulus failed to elicit VT, timed double or triple ventricular extrastimuli were delivered until the arrhythmia was provoked or until all extrastimuli failed to evoke ventricular responses.

If programmed electrical stimulation could not initiate VT, isoproterenol was infused intravenously at a rate of 1 to 4 μg/min until the sinus rate was accelerated to a maximum of 150 beats/min. If intravenous infusion of isoproterenol alone did not provoke an onset of VT, programmed electrical stimulation was repeated during isoproterenol infusion.[16]

After initiation of a sustained paroxysm of VT, timed ventricular premature stimuli, short bursts of rapid (overdrive) ventricular pacing, or both, were delivered to terminate the VT.

**Classification of mechanisms of VT:** Mechanisms of VT can be only presumptive during electrophysiologic studies in humans.[17] The 3 major ones are reentry, abnormal automaticity, and triggered activity. VT of a reentrant mechanism is suggested by the ability to initiate the VT with ventricular extrastimulation, or terminate the VT with ventricular extrastimulation or ventricular overdrive pacing. VT of automaticity is caused by rapid automatic discharge related to spontaneous phase 4 depolarization.[18] Its presence is suggested by the fact that it can neither be initiated nor terminated by programmed electrical stimulation.[17] In contrast, triggered activity related to delayed afterdepolarizations[19,20] does not arise spontaneously and is dependent upon previous depolarizations for its initiation. Clinical electrophysiologic studies[21,22] have suggested that this type of VT may be initiated during sinus rhythm or during atrial or ventricular paced rhythm within a critical range of cycle lengths and may be abolished by intravenous infusion of slow channel blockers such as verapamil.

## Results

**Clinical observations:** There were 9 men and 3 women aged 18 to 74 years (mean 49). The clinical data are summarized in Table I. Six patients had arteriosclerotic coronary heart disease (5 had prior myocardial infarction and 2 had ventricular aneurysm), 3 patients had cardiomyopathy (2 dilated and 1 hypertrophic), and the remaining 3 patients were judged to have no clinically recognizable heart disease except for the rhythm disturbance. None had prolongation of the Q-T interval. All 12 patients had a history of recurrent sustained VT that occurred during exertion but not at rest, the duration of which ranged from 3 months to 5 years. The physical activities that precipitated onset of VT included walking, jogging, house cleaning, and playing golf or tennis. All of them had had palpitations, dizziness, syncope, or a combination of these. Three patients (Cases 2, 8, and 11) also had had nonfatal cardiac arrest, presumably due to degeneration of VT to ventricular fibrillation.

Before electrophysiologic studies, we analyzed the onset of sustained VT induced during treadmill exercise testing: 1 patient had VT during stage II, 2 patients during stage III, 4 patients during stage IV, and 1 patient during stage V of the Bruce protocol; in the remaining 4 patients VT developed during the recovery period after exercise. None of the 12 patients had chest pain or exhibited ischemic S-T segment depression before the onset of VT. Three patients (Cases 1, 4, and 12) received intravenous lidocaine and 2 patients (Cases 2 and 8) required direct-current countershock because of hemodynamic deterioration.

The rates of VT ranged from 150 to 210 beats/min. Seven patients had VT of a right and 5 patients of a left bundle branch block pattern.

**Electrophysiologic studies:** Except for 2 patients (Cases 6 and 12), we were able to provoke paroxysms of sustained VT with a QRS morphology identical to that induced with treadmill exercise testing. Based on the mode of initiation and termination of the arrhythmia, we classified the 12 patients into 3 groups:

1. *Induction of VT suggestive of reentry.* In 7 patients (Cases 1, 2, 4, 8, 9, 10, and 11), the mechanism of VT was considered due to reentry as the tachycardia

**TABLE I Clinical Observations**

| Case | Age (yr) & Sex | Type of Cardiac Disease | Duration of Symptomatic VT (mo) | Stage of TET (VT Induction) | VT | |
|---|---|---|---|---|---|---|
| | | | | | Rate (beats/min) | QRS Morphology BBB Pattern |
| 1 | 74F | Coronary (HMI) | 6 | II | 180 | Right |
| 2 | 70M | Coronary (HMI) | 12 | III | 200 | Right |
| 3 | 18M | 0 | 24 | IV | 200 | Left |
| 4 | 56M | Cardiomyopathy | 60 | RP | 210 | Right |
| 5 | 52M | 0 | 18 | RP | 150 | Left |
| 6 | 41M | Cardiomyopathy | 3 | IV | 160 | Left |
| 7 | 28F | Cardiomyopathy | 12 | IV | 160 | Left |
| 8 | 58M | Coronary (HMI) | 24 | IV | 190 | Right |
| 9 | 32M | 0 | 12 | V | 180 | Left |
| 10 | 47M | Coronary (HMI) | 6 | RP | 200 | Right |
| 11 | 39F | Coronary (HMI) | 36 | III | 160 | Right |
| 12 | 61M | Coronary | 6 | RP | 170 | Right |

BBB = bundle branch block; HMI = healed myocardial infarction; RP = recovery period; TET = treadmill exercise testing; VT = ventricular tachycardia.

could be initiated by programmed ventricular extrastimulation—6 patients from the right ventricle (2 patients with single ventricular extrastimuli, 1 patient with double ventricular extrastimuli, and 3 patients with triple ventricular extrastimuli) and 1 patient from the left ventricle with double ventricular extrastimuli. One example to illustrate provocation of the same tachycardia with exercise and with ventricular extrastimulation is shown in Figures 1 to 3. The VT so induced could be terminated by ventricular overdrive pacing in 4 patients and by direct-current countershock because of circulatory collapse in 3 patients (Cases 2, 4, and 11).

*2. Induction of VT suggestive of catecholamine-sensitive automaticity.* In 3 patients (Cases 3, 5, and 7), the mechanism of VT was judged due to automaticity because the tachycardia could not be initiated with programmed electrical stimulation. In each instance, VT was provoked by isoproterenol infusion at a dose of 2 to 4 μg/min. Furthermore, VT could not be terminated with timed ventricular extrastimuli or ventricular overdrive pacing; however, it could be abolished by dis-

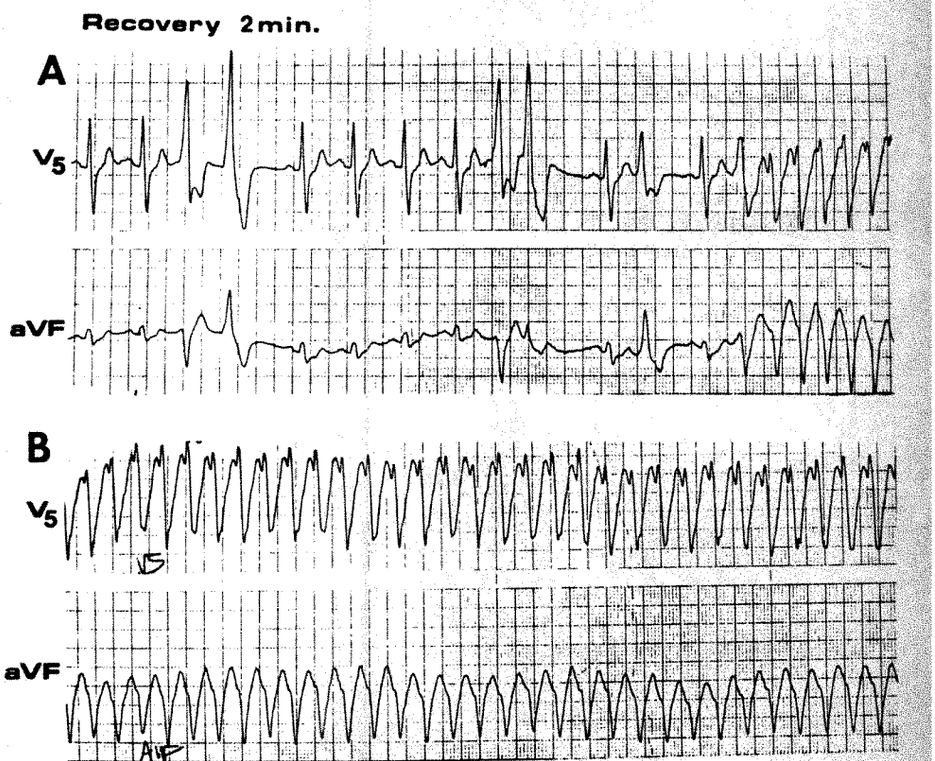

**FIGURE 1.** Onset of sustained VT during the recovery period after a treadmill exercise testing in a 47-year-old man with arteriosclerotic heart disease. The treadmill test was negative for myocardial ischemia up to a heart rate of 160 beats/min. Tracings A and B are continuous and electrocardiographic leads $V_5$ and aVF were simultaneously recorded. Multiform ventricular extrasystoles appear at 2 minutes into the recovery period and are followed by an onset of sustained VT at a rate of 200 beats/min.

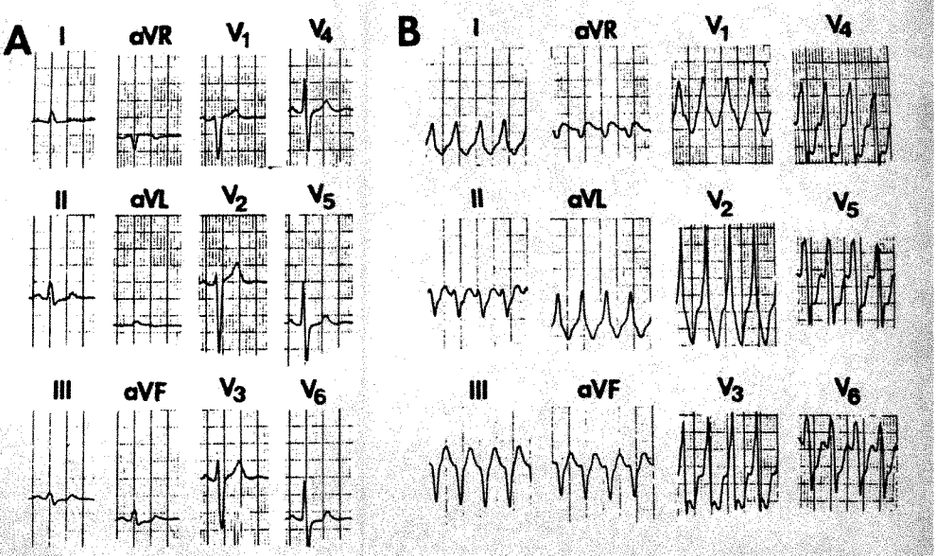

**FIGURE 2.** Same patient as in Figure 1. Comparison between 12-lead electrocardiogram taken during normal sinus rhythm (**A**) and that taken during exercise-induced VT (**B**) as demonstrated in Figure 1. Note that the VT has a positive QRS deflection in leads $V_1$ and I, and a negative QRS deflection in lead III.

continuing isoproterenol infusion. One example to illustrate provocation of the same tachycardia with exercise and with isoproterenol infusion is shown in Figures 4 to 6.

*3. Failure to reproduce VT.* In 2 patients (Cases 6 and 12) exercise-induced VT could not be reproduced during electrophysiologic studies. In 1 (Case 12), programmed right ventricular stimulation provoked ventricular flutter-fibrillation necessitating direct-current countershock. The mechanism of exercise-induced VT could not be classified in this patient. In the remaining patient (Case 6), programmed electrical stimulation and isoproterenol infusion failed to induce ventricular arrhythmia. The mechanism of exercise-induced VT was presumed to be due to automaticity.

**Pharmacologic testing and subsequent follow-up:** In 3 of the 7 patients with VT suggestive of reentry, propranolol was first administered intravenously (0.15 to 0.20 mg/kg) and failed to suppress the inducibility of the arrhythmia. Subsequently, 2 of these 3 patients responded to intravenous infusion of procainamide (15 to 20 mg/kg). In the remaining 4 patients, 2 responded to intravenous infusion of procainamide and 2 did not. Overall, 4 patients (Cases 1, 9, 10, and 11) responded to intravenous infusion of procainmide and were treated with oral procainamide (2 to 6 g/day). The 3 patients (Cases 2, 4, and 8) who did not respond to intravenous procainamide were subsequently treated with oral amiodarone (400 to 600 mg/day) since the arrhythmia was refractory to other antiarrhythmic drugs. In a follow-up period of 5 months to 2 years (mean 14 ± 3 months), 3 patients (Cases 1, 9, and 10) required readjustment of medications because of recurrence of symptoms, but all were clinically improved.

In the 3 patients with VT suggestive of catecholamine-sensitive automaticity, intravenous infusion of propranolol (0.15 to 0.20 mg/kg) prevented acceleration of the sinus rate beyond 100 beats/min and suppressed inducibility of VT during isoproterenol infusion in all 3 patients. They were subsequently treated with oral nadolol (120 to 320 mg/day). During a follow-up period of 6 to 15 months (mean 8 ± 2), 1 patient (Case 5) required addition of oral procainamide (2 g/day) to control exertion-induced palpitations and the remaining 2 patients remained free of symptoms.

Amiodarone was given to the 2 patients in whom electrophysiologic studies failed to reproduce the arrhythmia because of a history of failure to respond to conventional drugs. These 2 patients did well without recurrence of symptoms during a follow-up period of 4 and 7 months, respectively.

## Discussion

Observations made in the present study indicate that electrophysiologic studies can reproduce exercise-induced sustained VT in 10 of the 12 patients, and that the occurrence of exercise-induced sustained VT can be caused either by reentry or by catecholamine-sensitive automaticity.

**Mechanism of exercise-induced ventricular arrhythmias:** Several clinical studies[4,5,7,8] have demonstrated that ventricular arrhythmias may be heralded by ischemic S-T segment depression or angina pectoris, particularly in patients with arteriosclerotic coronary heart disease. Development of ischemic S-T segment depression, angina pectoris, or both usually diminishes the duration of exercise and thereby decreases the degree of myocardial stress preventing provocation of ventricular arrhythmias. Several investigators[6-8] have noted that exercise-induced ventricular arrhythmias often occur in the absence of ischemic S-T segment depression or angina pectoris. It is postulated that enhanced sympathetic nervous activity or increased secretion of catecholamines may alter electrophysiologic properties of the ventricular myocardium or the subendocardial Purkinje network, thereby enhancing automaticity or favoring the occurrence of reentry, or both.[23] Although myocardial ischemia cannot be completely excluded without perfusion scintigraphy, the results of our study confirmed that either reentry or catecholamine-sensitive automaticity may cause exercise-induced sustained VT.

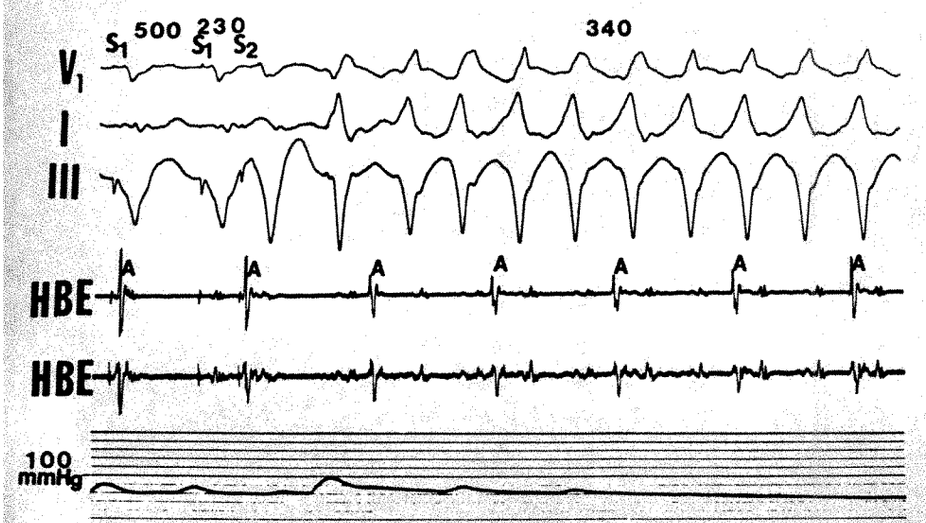

**FIGURE 3.** Same patient as in Figures 1 and 2. Initiation of sustained VT with programmed right ventricular extrastimulation. Electrocardiographic leads $V_1$, I, and III are simultaneously recorded with the His bundle electrographic lead (HBE). Right femoral arterial pressure is recorded at the **bottom**. During right ventricular pacing at a cycle length ($S_1$–$S_1$) of 500 ms, a ventricular premature beat ($S_2$) with a premature coupling interval ($S_1$–$S_2$) of 230 ms initiates an onset of VT with a cycle length of 340 ms. Note that the QRS morphology of the VT is identical to that induced during treadmill exercise testing (Fig. 2). The VT could be terminated by overdrive suppression (not shown). A = atrial electrogram.

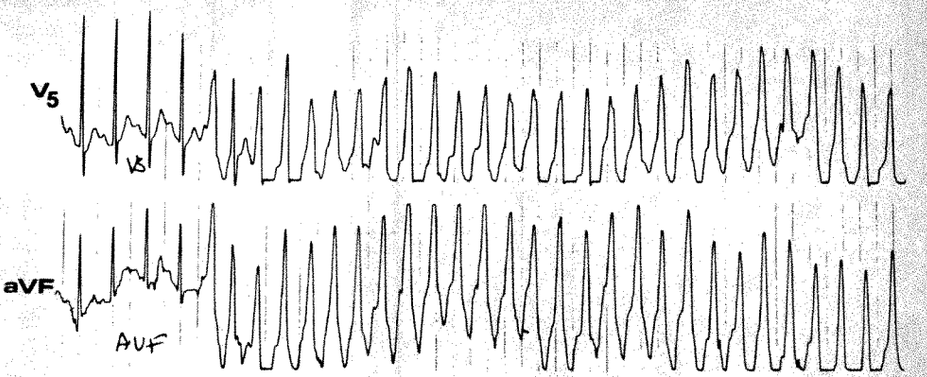

**FIGURE 4.** Onset of sustained VT at 1.1 minute into stage IV of a treadmill exercise testing in an 18-year-old man without clinical evidence of organic heart disease. The sinus rate is accelerated to 150 beats/min before the onset of VT at a rate of 190 beats/min. Electrocardiographic leads $V_5$ and aVF are simultaneously recorded.

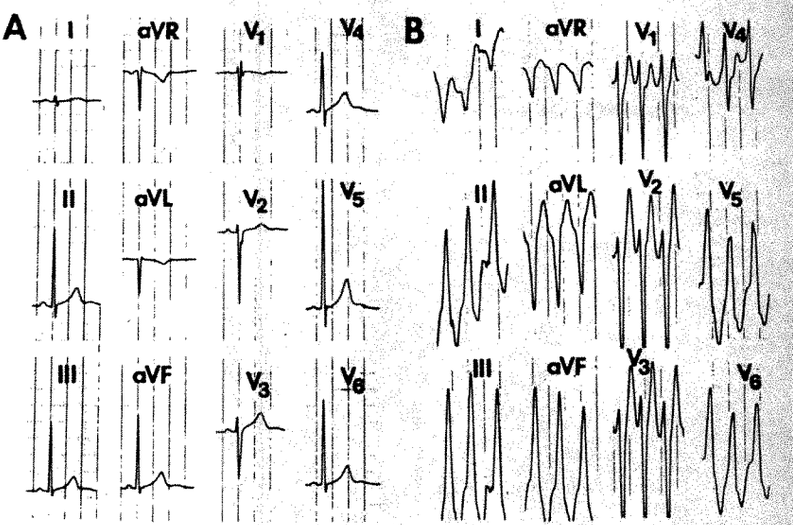

**FIGURE 5.** Same patient as in Figure 4. Comparison between 12-lead electrocardiogram taken during sinus rhythm (**A**) and that taken during exercise-induced VT (**B**) as demonstrated in Figure 4. Note that the VT has a predominantly negative QRS deflection in leads $V_1$ and I, and a positive QRS deflection in lead III.

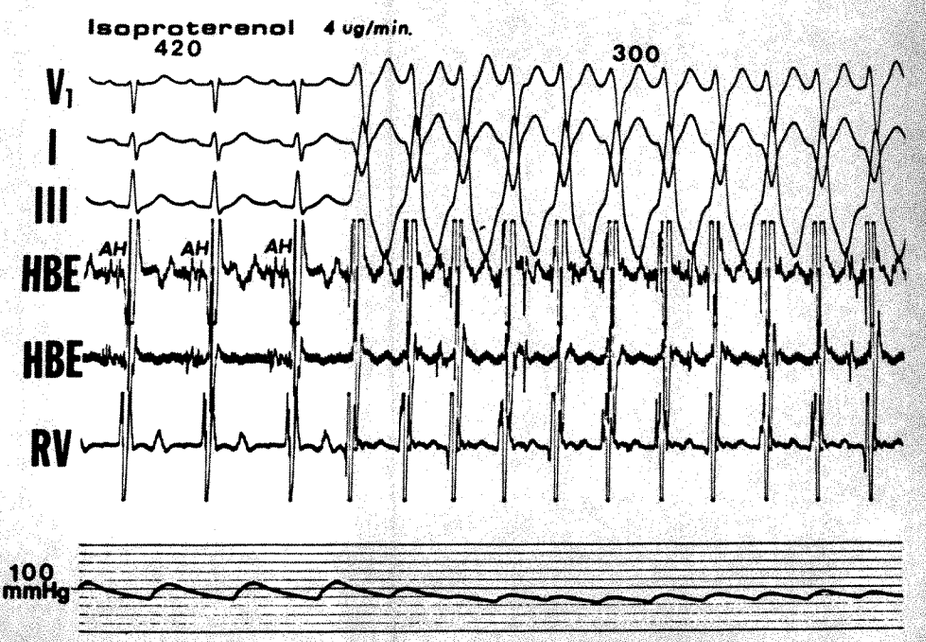

**FIGURE 6.** Same patient as in Figures 4 and 5. After failure of programmed electrical stimulation to induce arrhythmia, isoproterenol infusion at 4 $\mu$g/min accelerates the sinus rate (cycle length 420 ms) and provokes an onset of sustained VT with a cycle length of 300 ms. Electrocardiographic leads $V_1$, I, and III, His bundle electrographic lead (HBE), and right ventricular electrogram (RV) are simultaneously recorded. Right femoral arterial pressure is recorded at the bottom. A = atrial electrogram; H = His bundle electrogram. Note that the QRS morphology of the VT is identical to that induced during treadmill exercise testing (see Fig. 5).

Triggered activity related to delayed afterdepolarizations has been raised as a possible mechanism of exercise-induced VT.[24] Based on our recent study,[22] we believe that VT caused by such a mechanism has certain electrophysiologic characteristics: (1) its onset depends on a critical range of cycle lengths; therefore, it may or may not require exercise to induce the arrhythmia; (2) it can be initiated during sinus, atrial, or ventricular paced rhythm within the critical range of cycle lengths; (3) it is more easily triggered with pacing the atrium or ventricle for several beats than with single extrastimuli; (4) the interval between the first beat of tachycardia and the last sinus or paced beat (QRS complex) gradually decreases as the sinus or paced cycle length progressively shortens; and (5) its initiation can be prevented by intravenous infusion of slow channel blockers such as verapamil. In the evaluation of patients with exercise-induced VT, the possibility of having triggered activity as the underlying mechanism should also be considered.

**Treatment of exercise-induced ventricular arrhythmias:** In patients with exercise-induced ventricular arrhythmias related to myocardial ischemia, treatment should be directed toward prevention of the development of myocardial ischemia. This includes the use of nitrates, beta-adrenergic blocking agents, and slow channel blockers in the presence or absence of coronary artery spasm as a contributing factor.[25] In this situation, aortocoronary bypass grafting may be expected to be useful in abolishing the arrhythmia.[26,27]

In patients with exercise-induced ventricular arrhythmias not related to myocardial ischemia, the treatment should, however, be directed toward controlling the underlying mechanism. In this series, beta-adrenergic blockade with intravenous propranolol failed to suppress inducibility of VT suggestive of a reentrant mechanism (3 patients), but was effective in preventing induction of VT suggestive of catecholamine-sensitive automaticity (also 3 patients). Overall, amiodarone appeared to be an effective antiarrhythmic agent for cases that are refractory to or intolerant of conventional drugs (5 patients). We realize that the number in each group of patients is small, and further studies are necessary to define the long-term efficacy of various antiarrhythmic agents in the treatment of exercise-induced VT.

Myocardial revascularization is not expected to be useful in abolishing ventricular arrhythmias not related to ischemia.[28] Nevertheless, it should be pointed out that VT caused by reentry or automaticity may be corrected by surgical removal of the reentrant pathways or the automatic focus.[29]

**Clinical implications:** Observations made in the present study have the following important clinical implications: (1) Exercise-induced ventricular arrhythmias may or may not be related to myocardial ischemia, and electrophysiologic mechanisms responsible for these arrhythmias vary among patients. Reentry, automaticity, and triggered activity all need to be considered. Understanding of the underlying pathophysiology allows a more rational approach to the treatment. (2) In patients with exercise-induced sustained VT, electrophysiologic studies may be useful in reproducing the arrhythmia, thereby allowing serial pharmacologic testing for selecting a proper antiarrhythmic regimen.

**Acknowledgment:** We thank Ardith Perry for technical assistance in performing treadmill exercise testing and Lynn Whittier for secretarial assistance in the preparation of this manuscript.

# Programmed Electrical Stimulation of the Heart in Coronary Artery Disease

PETER R. KOWEY, MD, EDWARD D. FOLLAND, MD, ALFRED F. PARISI, MD, and BERNARD LOWN, MD

**The induction of ventricular arrhythmia in patients with a history of malignant ventricular arrhythmia by programmed electrical stimulation (PES) is associated with a poor prognosis. However, the incidence and significance of inducible arrhythmia in patients with stable coronary artery disease (CAD) who do not have a history of serious arrhythmia are unknown. We studied 32 such patients (31 men, mean age 55 years) with PES at the time of cardiac catheterization. Fourteen patients (Group I) manifested ≥3 extraventricular responses when challenged with 1 to 3 propagated right ventricular extrastimuli during ventricular pacing. Twelve (86%) of these 14 had evidence of left ventricular dysfunction (LVD), defined by a global ejection fraction of <50% or regional wall motion abnormalities. The remaining 18 patients (Group II) manifested ≤2 responses to extrastimulation. Only 4 (22%) of these 18 had LVD. Proximal 3-vessel CAD was more frequent in Group I patients (10 of 14, 71%) than in Group II (7 of 18, 39%). Only 5 patients (4 from Group I and 1 from Group II) demonstrated complex arrhythmia during exercise testing or ambulatory monitoring. The induction of extraventricular responses during PES may serve as an independent marker of electrical instability in the coronary population and is a much more common finding in those with LVD.**

Identifying the patient at risk for sudden cardiac death is one of the key problems in contemporary cardiology.[1-3] Patients with CAD have been found to be uniquely susceptible to sudden death, but current methods to distinguish those at highest risk are neither specific nor sensitive.[4,5] One approach is based on the ventricular premature beat (VPB) hypothesis[6] and uses exercise testing and ambulatory monitoring to expose advanced grades of ventricular premature depolarizations.[7,8] Since about 40% of patients with ischemic heart disease have advanced grades of VPBs on monitoring and exercise testing, it is necessary to select from this subgroup the much smaller group of patients who are susceptible to sudden death. This more precise identification of high-risk patients will require additional techniques.

PES has been increasingly useful in the study and treatment of recurrent ventricular arrhythmia. Heretofore, this method has been largely limited to the selection of a therapeutic regimen in symptomatic patients.[9,10] Whether PES can be applied to a group of patients with CAD who are at risk of sudden death in order to determine the degree of susceptibility has not been systematically explored.

The objective of the present study was to evaluate the response of patients with stable angina pectoris to programmed electrical stimulation. We were most interested in establishing whether a relation exists between the number of responses to PES and markers of severity of CAD such as the left ventricular ejection fraction, regional wall motion abnormalities, and extent of atherosclerotic lesions determined by angiography. In addition, we compared the response to extrastimulation with the amount of arrhythmia which could be exposed by exercise testing and ambulatory monitoring.

## Methods

Consenting patients with a history of stable angina pectoris who underwent diagnostic cardiac catheterization at the West Roxbury Veterans Administration Medical Center were included in the study. Informed consent was obtained in all cases using a form previously approved by the Human Studies Committee at the West Roxbury Veterans Administration Medical Center. Patients were excluded if there was (1) a history of a myocardial infarction in the previous 3-month period, (2) a suspicion of significant valvular heart disease, (3) unstable angina pectoris defined as angina at rest accompanied by S-T segment changes, or (4) a history of unexplained

syncope or known ventricular tachycardia or fibrillation. All medication was withdrawn with the exception of digitalis, beta-adrenergic blocking agents, and nitrate derivatives. Five half-lives of the medication withdrawn were allowed to elapse before any testing was performed.

**Exercise testing and ambulatory monitoring:** Before catheterization all patients underwent exercise treadmill testing according to the protocol of Bruce and Doan.[11] Each patient exercised to fatigue but the test was prematurely terminated for severe angina pectoris, claudication, ventricular tachycardia, S-T segment elevation, or hypotension. Heart rate and blood pressure were continuously monitored along with rhythm, before, during, and after the exercise period.

Ambulatory monitoring was carried out within 48 hours of catheterization using a portable cassette system. A 24-hour period was chosen since it provided the highest yield of arrhythmia within the time constraints of the patient's hospitalization and represented 1 complete diurnal sleep-wake cycle. The recording system allowed simultaneous recording of 2 electrocardiographic leads ($V_1$ and $V_5$). An audiovisual scanning technique was used to review tape records. The accuracy of the interpretation was assessed by a physician who personally reviewed direct printouts of each grade of VPB.

For purposes of quantification, VPBs exposed by either monitoring or exercise testing were graded according to the Lown grading system, wherein Grade 0 = no VPBs; Grade 1 = <30 VPBs/h; Grade 2 = >30 VPBs/h; Grade 3 = multiform VPBs; Grade 4A = ventricular couplets; Grade 4B = ventricular salvos (≥3); and Grade 5 = early cycle (R on T) VPBs.[6]

**Cardiac catheterization:** Patients were taken to the cardiac catheterization laboratory in the postabsorptive state, after having received 5 to 10 mg of oral diazepam. A maximum of 10 ml of 1% xylocaine was used as the local anesthetic for introduction of the catheters using an antecubital or femoral approach. Right heart catheterization was first carried out and included determinations of right heart chamber pressures, pulmonary capillary wedge pressures, and oxygen saturation. A left heart catheterization was then performed which included left ventricular angiography and coronary arteriography. At the conclusion of the left heart study, all catheters were withdrawn. In patients found to have a lesion of the left main coronary artery of >75% and in those who had severe angina pectoris during the catheterization, the procedure was ended. A total of 12 patients were thus disqualified. In the remainder of the patients, electrophysiologic studies were carried out after a waiting period of at least 30 minutes.

**Electrophysiology study:** A quadripolar catheter (interelectrode distance of 1.0 cm) was introduced directly into the cephalic vein or into the femoral vein, using the venous introducer which was employed during the right heart catheterization. This pacing catheter was passed directly into the apex of the right ventricle. An intraventricular electrogram was recorded from the proximal 2 poles of the quadripolar unit, together with standard electrocardiographic leads I, II, and $V_1$. Signals were recorded on an Electronics-for-Medicine multichannel recorder (VR-12) at a paper speed of 25 to 50 mm/s using a frequency range of 30 to 500 Hz. The distal 2 poles of the quadripolar catheter were used for pacing and programmed stimulation. A Lown design cardiac stimulator was used, capable of delivering test stimuli of 2 ms duration with a square wave contour. The unit included a constant current operational power supply with a 2% accuracy, and a timing accuracy of ±3 ms. This unit included a ventricular demand pacemaker adjusted to deliver rectangular pulses of 2 ms duration. Each patient was paced at a rate which was 10 beats/min greater than the intrinsic heart rate. Pacing current used was the lowest amount necessary to achieve consistent ventricular capture.

The mid-diastolic threshold was determined by setting the first extrastimulus ($S_2$) approximately 400 ms after the pacing artifact ($S_1$), beyond the inscription of the T wave on the intracavitary electrocardiogram. $S_2$ was delivered after 8 consecutive ventricular paced beats. After the delivery of the extrastimulus, the output of the pacemaker was interrupted for 3 seconds to allow for a clear observation of the stimulus responses. The current of $S_2$ was set at 0.2 mA and increased in 0.2 mA steps until an extrasystole ($V_2$) was provoked. That current defined the mid-diastolic threshold.

The protocol used for the extrastimulation testing is displayed in Figure 1. The extrastimulus ($S_2$) was initially set at twice the mid-diastolic threshold, 400 ms after the pacing artifact. $S_2$ was then delivered progressively earlier in the cardiac cycle, scanning in 10 ms steps, until the effective refractory period was reached. If no extra responses were observed, $S_2$ was reset to thrice mid-diastolic threshold and scanning toward the refractory period was repeated. If $S_2$ failed to elicit extraventricular responses, it was set at a point 10 ms outside the effective refractory period at an intensity equal to twice mid-diastolic threshold. A second extrastimulus ($S_3$) was then added 400 ms after $S_2$, at twice and thrice its mid-diastolic threshold, and scanning in 10 ms increments toward $S_2$ was carried out for each stimulus intensity. Again, if no repetitive forms were elicited, a third stimulus ($S_4$) was similarly introduced. The end point of testing was the introduction of 3 extrastimuli, the third delivered at thrice the mid-diastolic threshold, or the provocation of ≥3 extraventricular responses to any test sequence. All stimulation sequences which provoked extraventricular responses were repeated unless sustained ventricular arrhythmia was induced. A response was considered present only if it was observed in 2 of 3 stimulation sequences. His bundle recordings were not obtained. However, electrocardiograms were scrutinized and

an assessment made of whether the responses elicited were due to bundle branch reentry or intraventricular reentry. Criteria for bundle branch reentry were those used by Greene et al[12] and included delay between the ventricular premature stimulus and the extra beat and a QRS morphology similar to the paced complex.

**Analysis of data:** Results of exercise testing, ambulatory monitoring, and cardiac catheterization were analyzed by 2 cardiologists who were blinded to the results of electrophysiologic testing. In addition to quantification of ventricular arrhythmia, each exercise test was scrutinized for evidence of ischemic electrocardiographic response, exercise duration, and indexes of exercise effort, including peak heart rate achieved and functional aerobic impairment. Catheterization results included the number of coronary vessels involved with atherosclerotic lesions, together with an assessment of the proximity and severity of each lesion. A lesion was considered significant if >75% of luminal diameter was obstructed. Ejection fraction was determined using single plane left ventricular angiography in a right anterior oblique projection. Systolic and diastolic volumes were calculated utilizing standard area-length equations.[13] Cineangiograms were likewise scrutinized for evidence of regional wall motion abnormalities using the area method. Segmental ejection fractions were determined for each of 5 major regions of the ventricle. The ejection fraction of each region was calculated as the difference between the diastolic and systolic regional areas divided by the diastolic regional area. A segmental ejection fraction was deemed abnormal if it fell below the 97% confidence interval defined by a group of 17 normal patients.[14] All values given in text represent mean ± standard error of the mean.

Statistical analysis of the data was performed using an unpaired Student's $t$ test wherein differences were considered significant when $p < 0.05$.

## Results

**Clinical characteristics:** A total of 32 patients participated in the study. There were 31 men and 1 woman; the mean age was 55 years. Patients were divided into 2 groups based on their response to programmed electrical stimulation. Group 1 consisted of 14 patients with ≥3 extraventricular responses to up to 3 ventricular stimuli. There were 18 patients in Group II who had 0 to 2 extra responses to 3 stimuli. Table I is a summary of the clinical information for each group. The mean age, angina severity, and medications used were not significantly different. There was a slightly greater number of patients in Group II receiving beta-adrenergic blocking agents (p = not significant [NS]), but the mean daily dose of propranolol taken was similar (120 ± 10 versus 150 ± 8 mg; p = NS). There was a higher incidence of prior myocardial infarction in Group I patients and more frequent congestive failure.

| Grade | | |
| 0–1 | 9 | 15 |
| 2 | 3 | 2 |
| 3 | 2 | 1 |
| 4A | 0 | 0 |
| 4B | 0 | 0 |

The results of exercise testing and ambulatory monitoring are shown in Table II. There was no statistically significant difference between the 2 groups in exercise duration or peak heart rate response. The incidence of S-T segment depression of >1 mm was comparable. Five patients manifested Lown Grade 3 or 4 arrhythmia during either exercise testing or ambulatory monitoring.

**Electrophysiologic testing:** There was no significant difference between the 2 groups in either the mean cycle length used during ventricular pacing (750 ± 15 ms versus 800 ± 12 ms) or in mid-diastolic threshold for $S_2$ (0.8 ± 0.1 versus 0.9 ± 0.2 mA). The threshold current for ventricular pacing ($S_1$) was <2 mA in all cases. The results of electrophysiologic testing are presented in Figure 2. Five patients in Group II manifested no extra responses, 8 had 1 extra response, and 5 had 2 responses. Of these 18 Group II patients, 14 had a global ejection fraction of >50%, including only 1 who displayed an abnormality of wall motion on left ventricular angiography. Eleven of the 14 patients in Group I were shown to have an ejection fraction of <50% ($p < 0.01$ compared with Group II). One of the 3 patients with a global ejection fraction of >50% had inferior wall hypokinesia.

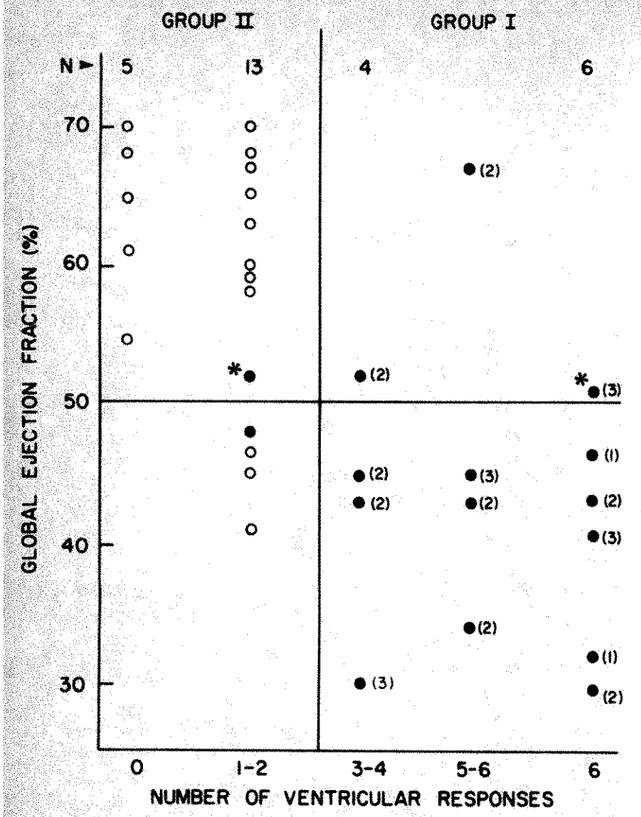

**FIGURE 2.** Number of extraventricular responses provoked during electrophysiologic testing correlated with global ejection fraction. **Parentheses** indicate the number of stimuli used in each Group I patient. **Asterisks** denote the presence of regional wall motion abnormalities in patients with global ejection fraction >50%. **Open and closed circles** denote whether responses resemble bundle branch or intraventricular reentry, respectively.

The number of extrastimuli required to elicit ≥3 responses in Group I patients is shown in parentheses in Figure 2. Although 2 of the patients had >6 responses induced with but 1 stimulus, there was no apparent correlation between severity of ventricular dysfunction and ease of provocation of extra responses. There was also no relation between the severity of dysfunction and the number of responses elicited. More than 6 responses were observed in 6 patients who had global ejection fractions from 28 to 52%. One patient in the series had unexpected ventricular tachycardia which accelerated and required immediate cardioversion. The remainder of the episodes of ventricular tachycardia were self-limited or broken by deep cough. Also shown in Figure 2 is a designation of whether responses resembled bundle branch or intraventricular reentry. Eleven of the 13 patients with 1 or 2 responses manifested bundle branch reentry while all multiple responses of ≥3 appeared to represent intraventricular reentry.

**Cardiac catheterization:** Fourteen of the 18 Group II patients had no regional wall motion abnormalities, in contrast to Group I patients, of whom only 2 had a normal wall motion pattern shown on angiography (Table III). Eight Group I patients with wall motion abnormalities manifested hypokinesia of the anterior and apical segments. The remaining 3 patients had a pattern of diffuse hypokinesia. Akinetic or dyskinetic regions were observed in 3 patients, all of whom were in Group I (one with 4 responses and 2 with >6 responses). There was also a lower left ventricular end-diastolic pressure and end-diastolic volume in Group II patients compared with Group I.

† $p < 0.001$.

The results of coronary arteriography are also displayed in Table III. There was a slightly higher frequency of severe (>75% stenosis) 3-vessel coronary disease in the inducible Group I patients and a greater incidence of 1- or 2-vessel disease in the noninducible Group II patients, but the differences were not statistically significant. There was also no significant difference in the state of collaterals vessels and quality of distal vasculature between the 2 groups.

## Discussion

Techniques routinely used to define coronary anatomy and left ventricular function permit only general conclusions regarding the patient's propensity to die suddenly. Furthermore, methods commonly employed to expose ventricular premature depolarizations, such as exercise testing and ambulatory monitoring, serve well as general screening methods but cannot be used, in many cases, for a precise assessment of risk. PES of the ventricle appears to be capable of uncovering the electrophysiologic lesion that predates the development of ventricular fibrillation. The bulk of experience with this technique, however, has focused on those patients who have had symptomatic arrhythmia and it has been used for the selection of an effective therapeutic regimen. There have been few previous studies which have specifically examined the application of these methods to a high-risk population, free of symptomatic arrhythmia.[15-18] Greene et al[15] studied patients with a recent myocardial infarction and found that the elicitation of repetitive responses was predictive of future cardiac death. Hamer et al[16] also found a higher incidence of sudden death after myocardial infarction in patients who manifested ≥5 extra responses to pro-

grammed stimulation. In a population of patients with heart disease of several types, Gomes et al[17] found that repetitive responses, even those caused by local reentry, were not a reliable predictor of sudden death. Naccarelli et al[18] also found a low predictive accuracy of repetitive responses in a mixed population.

The purpose of the present study was to apply ventricular stimulation techniques in a group of patients, all having stable coronary disease, in order to define the incidence of inducible arrhythmia in this particular population. We found that nearly 40% of the patients studied manifested ≥3 extraventricular responses to 1 to 3 stimuli. This incidence of inducibility is similar to that obtained in patients studied after myocardial infarction[15–16] but greater than that observed in other studies of patients free of symptomatic ventricular arrhythmia.[19,20] The differences in yield are difficult to interpret given the diversity in testing protocols and end points. For example, we used a regimen of cardiac testing which consisted of 1 to 3 ventricular stimuli delivered during ventricular pacing. This type of protocol consistently provokes the greatest number of extra responses in patients with a history of ventricular tachycardia, when compared with other regimens which employ single ventricular stimuli delivered during atrial drive or sinus rhythm.[21,22] In any case, the similar rates of inducibility in our study and previous postinfarction studies suggest that a myocardial infarction renders the heart more susceptible to extrastimulation. The fact that there was no correlation between extent of LVD, defined by global ejection fraction, and the number of responses provoked suggests that the presence rather than the extent of infarct renders the ventricle unstable. This general association between presence of LVD and electrical instability is in agreement with a previous study by Josephson et al[23] who showed a higher rate of inducibility in patients who suffered a cardiac arrest and had evidence of LVD compared with those victims with normal left ventricular function.[23]

We were unable to demonstrate a relation between the extent of CAD and the inducibility of arrhythmia, although there was a trend toward a greater frequency of single-vessel disease in noninducible patients and 3-vessel involvement in those who were inducible. Therefore, the extent of CAD may not influence the susceptibility of the ventricle to electrical stimulation. Studies of larger numbers of patients with varying amounts of atherosclerotic disease will be required to answer this question.

The ability to induce ventricular arrhythmia by programmed stimulation did not correlate with detection of complex ventricular ectopic activity by exercise testing or ambulatory monitoring. In fact, only 5 of the 32 patients manifested either Grade 3 or 4 arrhythmia by either method. It is clear that the disclosure of complex ventricular arrhythmia indicates an increased risk of sudden cardiac death.[24] However, as with any screening measure, absence of ventricular arrhythmia in any individual patient may not obviate that risk and more sensitive, albeit invasive, techniques may be indicated. Programmed stimulation does appear to provide a more sensitive measure of electrical stability in a population of patients with stable CAD. Its specificity and predictive accuracy have yet to be determined.

**Limitations of the study:** Our study was conducted after left ventricular angiography and coronary arteriography. It is conceivable that radiographic contrast material rendered the ventricle more susceptible to electrical stimulation. This is unlikely since electrical testing was performed after a 30-minute respite when electrocardiogram, blood pressure, and heart rate had returned to baseline values.

Patients were studied while continuing cardioactive medication, including digitalis, nitrates, and propranolol. This constitutes a problem since these drugs, in particular beta-blocking agents, may alter inducibility by reducing myocardial ischemia or by a primary antiarrhythmic effect. There was no statistically significant difference between inducible and noninducible groups in the number of patients receiving these drugs nor in the dose used. Furthermore, there was no intergroup difference in exercise duration, peak rate achieved during exercise, number of patients with S-T segment depression, or grade of arrhythmia provoked with exercise or detected by ambulatory monitoring. The similarities in clinical data in inducible and noninducible patients suggest that the results were not significantly influenced by continuation of cardiac drugs.

The electrophysiologic mechanism of the responses elicited in our patients was not fully elucidated. We chose not to employ His bundle recordings, since to do so would have added to the complexity and length of the procedure. His recordings are of obvious importance in differentiating reentry within the His-Purkinje system (macroreentry), a response observed in some normal subjects, from reentry within the ventricle (microreentry), which is felt to be a precursor of sustained arrhythmia.[25,26] The end point of testing in our study was the elicitation of ≥3 ventricular responses. This end point was chosen because reentry within the His-Purkinje system is rarely if ever sustained for >2 beats.[27] Greene et al[12] have pointed out that microreentry is frequently the mechanism of 1 and 2 beat responses in patients with a history of serious arrhythmia. In fact, all responses which persisted for ≥3 beats appear to represent intraventricular reentry using the less precise method of assessing mechanism by timing of the response and QRS morphology.

Finally, no long-term information is available from this study since nearly all of the patients eventually underwent coronary artery bypass surgery. Revascularization procedures have been found to have variable effects on the inducibility of ventricular arrhythmia.[28] Therefore, conclusions regarding the specificity and predictive accuracy of PES in a stable coronary population will await studies which provide more comprehensive follow-up information in patients who do not undergo coronary surgery, or who are studied after revascularization procedures.

**Conclusion:** This study suggests that techniques of PES may be safely applied in patients with CAD. As a group, patients with LVD tended to have more inducible arrhythmia than those with normal ventricles. However, there was a wide spectrum of inducible ar-

rhythmias within the group of patients with ventricular dysfunction; thus the response of any individual patient could not be predicted by routine markers of CAD severity, such as extent of atherosclerotic lesions. Furthermore, most of the inducible patients did not manifest high-grade ventricular ectopy during exercise testing or ambulatory monitoring. The significance of provocable arrhythmia in asymptomatic coronary patients is presently unknown and will only be determined in a long-term study of their outcome. However, if characterization of the response to PES proves to be a marker of the risk of sudden death, these techniques should be integrated into the invasive evaluation of the patient with CAD.

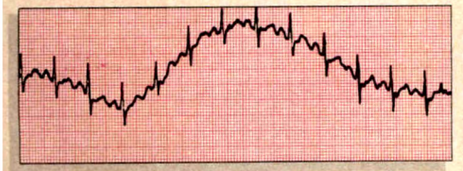
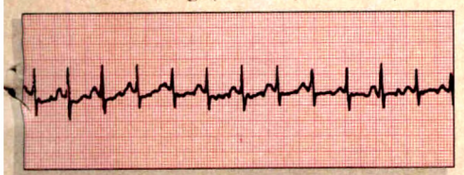
# THE SQUARE ROOT OF A STABLE BASELINE.



# QUINTON'S NEW QP² ELECTRODE.



Now there's a new generation of Quik-Prep™ electrodes: QP². It has a new square shape. And a new lower price. But one thing's still the same: with QP², you'll get stable baselines test after test.

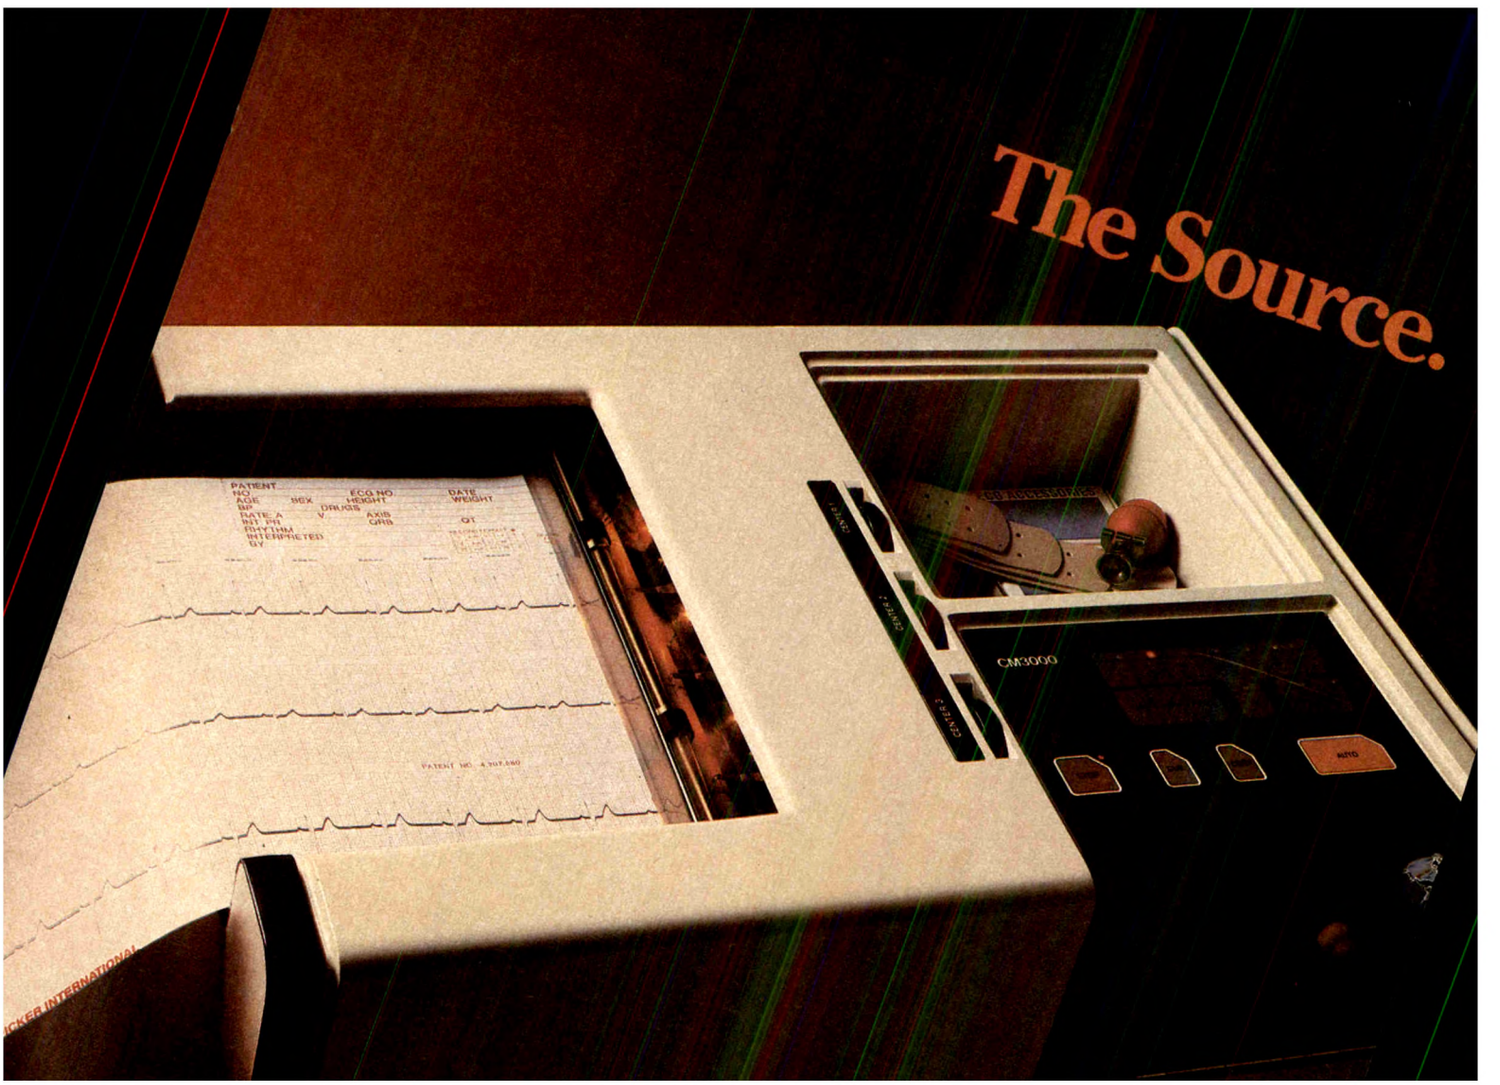
### The key to better ECG traces.

Unprepped skin,
Bruce Test Stage (4.2 MPH, 16% Grade)

Quik-Prepped Skin,
Bruce Test Stage 4 (4.2 MPH, 16% Grade)

The two traces pictured here were taken from the same patient, the same day, using the same equipment. The difference? Quik-Prep's patented skin preparation system. The Quik-Prep applicator, when used in conjunction with a new QP² electrode, precisely measures the electrical impedance of the skin/electrode combination. It provides exactly the amount of skin preparation needed to insure a stable baseline. No more. No less.

### Improved adhesion and conductivity.



Quik-Prep set the standard for electrode accuracy and dependability. Now it's even better. Quinton engineers redesigned the snap and the silver-silver chloride electrode to insure a more solid connection and improved electrical characteristics. And because new QP² is square, it offers more surface adhesion.

### Designed to be affordable.

New QP² is priced significantly lower than the original Quik-Prep electrode. That makes it affordable for a wide variety of uses from stress testing to Holter monitoring to critical care areas—any situation where patient movement can affect ECG baselines. And because it's faster than traditional prepping techniques, you'll save valuable technician time every test.

***Discover the square root of a stable baseline. For a demonstration of QP², call Quinton tollfree at 1-800-426-0347 or write us at 2121 Terry Ave., Seattle, WA 98121. Distributed worldwide.***

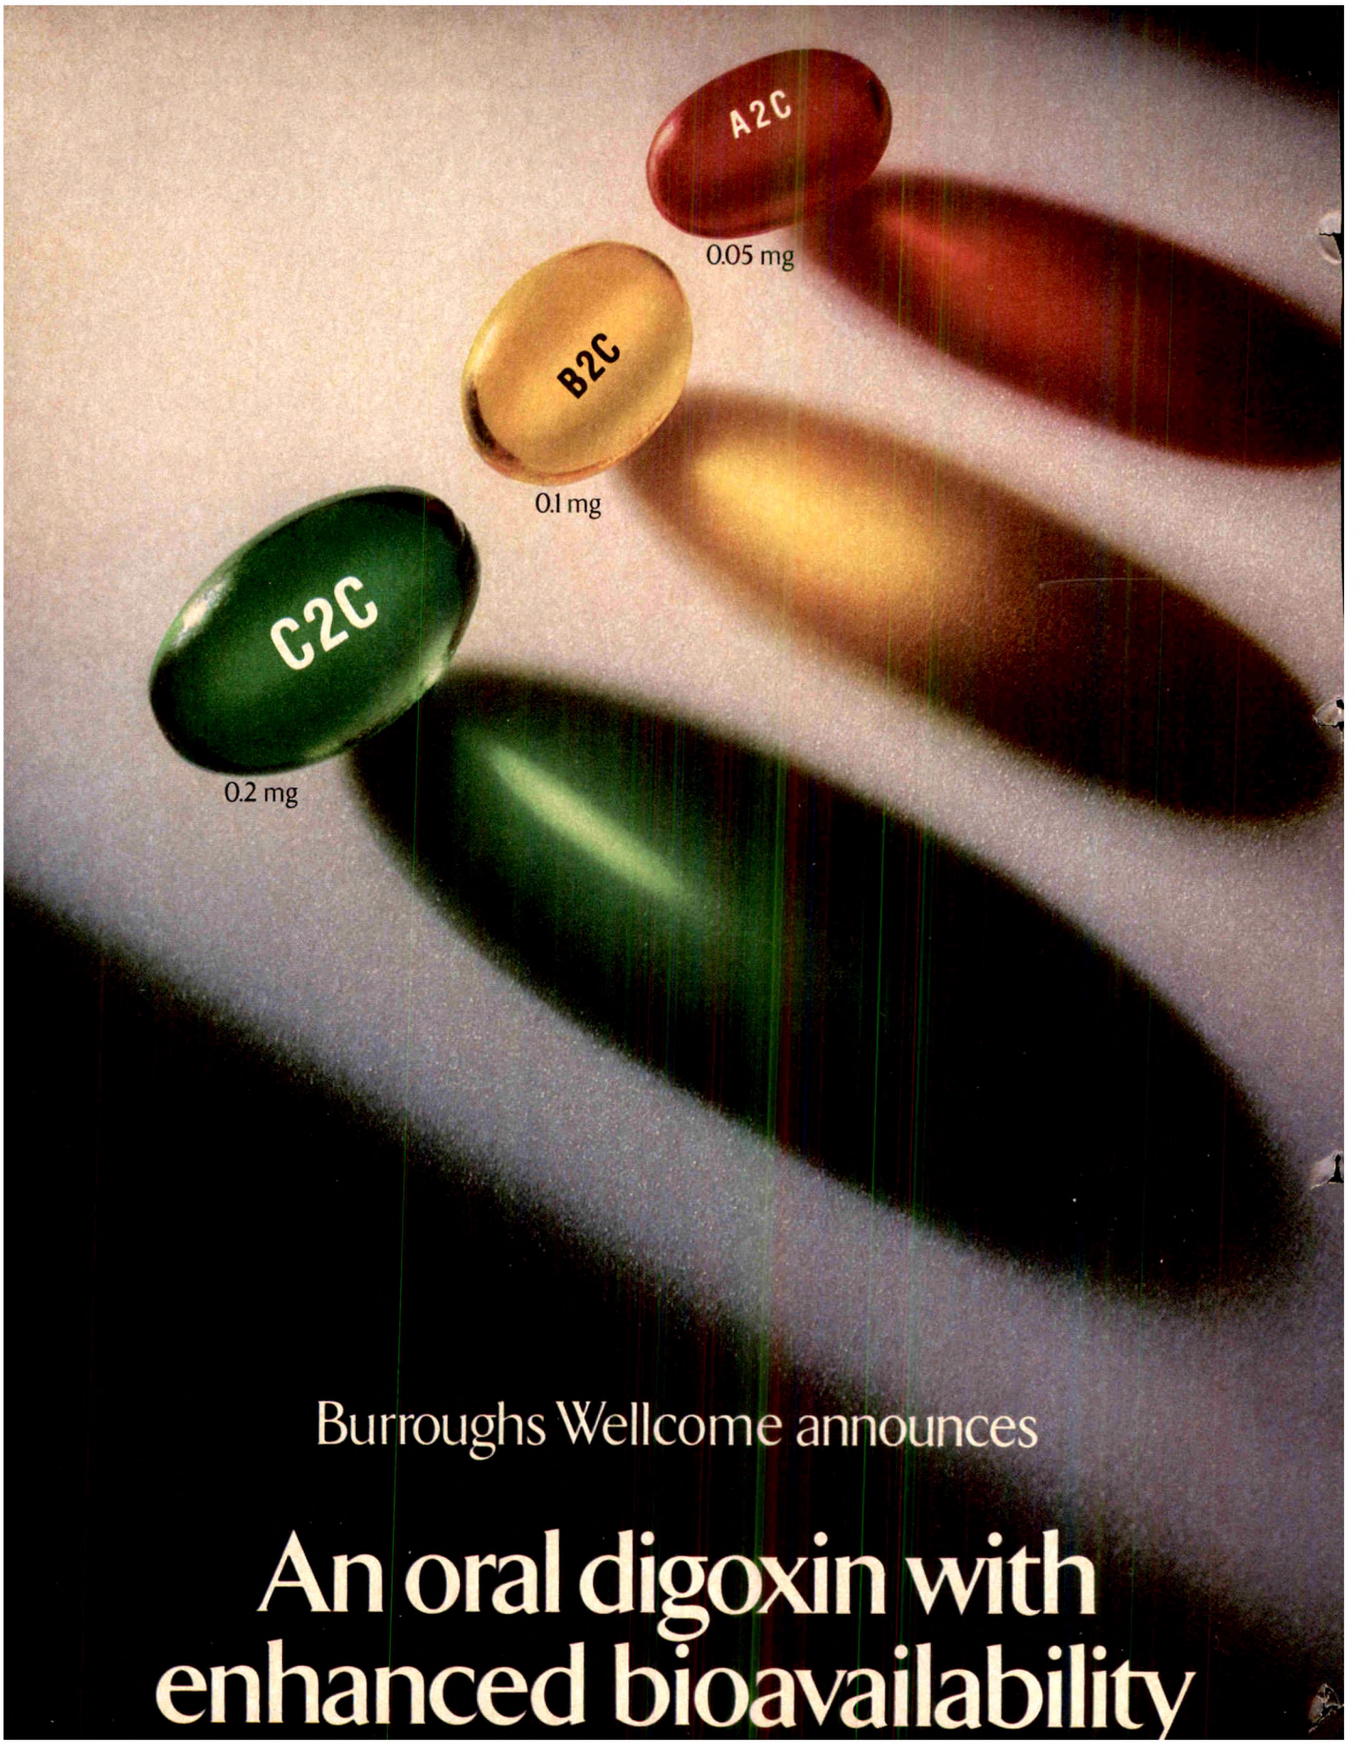
ICKER INTERNATIONAL

# Picker International is the source for cardiography systems.

# To you, this is important.



Having a single source dedicated to meeting all of your cardiography equipment needs can save time in your decision making process.

And, a single source for your service and supply needs can save you time after your purchase, as well.

This three channel ECG with its versatile interactive memory is just one of the exciting new products available from our Cambridge Medical Instruments Group. Others include automatic and manual single channel ECG's; conventional and computer assisted stress test systems; ambulatory and telemetry monitoring systems; and the first truly portable ultrasound system.

We'd like to tell you more about our cardiography systems. Please write Picker International, Inc., 73 Spring St., Ossining, NY 10562; Telephone 914/941-8100 or Telex 137337.

PICKER INTERNATIONAL

Burroughs Wellcome announces

# An oral digoxin with enhanced bioavailability

# Absorption of digoxin from LANOXICAPS® is 90-100% complete!

The enhanced digoxin absorption from LANOXICAPS® compared to tablets and elixir is associated with reduced between-patient and within-patient variability in steady-state serum concentrations.

| Comparison of bioavailability and equivalent doses | | | | |
|---|---|---|---|---|
| Product | Bioavailability | Equivalent Doses (in MG)* | | |
| Lanoxin® Tablet | 60-80% | 0.125 | 0.25 | 0.5 |
| Lanoxin® Elixir | 70-85% | 0.125 | 0.25 | 0.5 |
| Lanoxin® Injection/IM | 70-85% | 0.125 | 0.25 | 0.5 |
| Lanoxin® Injection/IV | 100% | 0.1 | 0.2 | 0.4 |
| **LANOXICAPS®** Capsules | 90-100% | 0.1 | 0.2 | 0.4 |

*1 mg = 1,000 μg

Due to the more complete absorption of digoxin from Lanoxicaps, recommended oral doses are 80% of those for tablets, elixir, and IM injection.

Lanoxicaps may help make a smoother transition for patients who are being switched from intravenous to oral therapy. Also, consider Lanoxicaps for all your newly diagnosed patients.

Colors of Lanoxicaps are distinctive, for less confusion or misidentification by patients. Please see next page for brief summary of prescribing information.

**LANOXICAPS®** brand DIGOXIN SOLUTION IN CAPSULES 50 μg (0.05 mg), 100 μg (0.10 mg), and 200 μg (0.20 mg)
*Brief Summary of Prescribing Information*

**INDICATIONS AND USAGE**
**Heart Failure:** The increased cardiac output resulting from the inotropic action of digoxin ameliorates the disturbances characteristic of heart failure (venous congestion, edema, dyspnea, orthopnea and cardiac asthma).

Digoxin is more effective in "low output" (pump) failure than in "high output" heart failure secondary to arteriovenous fistula, anemia, infection or hyperthyroidism.

Digoxin is usually continued after failure is controlled, unless some known precipitating factor is corrected. Studies have shown, however, that even though hemodynamic effects can be demonstrated in almost all patients, corresponding improvement in the signs and symptoms of heart failure is not necessarily apparent. Therefore, in patients in whom digoxin may be difficult to regulate, or in whom the risk of toxicity may be great (e.g., patients with unstable renal function or whose potassium levels tend to fluctuate) a cautious withdrawal of digoxin may be considered. If digoxin is discontinued, the patient should be regularly monitored for clinical evidence of recurrent heart failure.

**CONTRAINDICATIONS**
Digitalis glycosides are contraindicated in ventricular fibrillation.

Any untoward effect requiring permanent discontinuation of other digitalis preparations usually constitutes a contraindication to digoxin, as is hypersensitivity to digoxin itself. Allergy to digoxin, though rare, does occur. It may not extend to all preparations, and another digitalis glycoside may be tried with caution.

**WARNINGS**
The use of digoxin or other digitalis glycosides is unwarranted in the treatment of obesity.

Digoxin in soft capsules should be administered in divided daily doses to minimize any potential adverse reactions. Where compliance is considered a problem, single daily dosing may be appropriate.

Anorexia, nausea, vomiting, and arrhythmias may accompany heart failure or may be indications of digitalis intoxication. Clinical evaluation of the cause of these symptoms should be attempted before further digitalis administration.

Patients with renal insufficiency require smaller than usual maintenance doses of digoxin (see DOSAGE AND ADMINISTRATION section in complete prescribing information).

Heart failure accompanying acute glomerulonephritis requires extreme care in digitalization. Low loading and maintenance doses and concomitant use of antihypertensive drugs may be necessary. Careful monitoring is essential. Digoxin should be discontinued as soon as possible.

Patients with severe carditis, such as carditis associated with rheumatic fever or viral myocarditis, are especially sensitive to digoxin-induced disturbances of rhythm.

Newborn infants display considerable variability in their tolerance to digoxin. Premature and immature infants are particularly sensitive, and dosage must not only be reduced but must be individualized according to their degree of maturity. Note: Digitalis glycosides are an important cause of accidental poisoning in children.

**PRECAUTIONS**
**General:** Digoxin toxicity develops more frequently and lasts longer in patients with renal impairment because of the decreased excretion of digoxin. Therefore, dosage requirements will be decreased in patients with moderate to severe renal disease (see DOSAGE AND ADMINISTRATION section in complete prescribing information). More time is required to achieve an initial or new steady-state concentration in patients with renal impairment than in patients with normal renal function.

In patients with hypokalemia, toxicity may occur despite serum digoxin concentrations within the "normal range," because potassium depletion sensitizes the myocardium to digoxin. Hypokalemia may result from diuretic, amphotericin B, or corticosteroid therapy, and from dialysis or mechanical suction of gastrointestinal secretions. It may also accompany malnutrition, diarrhea, prolonged vomiting, old age, and long-standing heart failure. In general, rapid changes in serum potassium or other electrolytes should be avoided, and intravenous treatment with potassium should be reserved for special circumstances as described below (see *Treatment of arrhythmias produced by overdosage*, in OVERDOSAGE section).

Calcium, particularly when administered rapidly by the intravenous route, may produce serious arrhythmias in digitalized patients. Hypocalcemia can nullify the effects of digoxin in man; digoxin may be ineffective until serum calcium is restored to normal.

Hypomagnesemia may predispose to digitalis toxicity. If low magnesium levels are detected in a patient on digoxin, replacement therapy should be instituted.

Quinidine causes a rise in serum digoxin concentration, with the implication that digitalis intoxication may result. This rise appears to be proportional to the quinidine dose. Because of the considerable variability of this interaction, digoxin dosage should be carefully individualized.

Patients with acute myocardial infarction or severe pulmonary disease may be unusually sensitive to digoxin-induced disturbances of rhythm.

Atrial arrhythmias associated with hypermetabolic states (eg, hyperthyroidism) are particularly resistant to digoxin treatment. Large doses of digoxin are not recommended as the only treatment of these arrhythmias and care must be taken to avoid toxicity. In hypothyroidism, the digoxin requirements are reduced. Digoxin responses in patients with compensated thyroid disease are normal.

Reduction of digoxin dosage may be desirable prior to electrical cardioversion to avoid induction of ventricular arrhythmias, but the physician must consider the consequences of rapid increase in ventricular response to atrial fibrillation if digoxin is withheld 1 to 2 days prior to cardioversion. If there is a suspicion that digitalis toxicity exists, elective cardioversion should be delayed. If it is not prudent to delay cardioversion, the energy level selected should be minimal at first and carefully increased in an attempt to avoid precipitating ventricular arrhythmias.

Incomplete AV block, especially in patients with Stokes-Adams attacks, may progress to advanced or complete heart block if digoxin is given.

In some patients with sinus node disease (i.e., sick sinus syndrome), digoxin may worsen sinus bradycardia or sinoatrial block.

In patients with Wolff-Parkinson-White syndrome and atrial fibrillation, digoxin can enhance transmission of impulses through the accessory pathway. This effect may result in extremely rapid ventricular rates and even ventricular fibrillation.

Digoxin may worsen the outflow obstruction in patients with idiopathic hypertrophic subaortic stenosis (IHSS). Unless cardiac failure is severe, it is doubtful whether digoxin should be employed.

Patients with chronic constrictive pericarditis may fail to respond to digoxin. In addition, slowing of the heart rate by digoxin in some patients may further decrease cardiac output.

Patients with heart failure from amyloid heart disease or constrictive cardiomyopathies respond poorly to treatment with digoxin.

Digoxin is not indicated for the treatment of sinus tachycardia unless it is associated with heart failure.

Intramuscular injection of digoxin is extremely painful and offers no advantages unless other routes of administration are contraindicated.

**Drug Interactions:** Potassium-depleting *corticosteroids* and *diuretics* may be major contributing factors to digitalis toxicity. *Calcium*, particularly if administered rapidly by the intravenous route, may produce serious arrhythmias. *Quinidine* causes a rise in serum digoxin concentration, with the implication that digitalis intoxication may result. *Antacids, kaolin-pectin, sulfasalazine, neomycin,* and *cholestyramine* may interfere with intestinal digoxin absorption, resulting in unexpectedly low serum concentrations. *Thyroid* administration to a digitalized hypothyroid patient may increase the dose requirement of digoxin. Concomitant use of digoxin and *sympathomimetics* increases the risk of cardiac arrhythmias, because both enhance ectopic pacemaker activity. *Succinylcholine* may cause a sudden extrusion of potassium from muscle cells, and may thereby cause arrhythmias in digitalized patients. Although *propranolol* and digoxin may be useful in combination to control atrial fibrillation, their additive effects on AV node conduction can result in complete heart block.

**ADVERSE REACTIONS**
The frequency and severity of adverse reactions to digoxin depend on the dose and route of administration, as well as on the patient's underlying disease or concomitant therapies (see PRECAUTIONS section). The overall incidence of adverse reactions has been reported as 5% to 20%, with 15% to 20% being considered serious (1% to 4% of patients receiving digoxin). Cardiac toxicity accounts for about one-half, gastrointestinal disturbances for about one-fourth, and CNS and other toxicity for about one-fourth of these adverse reactions.

**Adults:**
*Cardiac*—Unifocal or multiform ventricular premature contractions, especially in bigeminal or trigeminal patterns, are the most common arrhythmias associated with digoxin toxicity in adults with heart disease. Ventricular tachycardia may result from digitalis toxicity. Atrioventricular (AV) dissociation, accelerated junctional (nodal) rhythm, and atrial tachycardia with block are also common arrhythmias caused by digoxin overdosage.

Excessive slowing of the pulse is a clinical sign of digoxin overdosage. AV block (Wenckebach) of increasing degree may proceed to complete heart block.

Note: The electrocardiogram is fundamental in determining the presence and nature of these cardiac disturbances.

*Gastrointestinal*—Anorexia, nausea, vomiting, and, less commonly, diarrhea are common early symptoms of overdosage. Uncontrolled heart failure may also produce such symptoms.

*CNS*—Visual disturbances (blurred or yellow vision), headache, weakness, apathy, and psychosis can occur.

*Other*—Gynecomastia is occasionally observed.

**Infants and Children:**
Toxicity differs from the adult in a number of respects. Anorexia, nausea, vomiting, diarrhea, and CNS disturbances may be present but are rare as initial symptoms in infants. Cardiac arrhythmias are more reliable signs of toxicity. Digoxin in children may produce any arrhythmia. The most commonly encountered are conduction disturbances or supraventricular tachyarrhythmias, such as atrial tachycardia with or without block, and junctional (nodal) tachycardia. Ventricular

arrhythmias are less common. Sinus bradycardia may also be a sign of impending digoxin intoxication, especially in infants, even in the absence of first-degree heart block. Any arrhythmia or alteration in cardiac conduction that develops in a child taking digoxin should initially be assumed to be a consequence of digoxin intoxication.

**OVERDOSAGE** Treatment of arrhythmias produced by overdosage

**Adults:**

Digoxin should be discontinued until all signs of toxicity are gone. Discontinuation may be all that is necessary if toxic manifestations are not severe.

Potassium salts are commonly used, particularly if hypokalemia is present. Potassium chloride in divided oral doses totaling 3 to 6 grams of the salt (40 to 80 mEq K+) for adults may be given provided renal function is adequate (see below for potassium recommendations in infants and children).

When correction of the arrhythmia is urgent and the serum potassium concentration is low or normal, potassium should be administered intravenously in 5% dextrose injection. For adults, a total of 40 to 80 mEq (diluted to a concentration of 40 mEq per 500 ml) may be given at a rate not exceeding 20 mEq per hour, or slower if limited by pain due to local irritation. Additional amounts may be given if the arrhythmia is uncontrolled and potassium well tolerated. ECG monitoring should be performed to watch for any evidence of potassium toxicity (e.g., peaking of T waves) and to observe the effect on the arrhythmia. The infusion may be stopped when the desired effect is achieved.

Note: Potassium should not be used and may be dangerous in heart block due to digoxin unless primarily related to supraventricular tachycardia.

Other agents that have been used for the treatment of digoxin intoxication include lidocaine, procainamide, propranolol, and phenytoin, although use of the latter must be considered experimental. In advanced heart block, temporary ventricular pacing may be beneficial.

**Infants and Children:**

See Adults section (immediately above) for general recommendations for the treatment of arrhythmias produced by overdosage and for cautions regarding the use of potassium.

If a potassium preparation is used to treat toxicity, it may be given orally in divided doses totaling 1 to 1.5 mEq K+ per kilogram (kg) body weight (1 gram of potassium chloride contains 13.4 mEq K+).

When correction of the arrhythmia with potassium is urgent, approximately 0.5 mEq/kg of potassium per hour may be given intravenously, with careful ECG monitoring. The intravenous solution of potassium should be dilute enough to avoid local irritation; however, especially in infants, care must be taken to avoid intravenous fluid overload.

**DOSAGE AND ADMINISTRATION**

*Recommended dosages are average values that may require considerable modification because of individual sensitivity or associated conditions.* Diminished renal function is the most important factor requiring modification of recommended doses.

Due to the more complete absorption of digoxin from soft capsules, recommended oral doses are only 80% of those for tablets, elixir, and IM injection.

Because the significance of the higher peak serum concentrations associated with once-daily capsules is not established, divided daily dosing is presently recommended for:

1. infants and children under 10 years of age;
2. patients requiring a daily dose of 300 μg (0.3 mg) or greater;
3. patients with a previous history of digitalis toxicity;
4. patients considered likely to become toxic;
5. patients in whom compliance is not a problem.

Where compliance is considered a problem, once-daily dosing may be appropriate.

**Adults:**

*Adults: rapid digitalization with a loading dose*—Peak body digoxin stores of 8 to 12 μg/kg should provide therapeutic effect with minimum risk of toxicity in most patients with heart failure and normal sinus rhythm. Larger stores (10 to 15 μg/kg) are often required for adequate control of ventricular rate in patients with atrial flutter or fibrillation. Because of altered digoxin distribution and elimination, projected peak body stores for patients with renal insufficiency should be conservative (i.e., 6 to 10 μg/kg [see PRECAUTIONS section]).

The loading dose should be based on the projected peak body stores and administered in several portions, with roughly half the total given as the first dose. Additional fractions of this planned total dose may be given at 6- to 8-hour intervals, *with careful assessment of clinical response before each additional dose.*

If the patient's clinical response necessitates a change from the calculated dose of digoxin, then calculation of the maintenance dose should be based upon the amount actually given.

**Dosage for Previously Undigitalized Patients:**

In previously undigitalized patients, a single initial Lanoxicaps dose of 400 to 600 μg (0.4 to 0.6 mg) usually produces a detectable effect in 0.5 to 2 hours that becomes maximal in 2 to 6 hours. Additional doses of 100 to 300 μg (0.1 to 0.3 mg) may be given cautiously at 6- to 8-hour intervals until clinical evidence of an adequate effect is noted. The usual amount of Lanoxicaps that a 70-kg patient requires to achieve 8 to 15 μg/kg peak body stores is 600 to 1000 μg (0.6 to 1.0 mg).

*Adults: gradual digitalization with a maintenance dose*—The following table provides average Lanoxicaps daily maintenance dose requirements for patients with heart failure based upon lean body weight and renal function:

Usual Lanoxicaps Daily Maintenance Dose Requirements (μg) for Estimated Peak Body Stores of 10 μg/kg

| Corrected Ccr (ml/min per 70 kg) | Lean body weight (kg/lbs) 50/110 | 60/132 | 70/154 | 80/176 | 90/198 | 100/220 | Number of days before steady-state achieved |
|---|---|---|---|---|---|---|---|
| 0 | 50 | 100 | 100 | 100 | 150 | 150 | 22 |
| 10 | 100 | 100 | 100 | 150 | 150 | 150 | 19 |
| 20 | 100 | 100 | 150 | 150 | 150 | 200 | 16 |
| 30 | 100 | 150 | 150 | 150 | 200 | 200 | 14 |
| 40 | 100 | 150 | 150 | 200 | 200 | 250 | 13 |
| 50 | 150 | 150 | 200 | 200 | 250 | 250 | 12 |
| 60 | 150 | 150 | 200 | 200 | 250 | 300 | 11 |
| 70 | 150 | 200 | 200 | 250 | 250 | 300 | 10 |
| 80 | 150 | 200 | 200 | 250 | 300 | 300 | 9 |
| 90 | 150 | 200 | 250 | 250 | 300 | 350 | 8 |
| 100 | 200 | 200 | 250 | 300 | 300 | 350 | 7 |

*Example*—Based on the above table, a patient in heart failure with an estimated lean body weight of 70 kg and a Ccr of 60 ml/min should be given 200 μg (0.2 mg) of Lanoxicaps per day, usually taken as a 100 μg (0.1 mg) capsule after the morning and evening meals. Steady-state serum concentrations should not be anticipated before 11 days.

**Digitalizing Dose for Children:**

Usual Digitalizing and Maintenance Dosages for Lanoxicaps in Children With Normal *Renal Function Based on Lean Body Weight*

| Age | Digitalizing* Dose (μg/kg) | *Daily*† Maintenance Dose (μg/kg) |
|---|---|---|
| 2-5 Years | 25-35 | 25%-35% of the oral or IV loading dose‡ |
| 5-10 Years | 15-30 | |
| Over 10 Years | | |

*IV digitalizing doses are the same as Lanoxicaps digitalizing doses.

†Divided daily dosing is recommended for children under 10 years of age.

‡Projected or actual digitalizing dose providing desired clinical response.

More gradual digitalization can also be accomplished by beginning an appropriate maintenance dose. The range of percentages provided above can be used in calculating this dose for patients with normal renal function. In children with renal disease, digoxin dosing must be carefully titrated based upon desired clinical response.

Long-term use of digoxin is indicated in many children who have been digitalized for acute heart failure, unless the cause is transient. Children with severe congenital heart disease, even after surgery, may require digoxin for prolonged periods.

*It cannot be overemphasized that both the adult and pediatric dosage guidelines provided are based upon average patient response and substantial individual variation can be expected. Accordingly, ultimate dosage selection must be based upon clinical assessment of the patient.*

# Juxtaductal Aortic Coarctation

## Analysis of 84 Patients Studied Hemodynamically, Angiographically, And Morphologically After Age 1 Year

D. LUKE GLANCY, MD, ANDREW G. MORROW, MD, ALLAN L. SIMON, MD, and WILLIAM C. ROBERTS, MD

**Although many studies of juxtaductal coarctation of the aorta have been reported, none has correlated clinical, hemodynamic, angiographic, anatomic, and operative findings. Of 84 patients (62 male and 22 female; age range, 1 to 49 years [mean 17]), all had murmurs; 76 had absent, diminished, or delayed femoral pulsations; 50 had cuff systolic blood pressures in the arm >140 mm Hg, and 30 had diastolic pressures >90 mm Hg. The average pressure gradients (mm Hg) by direct measurements above and below the coarctation in 35 patients were peak systolic, 45; mean, 17; and diastolic, 5. Rib notching, visible in chest roentgenograms in 43 patients, correlated directly with age and inversely with the diameter of the coarctation. Moderate or marked cardiomegaly by radiograph was present in only 1 of 48 patients with isolated coarctation and in 17 of 36 with associated cardiovascular malformations. Electrocardiograms were abnormal in more than two thirds of patients with associated anomalies, but were normal in more than three fourths of those with isolated coarctation. In 70 excised, serially sectioned coarctations the aortic lumens were completely occluded in 4 patients, up to 0.5 mm in internal diameter in 22 patients, from 0.6 to 2 mm in 26 patients, from 2.1 to 5 mm in 14, and >5 mm in 4, and correlated directly with lumens measured angiographically. The most significant anatomic factor causing the coarctation was invagination of the media from the posterior aortic wall, but intimal proliferation (jet lesion) at and immediately distal to the invagination contributed to the narrowing. Three (each with associated anomalies) of 70 patients died early after coarctation repair. Systolic or diastolic blood pressures decreased early postoperatively in 58 (87%) of 67 surviving patients, and both pressures decreased in 42 (63%). Late postoperatively (mean follow-up, 4.7 years), the systolic blood pressure remained elevated in 25% of patients.**

Many reports have described 1 or more features of patients with juxtaductal aortic coarctation, but none has correlated clinical, hemodynamic, angiographic, operative, and detailed anatomic studies in a large number of patients. This report summarizes such observations in 84 patients over age 1 year at the time of study.

### Methods

**Patients:** The diagnosis of aortic coarctation was confirmed by examination of the resected coarctation specimen in 69 patients, by operative examination without resection in 2, by necropsy in 6, and by aortography in 7. The age and sex distributions of the 84 patients are shown in Figure 1. Additional congenital cardiovascular anomalies occurred in 36 patients (43%) (Table I).

Electrocardiograms and chest rogentgenograms were obtained in all 84 patients and aortograms in 52. Direct arterial pressures were measured above and below the aortic coarctation in 35. In 72 operatively excised or necropsy aortic coarctations, the specimens were serially sectioned longitudinally at 6 to 10 $\mu$m intervals. Every 10th section was stained with hematoxylin and eosin, and an occasional section from each patient was stained by the Verhoeff-van Gieson method for elastic fibers.

### Results

**Morphologic features:** In 71 of 72 specimens, the coarctation was juxtaductal: The aortic lumen was narrowed by elastic tissue which invaginated from the posterior wall of the aorta toward the aortic attachment of the ligamentum arteriosum or ductus arteriosus (Fig. 2 to 4). The elastic media of the invaginated aorta was

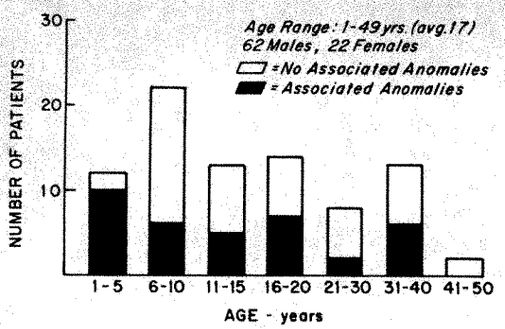

**FIGURE 1.** Ages of the 84 patients with juxtaductal aortic coarctation.

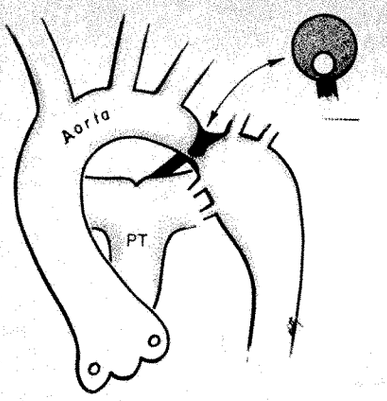

**FIGURE 2.** Diagram of isthmic (juxtaductal) aortic coarctation. The narrowing is caused by invagination of the elastic tissue media of the posterior wall of aorta toward the aortic attachment of the ligament or duct. Fibrous tissue, the result of turbulent blood flow, frequently accumulates on the intima distal to the invaginated aortic wall. Most blood reaching the aorta distal to the coarctation does so through dilated collateral arteries, including large intercostal arteries. **Inset:** a drawing of a cross section of the aorta at the level of the coarctation. PT = pulmonary trunk.

usually thicker on its distal than on its proximal side, and the media of the first several centimeters of aorta distal to the coarctation was usually thicker than that of the aorta just proximal to the narrowing. Near the free margin of the invagination the elastic fibers lost their parallel arrangement. A triangular wedge of fibrous tissue filled the adventitial side of the invagination so that the external aortic narrowing was usually slight compared with the aortic luminal narrowing. The invagination produced an eccentrically located aortic lumen. The *ligamentum or ductus* attached to the anterior wall of the aorta and was directed toward the elastic tissue invaginated from the opposite wall. Small spaces filled with acid mucopolysaccharide often separated elastic fibers of the aortic media. On the anterior aortic wall, opposite the coarctation, these spaces were more prominent proximal to the coarctation.

*Intimal "jet" lesions* formed at the free margins and on the distal side of the coarctation and frequently caused further narrowing of the aortic lumen. Intimal plaques containing atheromatous material were less common than jet lesions in resected specimens and were more often proximal to the coarctation. A tubular narrowing (7 cm long) rather than a distinct invagination of the aorta occurred in 1 patient.

*The relation of the ductus or ligamentum to the coarctation* was determined from serial sections in 63 of the 72 specimens. Maximal aortic narrowing was within 4 mm of the ductus or ligamentum in each: In 41 (65%), it was distal; in 11 (17.5%), it was directly opposite; and in 11 (17.5%), it was proximal to the ductus or ligamentum.

In 52 of 70 serially sectioned coarctations, the luminal diameter was ≤2.0 mm: totally occluded in 4 (6%) (by intimal fibrous tissue); ≤0.5 mm in 22 (31%); 0.6 to 2.0 mm in 26 (37%); 2.1 to 5.0 mm in 14 (20%), and >5.0 mm in 4 (6%).

Of 11 patients in whom it was examined at necropsy or at operation, the aortic valve was bicuspid in 7, tricuspid in 3 (including 1 that was mildly regurgitant and associated with discrete subaortic stenosis) and uni-

**TABLE I Associated Congenital Cardiovascular Anomalies in 84 Patients Aged >1 Year With Juxtaductal Aortic Coarctation**

| Anomaly | Number |
|---|---|

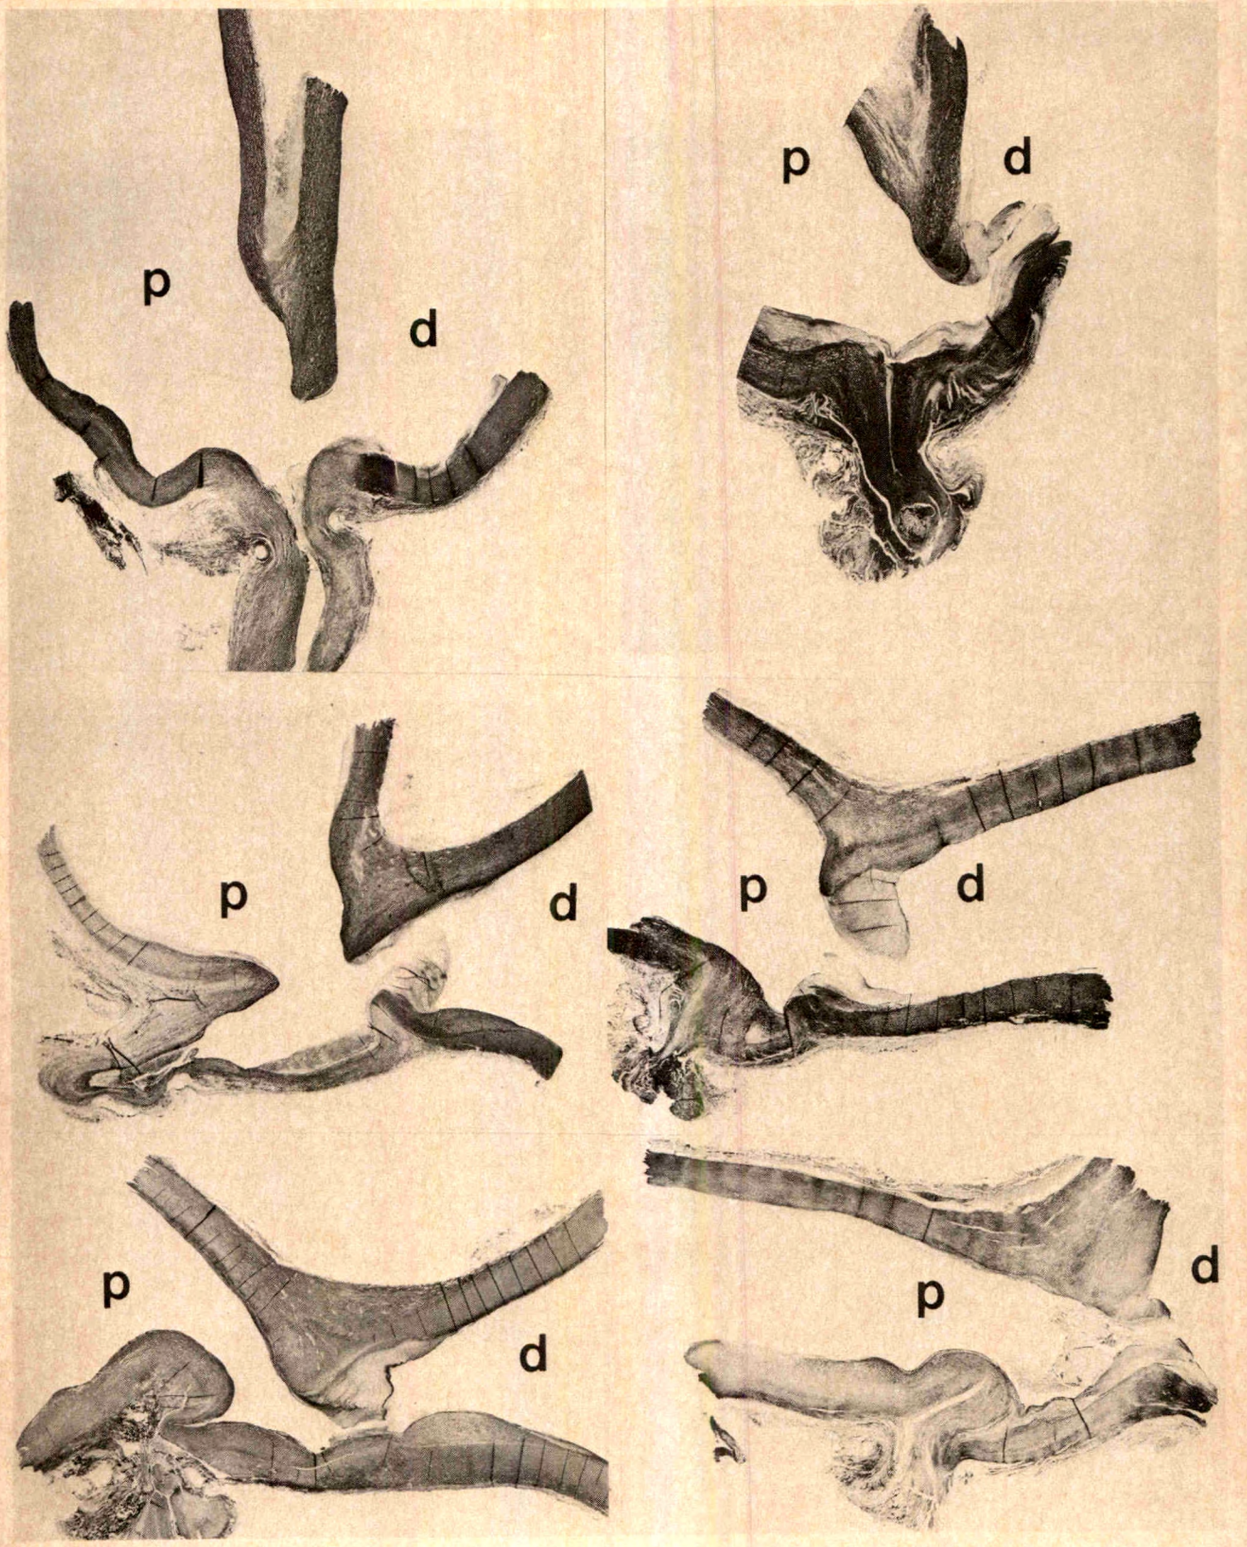

**FIGURE 3.** Histologic sections of 6 aortic coarctations from patients aged 3 to 35 years without associated malformations. Proximal (p) aortic lumen is to the **left;** distal (d) lumen is to the **right;** and the ligamentum arteriosum is **below.** In each specimen, the invaginated media (darkly staining) of the posterior wall of the aorta points toward the ligamentum arteriosum. Thickened intima (lightly staining) just distal to the invaginated V often produces additional aortic obstruction distal to the ligament. The largest luminal diameter (1.1 mm) is in the upper left specimen; the other lumens are narrowed to $\leq$0.5 mm. Each section has been cut longitudinally, stained by the Verhoeff-van Gieson method, and magnified 5 to 6.5 times (reduced 6%).

commissural in 1 (severely stenotic). Of the bicuspid valves, 3 were functionally normal; 2 were calcified and stenotic; 2 were incompetent (1 secondary to active Histoplasma capsulatum endocarditis and the other associated with the Marfan syndrome).

**Preoperative clinical features:** Table II lists the frequencies of various symptoms in the patients with and without associated cardiovascular anomalies. Leg discomfort occurred twice as often in patients without as in those with associated anomalies. More patients in the latter group had mild coarctation, which often was discovered during evaluation for other congenital cardiovascular anomalies. One or more episodes of overt congestive cardiac failure occurred in 15 patients with and in none without associated anomalies. Chest pain was typical of angina pectoris in only 4 patients, but 2 of them had aortic stenosis, and a third had discrete subaortic stenosis. The fourth patient, who had no other congenital anomalies, died from an acute myocardial infarct at age 37 years (1 year after resection of the aortic coarctation), and at necropsy the right coronary artery was completely occluded by atherosclerotic plaque. Three patients with isolated aortic coarctation had syncope, including 1 who had only a single episode during pregnancy. In addition, 1 patient with associated valvular aortic stenosis had syncope, and another had presyncopal episodes with exertion. Although 1 or more symptoms were present in most patients with aortic coarctation, these were seldom limiting when the anomaly was isolated.

*Diagnosis* in 65% of patients with isolated coarctation was made on routine physical examination or chest roentgenography. However, in only 2 of 22 adults did the initial discovery of a murmur or of systemic hypertension lead directly to operative treatment. In 17 other patients, delays of 10 to 33 years occurred between the initial discovery of a murmur or systemic hypertension, or both, and the patient's referral for operation, and in all 17 referral was at least 10 years after operative treatment was available. The remaining 3 adults were first discovered to have aortic coarctation at necropsy, but the diameter at the coarctation was ≥4 mm in each.

All 84 patients had systolic murmurs (Table III) (Fig. 5). Of the 48 with isolated coarctation, the murmur's intensity was grade 1/6 in 5 (10.5%); grade 2/6 or 3/6 in 38 (79%); and grade 4/6 in 5 (10.5%). Systolic murmurs most often were of maximal intensity at the upper left sternal edge and often were easily heard over the entire precordium, neck, and infra- and supraclavicular areas, between the scapulae and over axillary collateral vessels. The murmurs usually began after the first heart sound, were crescendo-decrescendo in character, and at times extended beyond the sound of aortic valve closure,

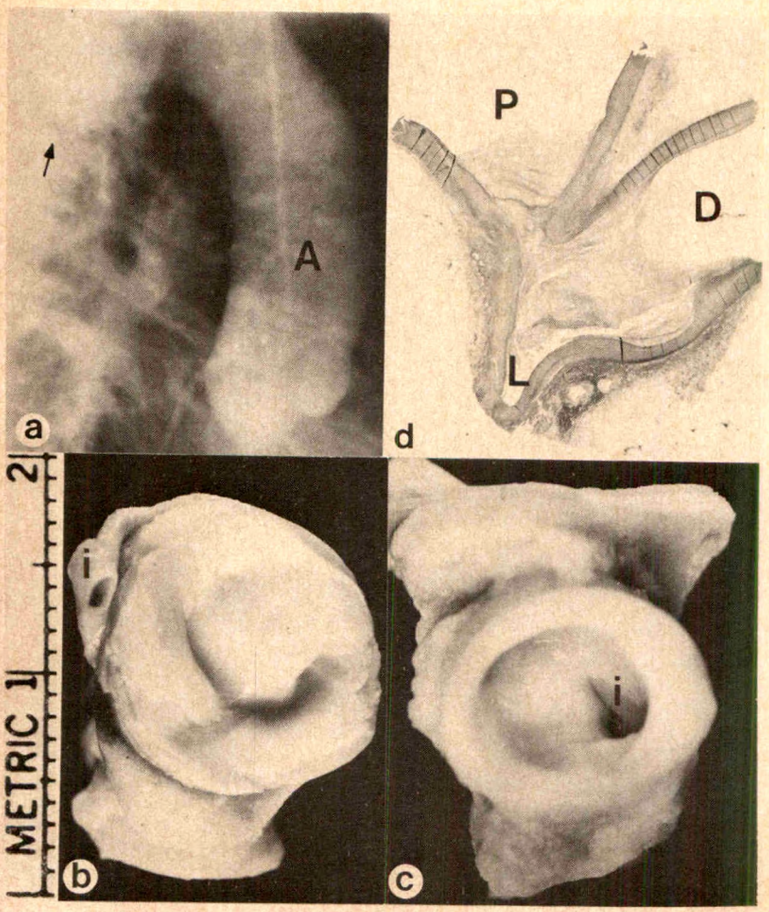

**FIGURE 4.** Coarctation with acquired complete occlusion of the aorta in a 27-year-old man. **a**, lateral film made 2.2 seconds after the injection of contrast material into the ascending aorta (A). No contrast is present beyond the coarctation (**arrow**). **b** and **c**, resected aortic coarctation viewed from its proximal (**b**) and distal (**c**) sides. The aorta is completely occluded. Dilated intercostal arteries (i) can be seen on the adventitial surface of aorta (**b**) and entering the distal aorta (**c**). **d**, longitudinal histologic section (Verhoeff-van Gieson stain; magnification ×6, reduced 25%). The invaginated posterior wall of the darkly stained aortic media narrows the aortic lumen to <1.0 mm. Final closure of the aortic lumen is the result of intimal fibrous tissue. D = distal aorta; L = ligamentum arteriosum; P = proximal aorta.

| Weight <11th percentile* | 2/20 | 10/16 |

* Children under 13 years of age.

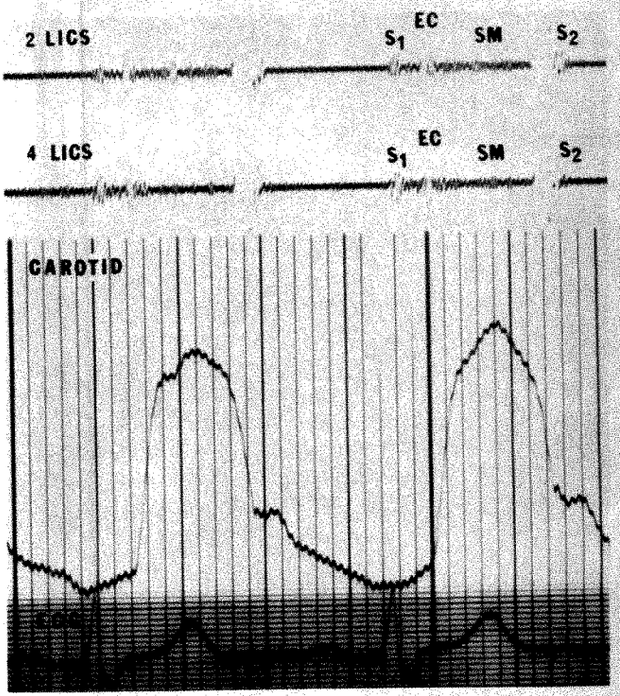

**FIGURE 5.** Phonocardiogram recorded in second (2 LICS) and fourth (4 LICS) left intercostal spaces, carotid pulse tracing, and electrocardiogram (ECG) in a patient with aortic coarctation. An ejection click (EC) follows the first heart sound ($S_1$) and occurs simultaneously with the beginning of the upstroke of the carotid pulse. SM = systolic murmur; $S_2$ = second heart sound.

especially over collateral arteries. Occasionally, apical diastolic rumbles were heard. In the other 36 patients, the associated anomalies modified the auscultatory findings.

Femoral arterial pulsations were absent, diminished or delayed in 76 patients (Fig. 6). In 5 of the 8 patients with normal femoral pulses on clinical examination, the coarctation specimen was serially sectioned: 4 had lumens ≥4 mm in diameter; the lumen in 1 was 0.2 mm in diameter but a large patent ductus inserted distal to the coarctation; and in the other 3 patients, hemodynamic and angiographic studies indicated that the obstruction was mild. Simultaneous arm and leg blood pressures were measured by cuff in 5 of these 8 patients, and in 3 the pressure was slightly lower in the leg. In 6 additional patients, femoral arterial pulsations were full but were decreased or delayed compared with brachial or radial pulsations. Palpable collateral pulsations occurred in over one third of the patients.

Systolic blood pressures in the arm were >140 mm Hg in 33 (69%) of the 48 patients without and in 17 (47%) of the 36 patients with associated anomalies (Table III), and diastolic arm pressures were >90 mm Hg in 21 (44%) of those without and in 9 (25%) of those with associated anomalies. Most patients had pressures that were greater than the pressures in 97.5% of the general population of the same age (Fig. 7). Systolic pressure was above this level in 67 (80%) of the 84 patients with coarctation and in 63 (90%) of the 70 patients undergoing operative repair. In most patients whose systolic pressures were within 2 standard deviations of the mean for the general population, the aortic coarctation was mild. Narrowing and tortuosity of retinal arteries were often seen; retinal hemorrhages, exudates, and papilledema were absent.

*The heights and weights* of the children <13 years of age had a normal distribution, in those with isolated coarctation, but were below the 11th percentile in >50% of those with associated malformations.

*The electrocardiograms* of most patients with isolated coarctation were normal, and those of most patients with associated anomalies were abnormal (Table IV). Increased QRS voltage was the most common ab-

**TABLE IV Electrocardiographic Findings in Aortic Coarctation**

| Associated Anomalies | Cases (n) | QRS Axis | | RVN ± LVH | R $V_5$ or $V_6$ >25 mm | S $V_1$ + R $V_5$ or $V_6$ >40 mm | LVH With Strain | Rhythm or Conduction Disturbance |

| 0 | 48 | 0 | 0 | 0 | 5 | 9 | 1 | 1 |
| + | 36 | 2 | 3 | 9 | 15/27* | 16/27* | 5/27* | 12† |

* Excludes the 9 patients with right (RVH) or combined right and left (LVH) ventricular hypertrophy.
† Prolonged (>0.20 second) P-R interval in 7 patients; sinus bradycardia plus atrioventricular dissociation in 1; junctional rhythm in 1; wandering supraventricular pacemaker in 1; and complete right bundle branch block and left anterior hemiblock in 2.

normality in patients with isolated coarctation; the increase was usually slight and no patient with isolated coarctation had R waves ≥30 mm in lead $V_5$ or $V_6$. In contrast, R waves of ≥30 mm occurred in 13 of 27 patients (excluding the 9 with right or combined ventricular hypertrophy) with associated anomalies.

*Chest roentgenography* performed in the 4 standard projections revealed the aortic coarctation in 66% of patients without and in 53% of those with associated anomalies (Table V). It was seen either directly, the so-called figure-of-3 sign, or indirectly by the deformity it produced in the barium-filled esophagus. The frequency of visible rib notching correlated directly with age, and inversely with the diameters of the coarctations measured in the resected specimens. Dilated, tortuous internal mammary arteries were identified in lateral chest roentgenograms in 7 patients. The ascending aorta appeared normal in 51 patients, slightly dilated in 31 patients, and moderately dilated in 2. The intrathoracic portions of the brachiocephalic arteries were normal in 45 patients, slightly dilated in 29 patients, moderately dilated in 9, and markedly dilated in 1 patient, in whom aneurysms of the aortic arch, left subclavian artery, and descending thoracic aorta were present. From the impression it produced on the barium-filled esophagus, the aorta just distal to the coarctation was normal in 34 patients, slightly dilated in 41, moderately dilated in 8 patients, and markedly dilated in 1.

*Increased pulmonary vascular markings* were noted in 9 patients, 8 of whom had left-to-right shunts, and findings of pulmonary venous hypertension were present in 4 patients, each of whom had congenital mitral regurgitation.

*Overall heart size* was normal in 30 (63%) of 48 patients with isolated aortic coarctation and was moderately enlarged in only 1 patient. In contrast, overall heart size was normal in only 2 (6%) of 36 patients with associated anomalies and almost half of the 36 had moderate or marked cardiomegaly. Seven patients (6 with isolated coarctation and 1 with associated con-

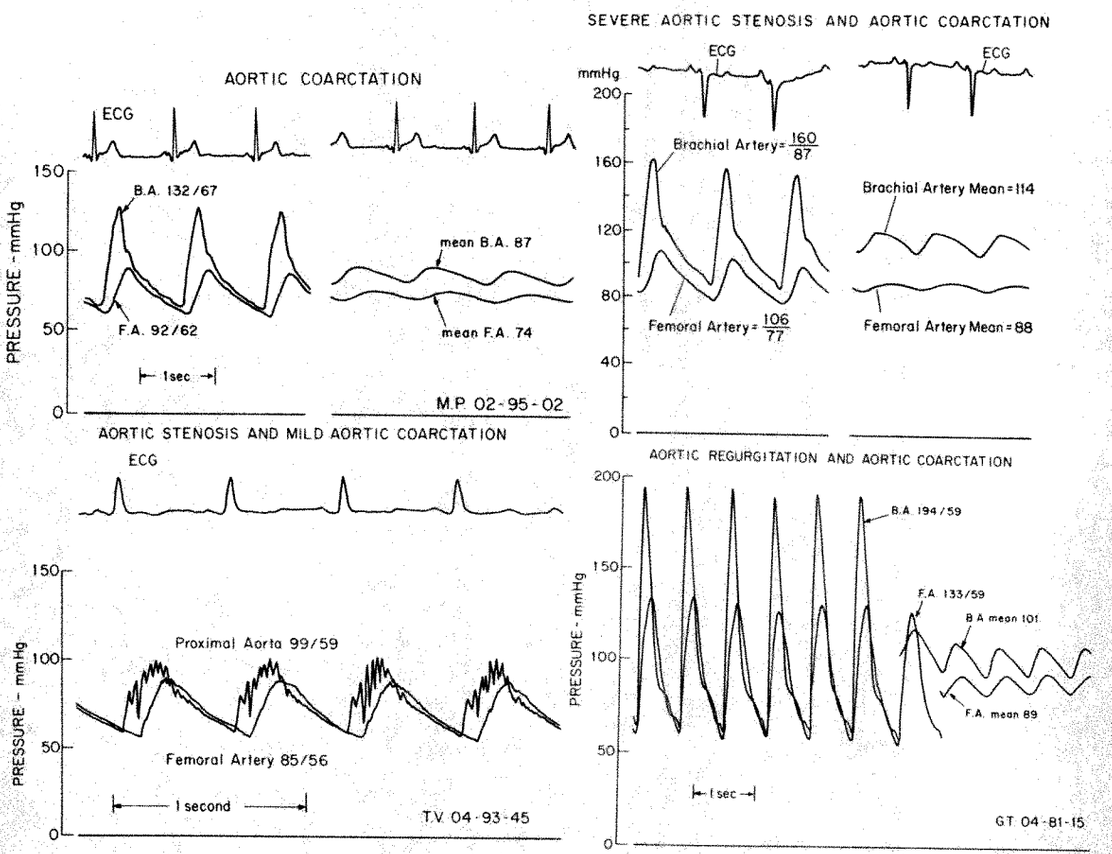

**FIGURE 6.** Pressure tracings above and below aortic coarctation. Electrocardiogram (ECG) and direct brachial arterial (BA) or aortic and femoral arterial (FA) phasic and mean pressure tracings. **Upper left,** in a 32-year-old man with isolated aortic coarctation. The peak FA pulse is 40 mm Hg lower than and occurs 0.09 second later than the peak of the BA pulse. The mean and diastolic pressures differ by only 13 and 5 mm Hg, respectively. **Upper right,** in a 38-year-old man. The peak FA pulse is 54 mm Hg lower than and occurs 0.10 second later than the peak BA pulse. The wide BA pulse pressure and the absence of an anacrotic shoulder do not suggest aortic stenosis, but a 145 mm Hg peak systolic pressure gradient was measured across the aortic valve, which was congenitally bicuspid and heavily calcified. **Lower left,** in a 5-year-old boy with moderately severe aortic valve stenosis and mild aortic coarctation. The small difference between the pulse pressure above and that below the coarctation could not be detected by palpation, but the systolic blood pressure measured by cuff was 8 mm Hg higher in the arm than the leg. **Lower right,** in a 19-year-old man with aortic regurgitation. The FA pulse was brisk and the pulse pressure wide, despite narrowing of the internal diameter of the aorta to <5 mm. Only when compared with the BA pulse is the FA pulse noted to be damped and its peak to occur 0.13 second after the peak of the BA pulse.

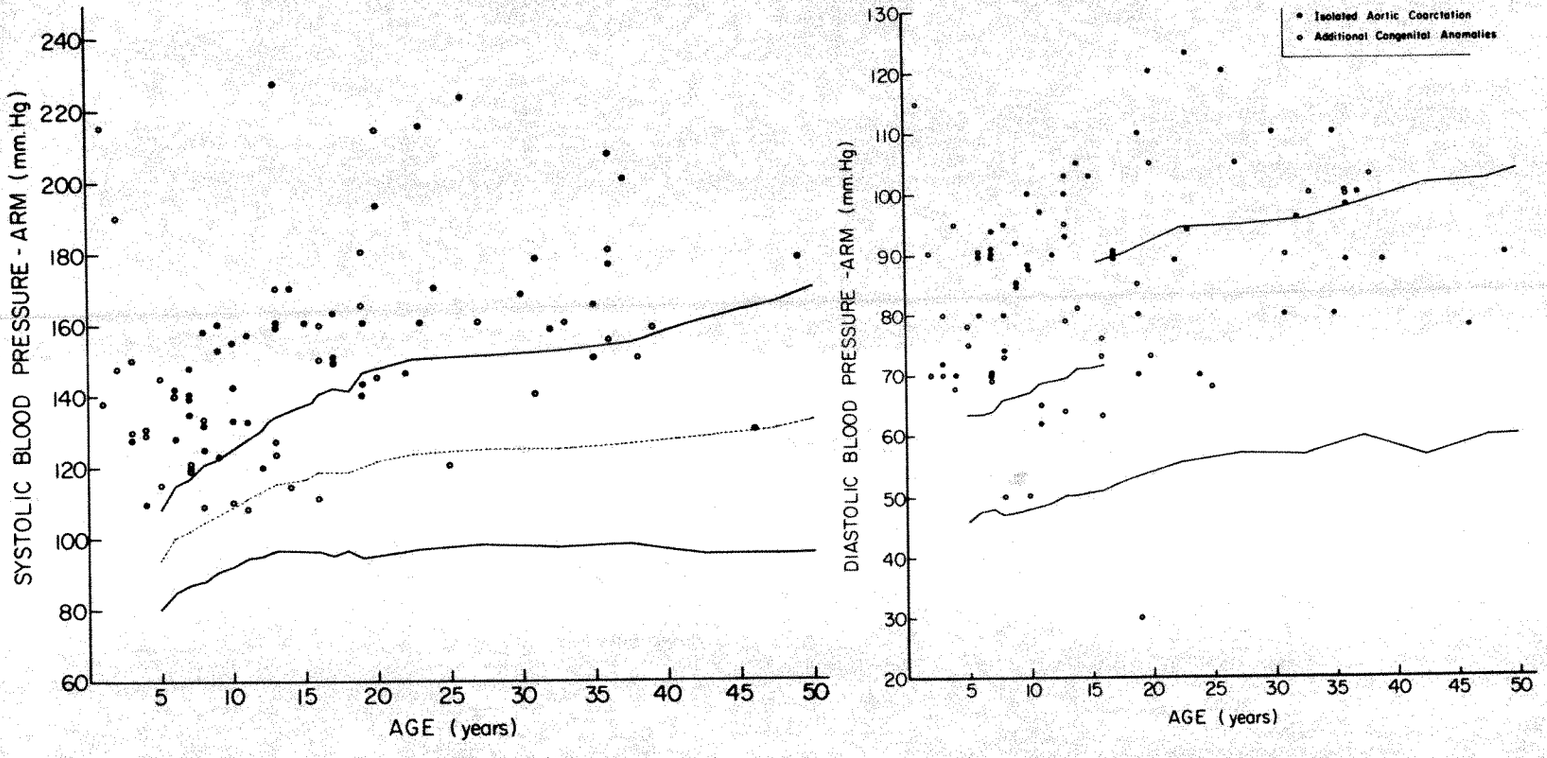

**FIGURE 7.** Systolic and diastolic blood pressures, taken in an arm by cuff, in the 48 patients with isolated aortic coarctation and in the 36 with associated congenital cardiovascular anomalies. The **dotted line (left)** is the mean systolic pressure of the general population. The **solid lines** include the pressures of 95% of the general population. A difference among reference studies[46–48] in technique of recording diastolic pressure accounts for the gap in the **upper line (right)**. Of the 84 patients, 67 (80%), including 63 (90%) of the 70 who subsequently underwent operative repair, had systolic pressures that were greater than the pressures in 97.5% of the general population of comparable age.

genital mitral regurgitation) with normal overall heart size had slight enlargement of individual cardiac chambers—the left ventricle in 5 and the left atrium in 2. Thus, 24 of the 84 patients had entirely normal cardiac silhouettes, and 23 of the 24 patients had isolated coarctation.

**Angiographic findings (Fig. 8 to 11):** *Dilatation of the descending aorta immediately distal to the coarctation* was the rule. In 45 patients, poststenotic dilatation was quantified angiographically by determining the ratio of the diameter of the aorta just distal to the coarctation to the diameter of the aorta at the level of the diaphragm: In 2 patients the ratio was 1:1; in 28 patients, 1.0 to 1.5:1; in 14 patients, 1.5 to 1.8:1; and in 1 patient, >1.8:1. Saccular aortic aneurysm distal to the coarctation occurred in 4 patients. Its cause was infective aortitis in 1 patient (Fig. 11). In another the aneurysm developed just distal to a stenotic anastomotic site for coarctation resection 6 years earlier. One patient had multiple saccular aneurysms both proximal and distal to a mild coarctation. In the fourth patient the aneurysm arose just distal to the coarctation. In all patients the aneurysms were resected along with the aortic coarctation. The intercostal arteries frequently were dilated, at times to aneurysmal proportions. In 1 patient the right subclavian artery originated just proximal to the coarctation and reached the right arm by passing behind the esophagus.

*The anatomic relation of the aortic coarctation to the origin of the left subclavian artery* was visualized on angiography in 47 patients: In 15 the coarctation was <1 cm; in 24 patients, 1.0 to 2.9 cm; and in 8 patients, 3.0 to 5.0 cm distal to the caudal margin of the origin of the left subclavian artery. The length of the narrowed aortic segment seen on angiography was <5 mm in 39 patients, 5 mm in 2 patients, and 8 mm in 1.

In 32 patients, both coarctation specimens and aortograms were available for correlative examinations. There was a direct correlation between the internal diameters of the coarctations measured angiographi-

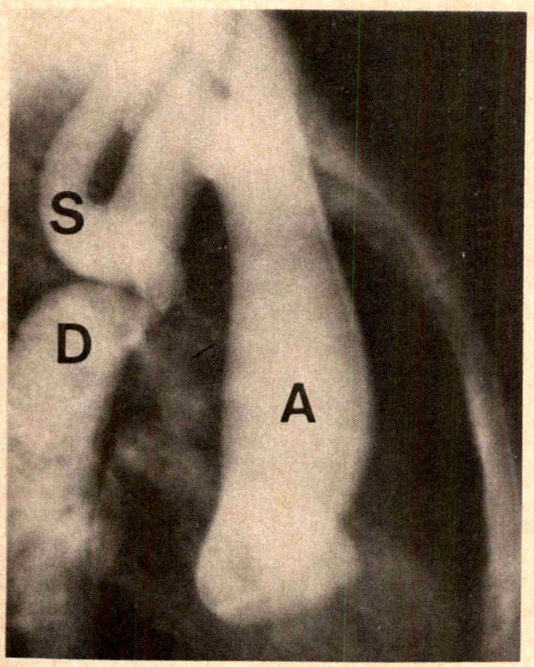

**FIGURE 8.** Lateral aortogram in a 35-year-old woman showing invagination of the posterior wall of aorta just distal to the origin of the left subclavian (S) artery, poststenotic dilation (D) of the descending aorta, and mild dilation of the ascending aorta (A). The patient also had mitral regurgitation.

**TABLE VII Operations for Aortic Coarctation (71 Patients)**

| | |
|---|---|
| Procedure | |
| Resection with direct anastomosis | 61 |
| Resection with graft | 8 |
| Anastomosis left subclavian artery to aorta | 1 |
| Not resected | 1 |
| Complications | |
| Mortality | 3 (4%) |
| Reoperation for bleeding | 6 (8%) |
| Reoperation for coarctation | 2 (3%) |
| Paradoxical hypertension postoperatively | 41 (58%) |
| Recurrent laryngeal nerve palsy | 8 (11%) |

| Systemic Arterial Pressures Postoperatively | | | |
|---|---|---|---|
| | Preoperative | Discharge | Follow-Up |
| Systolic >140 | 47/67 (70%) | 11/67 (16%) | 10/56 (18%) |
| Diastolic >90 | 29/67 (43%) | 7/67 (10%) | 3/56 (5%) |

cally and those measured anatomically, but the diameters measured angiographically (range 0 to 8 mm, average 3.5) tended to be larger than the diameters measured anatomically (range 0 to 4.1 mm, average 1.3). This discrepancy resulted from measuring the angiographic diameters when the aortas were distended by systemic arterial pressure and magnified approximately 25%.

*In 43 patients the magnitude of the collateral arterial circulation* was estimated angiographically: In 5 patients it was normal and in 38 it was increased: 1+ in 10, 2+ in 10, 3+ in 12, and 4+/4+ in 6. The magnitude of the collateral circulation was inversely proportional to the luminal diameters measured in 35 resected coarctations: In 17 patients with 0 to 2+ collateral arteries the average luminal diameter was 2.5 mm, and in 18 patients with 3+ or 4+ collateral arteries the average diameter was 0.7 mm.

**Hemodynamic findings:** *Direct arterial pressure measurements above and below the coarctation*, recorded in 35 patients, showed peak systolic pressure gradients averaging 55 mm Hg in the 12 patients with isolated coarctation and 41 mm Hg in the 23 with associated anomalies (Table VI, Fig. 6). The peak gradient was >60 mm Hg in only 6 (17%) of the 35 patients. The mean gradient averaged 21 mm Hg in the patients without and 16 mm Hg in those with associated anomalies, and was >30 mm Hg in 4 patients. The end-diastolic gradient average 6 mm Hg in patients without and 5 mm Hg in those with associated anomalies; it was >10 mm Hg in 3 patients and was absent in 4 patients.

An inverse correlation was found between the *luminal diameters of the resected aortic coarctations and the preoperative mean gradients* across them. With a luminal diameter of <1.5 mm, however, a progressively smaller lumen was not associated with a higher gradient, suggesting that with this degree of obstruction most of the blood reaches the distal aorta by collaterals vessels. Generally, the gradient across the coarctation and the systemic blood pressure increased with each successive decade through the third. No further increase in the average gradient or blood pressure occurred in patients >30 years of age, but 6 of these 15 patients had mild coarctation with aortic luminal diameters of >4 mm.

Simultaneous brachial and femoral arterial pressures were recorded in 21 patients, and the delay from the peak of the brachial pulse to the peak of the femoral brachial pulse averaged 0.14 second in 9 patients with isolated aortic coarctation and 0.09 second in 12 patients with associated anomalies.

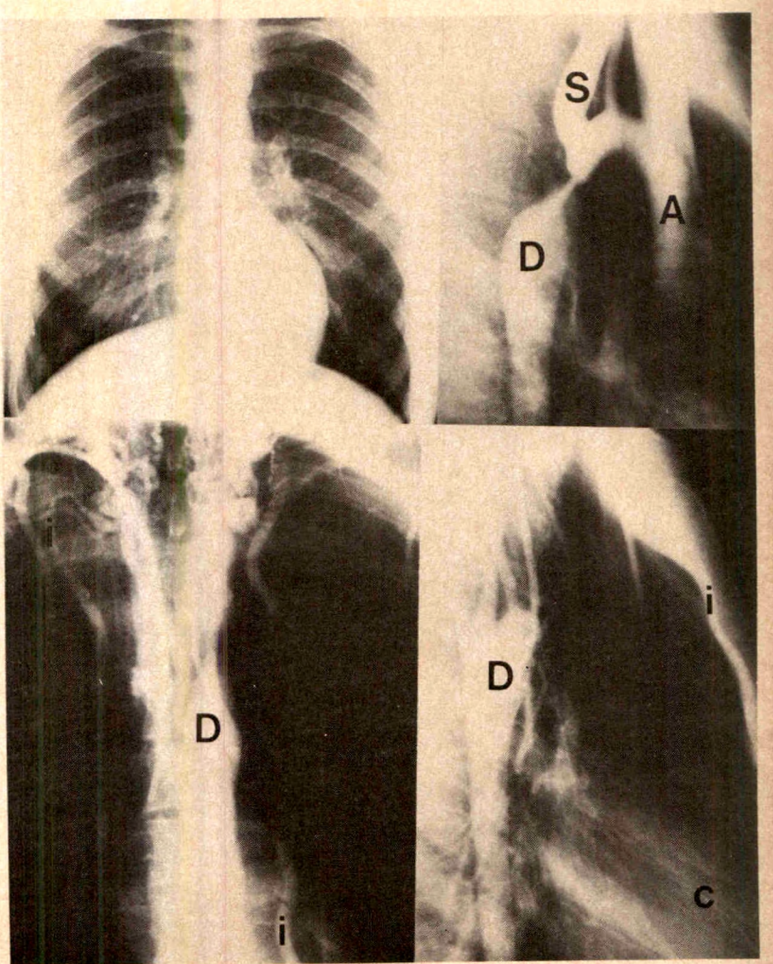

**FIGURE 9.** Posteroanterior chest roentgenogram (**upper left**) and aortograms in a 21-year-old man with aortic coarctation and no other cardiac malformations. The chest roentgenogram shows a figure-of-3 sign, notching of the fifth rib on the right and the fifth and sixth ribs on the left, mild left ventricular enlargement, and no dilatation of ascending aorta. The lateral film (**upper right**), obtained during injection of contrast material into ascending aorta (A), shows a jet of contrast entering the dilated descending aorta (D). The left vertebral artery has a separate origin from the aortic arch just proximal to the origin of the left subclavian artery (S). The anteroposterior (**lower left**) and lateral (**lower right**) films were taken after the ascending aorta had emptied of contrast medium and show the descending aorta (D) being filled by numerous dilated collateral arteries. The markedly dilated superior intercostal arteries enter the descending aorta just below the coarctation. Dilated internal mammary arteries (i) give origin to intercostal arteries (c).

**Operations, complications, and results:** Operation for aortic coarctation was performed in 71 patients (Table VII). In 61, the narrowed segment was resected and the distal aorta anastomosed directly to the proximal aorta, including part of the origin of the left subclavian artery when it arose just proximal to the coarctation. The suture line was always interrupted in 2 or more places. In 8 patients, the coarctation was resected and replaced by a tubular graft (Teflon® in 6 patients, homograft in 2). In 1 patient, the left subclavian artery was anastomosed to the distal aorta. In another patient with severe aortic valvular stenosis and relatively mild aortic coarctation, occlusion of the coarcted segment caused systolic pressure in the arm to increase to 260 mm Hg and the distal aorta to collapse; therefore, the coarctation was not resected.

Of the 70 patients undergoing operative repair of aortic coarctations, 3 (4%) died early after operation and each of them had multiple associated cardiovascular anomalies: A 15-month-old boy with ventricular septal defect, patent ductus arteriosus, preductile aortic coarctation, a large left-to-right shunt, and equal pulmonary and femoral arterial pressures died 4 hours after banding of the pulmonary trunk, ligation of the ductus, and anastomosis of the left subclavian artery to the distal aorta. A 20-year-old man with the Marfan syn-

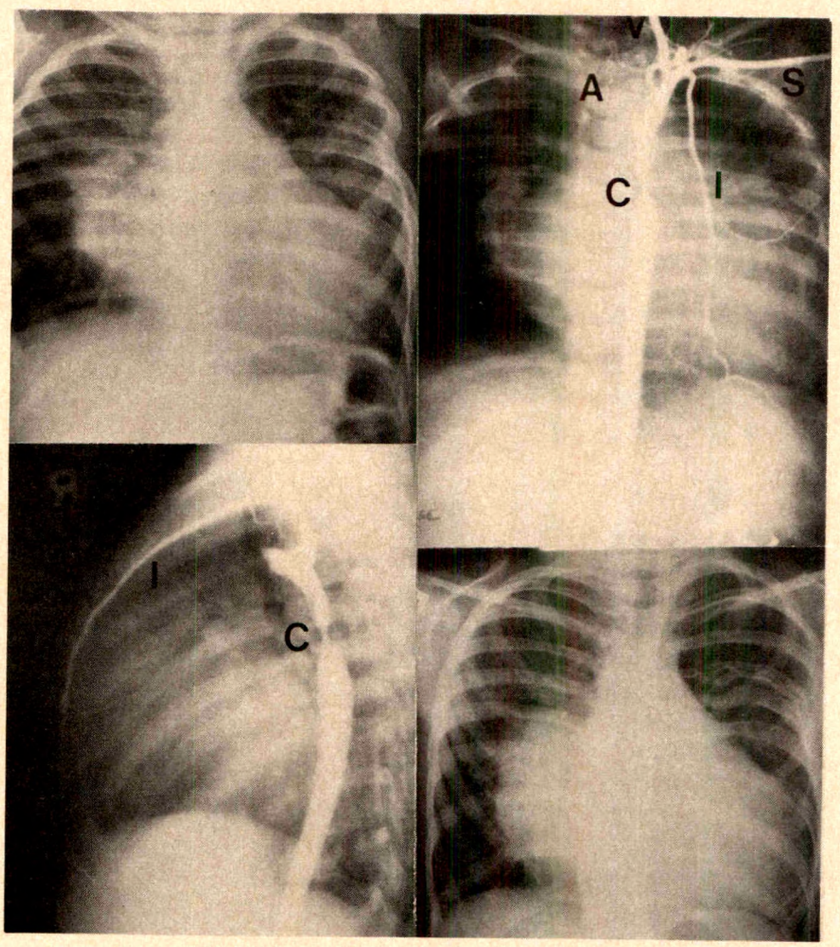

**FIGURE 10.** Chest roentgenograms and arteriograms in a girl with aortic coarctation and mitral regurgitation. Her younger sister died at 4 days of age with aortic coarctation and other congenital cardiovascular malformations. Slow growth, respiratory infections, and a precordial murmur prompted evaluation when she was 17 months of age. The arm blood pressure was 215/115 mm Hg, and she had congestive heart failure. The mitral valve was purely regurgitant and the pulmonary arterial pressure was 105/50 mm Hg. A typical aortic coarctation was resected. Postoperatively, systemic arterial pressure fell to 115/65 mm Hg, but 3 months later signs of infective "endocarditis" developed. While she was being treated for 10 weeks with antibiotic drugs, the femoral pulses gradually disappeared, the blood pressure increased to 205/145 mm Hg, congestive heart failure reappeared, and a chest radiogram (at 24 months) (**upper left**) again disclosed marked generalized cardiomegaly. Films taken in the anteroposterior (**upper right**) and lateral (**lower left**) projections after injection of contrast material into the left subclavian artery (S) showed a large internal mammary artery (I) and a tortuous anterior spinal artery (A) serving as collateral vessels around the aortic recoarctation (C). The vertebral artery (V) was large. The "recoarctation," which showed healing arteritis, was resected and a direct end-to-end anastomosis performed. The arm arterial pressure decreased to 110/80 mm Hg in 36 hours. Signs of mitral regurgitation persisted postoperatively and atrial fibrillation appeared before age 5 years. In addition, the electrocardiogram showed right axis deviation and biventricular hypertrophy. When 7 years old, the patient had striking generalized cardiomegaly with marked left atrial enlargement (**lower right**). She had severe mitral regurgitation and a pulmonary arterial pressure of 35/15 mm Hg, but no pressure gradient between brachial and femoral arteries. Congestive heart failure persisted intermittently, and she died from a respiratory infection at age 16 years.

drome, a severely regurgitant bicuspid aortic valve, mitral regurgitation, and a 1,000 g heart bled from dilated intercostal arteries after replacement of the coarctation with a Teflon graft. A 7-year-old boy with the scimitar syndrome, patent ductus arteriosus, preductile aortic coarctation, a moderate-size left-to-right shunt, and equal pulmonary arterial and descending aortic pressure died from obliterative pulmonary arterial disease and extensive intraalveolar hemorrhage 8 weeks after operation.

*Transient paradoxical postoperative hypertension*, diastolic blood pressure >20 mm Hg higher than the preoperative level, occurred in 41 patients (58%): in 31 (79%) of the 39 patients aged ≤15 years, in 10 (34%) of 29 patients aged >15 years, and in none of 6 patients aged >35 years. In 7 patients the postoperative diastolic blood pressure was >40 mm Hg higher than preoperative pressure. The systolic blood pressure also increased in 40 of the 41 patients. In 29 of the 41 patients, the increase in diastolic pressure exceeded the increase in systolic blood pressure. Seven (all boys ≤15 years of age) of the 41 patients had postoperative abdominal pain (4 patients), vomiting (3 patients), abdominal tenderness (2 patients), occult fecal blood (2 patients), epistaxis (1 patient) and/or subscapular pain (1 patient), when their systemic blood pressures were elevated above preoperative levels (an average of 43 mm Hg systolic and 41 mm Hg diastolic). Two patients also had generalized seizures.

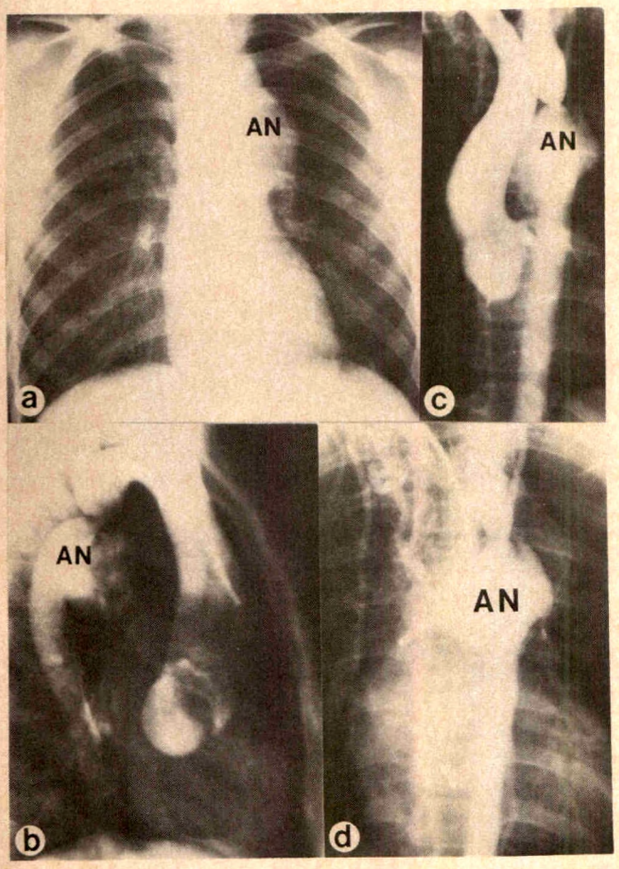

**FIGURE 11.** Posteroanterior chest X-ray (**a**), lateral aortogram (**b**) (taken 3 seconds after injection of contrast material into ascending aorta), and anteroposterior aortograms (**c** and **d**) taken 3 (**c**) and 5.5 (**d**) seconds after injection showing an aortic aneurysm (AN), infected by alpha streptococcus, just distal to a previously unrecognized coarctation in a 12-year-old boy.

Other postoperative complications occurred in 11 (38%) of the 29 patients >15 years of age (including 8 of 13 patients aged >25 years), and in 5 (13%) of 39 aged ≤15 years. The only complication associated with significant permanent sequelae was infective endocarditis in an 8-year-old boy who had septic cerebral emboli and residual hemiparesis and seizures. Thoracotomy was required for control of postoperative bleeding in 6 patients (including 2 of the 4 in whom aortic aneurysms had been resected) and for control of postoperative chylothorax in 1. Eight patients (including 3 requiring postoperative thoracotomy) had recurrent laryngeal nerve damage. In the 6 older patients (aged 19 to 49 years), difficulty with phonation occurred, and in 5 it was transient. One patient, a 49-year-old woman whose aneurysms above and below the coarctation were resected, also had transient left Horner's syndrome and diaphragmatic paralysis. Two patients, aged 8 and 17 years, had dysphagia without dysphonia; in 1 patient the entire left vagus nerve had been knowingly destroyed during removal of a rapidly expanding poststenotic aortic aneurysm infected with alpha streptococcus (Fig. 11). Superficial wound dehiscence, pneumothorax, and atelectasis occurred in 1 patient each.

Two patients required second operations for aortic coarctation. A 20-year-old man who had hypertension and diminished femoral pulses immediately after operation had a 50 mm Hg peak systolic pressure gradient across the proximal anastomosis of the Teflon graft used to replace the coarcted aortic segment, and 3 weeks after the first operation the graft was replaced and the proximal anastomosis made larger. Subsequent blood pressures were normal. An 18-month-old girl became normotensive and had good femoral pulses after resection of an aortic coarctation and end-to-end anastomosis of the aorta, but 2 months later she had infective aortitis accompanied by systemic hypertension (205/145 mm Hg) and gradual disappearance of the femoral pulses (Fig. 10). At age 24 months, the inflammatory narrowing at the site of previous anastomosis was resected, and an end-to-end anastomosis of the aorta was performed. The blood pressure subsequently was normal, and direct pressure measurements 5 years later revealed no gradient across the anastomosis.

By hospital discharge, either systolic or diastolic blood pressure had decreased to below preoperative levels in 58 (87%) of the 67 surviving patients and both pressures had decreased in 42 (63%). Whereas preoperative systolic pressures had been >140 mm Hg in 47 (70%) and diastolic pressures >90 mm Hg in 29 (43%), postoperative pressures were above these levels in only 11 (16%) and 7 (10%) patients, respectively (Table VII).

Of the 67 survivors, 60 have been followed up from 1 month to 15 years after discharge (mean follow-up 4.7 years). Although 53 (88%) of the 60 had preoperative

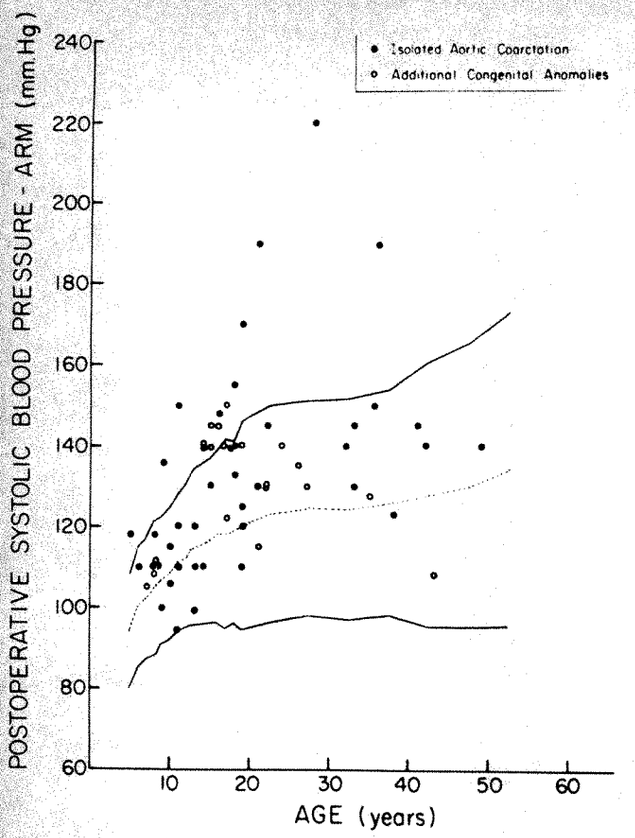

**FIGURE 12.** Systolic blood pressure recorded in the arm by cuff late postoperatively (1 month to 15 years; mean 4.7 years) in 60 patients after resection of aortic coarctation. Mean systolic pressure (±2 standard deviations) for the general population is indicated as in Figure 7.[46-48]

systolic blood pressures >97.5% of the general population, at the most recent postoperative follow-up only 15 (25%) had systolic pressures above these limits (Fig. 12), and in 9 of the 15 the pressure was 10 to 45 mm Hg lower than it was preoperatively. Furthermore, only 3 of the 15 patients have diastolic pressures that are unequivocally increased for their ages. Two of them underwent arterial puncture; the brachial-to-femoral arterial peak systolic gradients were 5 and 15 mm Hg, respectively. The third patient has good leg pulses, whereas none were palpable preoperatively. Despite lowering of blood pressure by operation, the distribution of pressures postoperatively differs from that in the general population (Fig. 12).

Of 11 patients ≥30 years of age with operative correction of aortic coarctation, all had had systolic and 8 had diastolic hypertension preoperatively, but in all 11 patients blood pressure decreased after operation, with the systolic blood pressure at discharge above normal in only 1. Of 9 patients followed up 3 months to 10 years, 1 still had systolic hypertension and 1 had diastolic hypertension.

In 18 patients, 12 of whom were operated on before age 11 years, intraarterial pressures were measured 5 to 15 years (average 11) after operation, which in 17 patients was resection with direct anastomosis. Peak systolic pressure gradients were absent in 8 patients, <10 mm Hg in 5, and 10 to 35 mm Hg in 5. In all patients the mean gradients were <12 mm Hg. In 5 patients pressure gradients were measured directly twice postoperatively (initially 0.3, 11, 12, 12, and 84 months postoperatively; and subsequently 10, 12, 14, 15, and 15 years postoperatively). The values obtained at the 2 studies were virtually identical.

In addition to the 3 patients who died after operation for coarctation, 7 others died later. Three died after operations for associated anomalies, and each of them had mild aortic coarctation: in 1 an earlier attempted resection of the coarctation had been abandoned because the distal aorta collapsed when the coarctated segment was occluded, and in the other 2 aortic coarctation was first discovered at necropsy. Two patients with mild coarctation died from Histoplasma capsulatum aortic valvular endocarditis and carcinoma of the breast. One patient died from coronary arterial occlusion 1 year postoperatively, and 1 patient, who required repeat operation and also had severe congenital mitral regurgitation, died at age 16 years (Fig. 10).

## Discussion

In this study the pathoanatomic features were remarkably uniform. In each patient the coarctation was juxtaductal, and in all but 1 patient the narrowing was discrete and caused by invagination of the media of the posterior aortic wall. Initimal jet lesions frequently caused further narrowing of the aortic lumen and in 4 patients led to complete occlusion.

Gupta and Wiggers[1] and McClenathan et al[2] demonstrated that the cross-sectional area of the aortic isthmus must be reduced 45 to 65% in the dog before any pressure differences are detected above and below the constriction. In contrast, turbulence may be produced by reductions in cross-sectional area as little as 25% and could play a role in the pathogenesis of poststenotic dilatation or even aneurysm formation in patients with mild coarctation. Once the aortic lumen has been narrowed to a critical size, most blood reaches the descending aorta by collateral vessels. The pressure gradient between the ascending and descending aorta then depends primarily on the resistance to flow in these collateral vessels. In the present study, patients whose resected aortic coarctations had luminal diameters ≤1.5 mm usually had rib notching on chest roentgenograms and extensive collateral vessels (seen on angiography), and no correlation existed between luminal diameter and mean gradient across the coarctation. Patients with luminal diameters >2.0 mm usually did not have rib notching or extensive collateral vessels, and the luminal diameter correlated inversely with the mean gradient across the coarctation. The luminal diameter at which collateral flow exceeds flow across the coarctation can be estimated using a modification of the Gorlin formula[3] and, in the intact aorta distended by systemic arterial pressure, is probably 1.5 to 4 mm depending on several factors, including the cardiac output.

*In older children and adults*, the increased pressure work performed by the left ventricle in patients with isolated aortic coarctation is accompanied by left ventricular hypertrophy without dilatation.[4] Ejection

fraction and cardiac output are usually in the high normal range.[4] Left ventricular filling pressures are normal or mildly increased at rest, but may increase to abnormal levels when afterload is markedly increased by exercise.[5] Renal, splanchnic, and leg blood flows are normal at rest,[6,7] but blood flow to the legs may not increase appropriately with exercise. Hemodynamic function may be altered markedly by associated anomalies.

In contrast, in symptomatic newborns with coarctation, left ventricular volume is normal but ejection fraction and systemic cardiac output are markedly reduced, presumably as a result of the sudden imposition of an increase in afterload as the ductus closes and the coarctation becomes obstructive. Left ventricular mass is normal, and a large volume of blood shunts left to right through the foramen ovale. Within weeks to months, the left ventricle hypertrophies and dilates slightly, and the ejection fraction and cardiac output improve.[8]

The high prevalence (43% of total group, 83% of patients 1 to 5 years old) and wide variety of associated congenital cardiovascular anomalies in our patients and in others[9–13] with aortic coarctation are striking. Patent ductus arteriosus, ventricular septal defect, various forms of hypoplastic left heart syndrome, and transposition of the great arteries are commonly associated with coarctation. In our patients, all of whom were >1 year of age, aortic valvular disease was the most common associated anomaly. Of 11 aortic valves examined directly, only 2 were both tricuspid and functioned normally. In patients with coarctation, high prevalence rates of aortic valvular malformations, especially bicuspid valves, are common[14–16], and high prevalence rates of mitral valvular disease have been noted by other investigators[17–20] in patients with coarctation.

One or more episodes of overt cardiac failure occurred in 15 (42%) of our 36 patients with associated anomalies, but in none of the 48 without them. Although described in patients with isolated juxtaductal aortic coarctation,[21,22] congestive heart failure is uncommon, especially after the neonatal period. Similarly, growth retardation, electrocardiographic abnormalities other than borderline voltage criteria for left ventricular hypertrophy, and moderate or marked cardiomegaly on chest roentgenograms are unusual in patients with coarctation alone and should always prompt a search for additional cardiovascular malformations.

Despite the pathognomonic features—arterial hypertension in the arms, delayed and diminished (or absent) femoral arterial pulses, and a systolic ejection murmur heard both between the scapulae and anteriorly—that are present in most patients with aortic coarctation, the diagnosis continues to be missed frequently. The reasons vary. Although it is almost always well above average for the patient's age in significant coarctation, systolic blood pressure may not be >140 or 150 mm Hg, a level considered the upper limit of normal for adults. Thus, that a systolic blood pressure of 125 mm Hg is abnormal for a 6-year-old child may not be appreciated, and further investigation may not be undertaken. Diastolic pressure usually is increased proportionally less than systolic pressure in patients with coarctation. When additional malformations are present, findings related to them may obscure or direct attention away from those resulting from the coarctation. With well-developed collateral vessels and a condition such as aortic regurgitation that causes a large aortic pulse pressure, femoral pulses may feel normal unless carefully compared with arm pulses. Delays in diagnosing coarctation usually result from failure to consider it.

In patients with aortic coarctation, the prognosis depends largely on the presence and type of associated malformations. Those who become symptomatic in the first months of life usually (up to 90% or more) have 1 or more additional malformations. The few patients with isolated coarctation who present with cardiac failure in the first months of life usually respond to digitalis and diuretic drugs and undergo elective operative repair when they are older.[13,22] Infants with associated malformations and cardiac failure rarely respond adequately to medical management, and without operation most die in infancy. Thus, prompt cardiac catheterization and operative correction of the coarctation (with ligation of the ductus and, if a moderate-to-large ventricular septal defect is present, banding of the pulmonary trunk) are mandatory. Despite this aggressive treatment, at least one third fail to survive 2 years.[9,13,23,24]

*When coarctation is first discovered after the patient is 2 years of age*, the prognosis is much less bleak than when symptoms occur in infancy. Nevertheless, life expectancy is considerably lower than that in the general population, even if additional malformations do not exist. Natural history data from before the operative era suggest that of the patients surviving infancy, 26% died by age 20 years, 65% by age 40 years, and 92% by age 60 years.[14,25,26] The mean age at death was 34 years. Congestive heart failure, aortic rupture, infective endocarditis, and intracranial hemorrhage accounted for 76% of deaths. These data come not only from the era before operation but, for the most part, also from the era before antibiotics and effective oral diuretic and antihypertensive agents were available. Prognosis has improved vastly with operative repair, but the life expectancy of patients treated operatively is still far below that of the general population.

There is general agreement that, except for minor narrowings, all juxtaductal aortic coarctations should be repaired operatively. In symptomatic infants with associated anomalies, operation often is lifesaving and should not be delayed. However, in asymptomatic patients, the optimal time for repair is a matter of conjecture. The longer the operation is delayed, the more likely it is that some complication will arise, and in older adults operative mortality and morbidity are increased and long-term results are less than optimal.[27] However, residual or recurrent coarctation with the need for a second operation is more likely to occur in those patients who were operated on in infancy.[13] Age 8 to 12 years has been suggested as the optimal time for elective repair.[28]

*The type of operative repair* is somewhat dependent on the patient's age. Resection with end-to-end anastomosis remains the standard operative technique. The

suture line is usually interrupted in 1 or more places to allow for growth of the aorta and its lumen as the child grows. In infants aortoplasty, usually with the aid of a Dacron® patch or a subclavian flap, may be the preferable procedure.[29-31] The Blalock-Park procedure[32] of transecting the left subclavian artery and anastomosing the proximal end to the distal aorta gives less satisfactory results and is rarely used now. In patients with coexisting tubular hypoplasia of the aorta, in whom the narrowed segment may be quite long, and in some older patients in whom the aorta may be too inelastic for a tension-free anastomosis to be performed, a patch, a flap, or a tubular synthetic graft is used.

Except in infants, patients >40 years of age, and those with associated anomalies, juxtaductal aortic coarctation can be corrected with a risk of death in the early postoperative period of approximately 1%. Because dilated collateral arteries are unavoidably damaged during operation, bleeding remains a significant postoperative problem. Similarly, postoperative difficulty in phonation, usually transient, is common because of the anatomic relation of the recurrent laryngeal nerve to the coarctation and the ligamentum arteriosum. Infective endarteritis (involving the anastomotic site), endocarditis (involving usually the aortic valve), and spinal cord damage[33,34] are less common but more serious complications.

*An increase in blood pressure during the first days after operation to above preoperative levels* is the most common postoperative complication of coarctation resection.[35] In contrast to other complications, which occurred more frequently in our older patients, paradoxical hypertension was seen more frequently in patients <16 years of age. It usually caused no symptoms, but occasionally was accompanied by abdominal pain, distention, nausea, and vomiting requiring nasogastric suction. Rarely, intestinal infarction may occur. These problems can be prevented by keeping postoperative blood pressure in the normal or near-normal range. The pathogenesis of paradoxical hypertension remains incompletely understood.

*Blood pressures in the arms are below preoperative levels in most patients by the time of discharge from the hospital.*[36-38] Furthermore, blood pressure continues to decrease subsequently. Nevertheless, as a group, these patients remain mildly hypertensive compared with the general population.[5,12,27,36-40] With exercise, striking elevations in systolic pressure may occur.[5,40]

*The cause of residual hypertension after coarctation repair* has been the subject of much speculation.[39-41] In a few patients, residual coarctation of significant degree is the cause, and this is most likely to occur when operation is performed during infancy.[41] In addition, mild degrees of residual coarctation are common. Karnell[39] performed postoperative aortography in 81 patients, and in each the diameter of the aortic isthmus, corrected for body surface area, was less than the mean of the diameters in control subjects.

Sehested et al[42] found the precoarctational aortic wall more rigid than the postcoarctational wall and postulated that this influences baroreceptors to tolerate a higher-than-normal pressure. They further postulated that this resetting of the baroreceptors might account not only for paradoxical hypertension in the early postoperative period, but also for sustained mild hypertension late postoperatively. Evidence of increased sympathetic activity many months postoperatively supports this hypothesis.[42,43] In addition, Samanek et al[44] studied patients an average of 11.5 years after coarctation resection and found resting and maximal blood flow reduced and vascular resistance increased in the arm muscles, whereas these were normal in the leg muscles. These findings imply permanent changes in the arteries and/or arterioles subjected to elevated pressure many years earlier, and such changes may contribute to persistent hypertension postoperatively.

Although the prognosis in patients with aortic coarctation is vastly improved by operative correction, these patients as a group do not have a normal life expectancy even when the coarctation is isolated.[15,16,27,39,45] The reasons for this are abundant. Residual hypertension is one. A second is that about 75% of patients have a biscuspid or other malformed aortic valve that predisposes to the development of aortic stenosis, regurgitation, or infective endocarditis, alone or in combination. Third, patients with aortic coarctation are subject to vascular accidents involving the central nervous system (subarachnoid hemorrhage from rupture of a Berry aneurysm, intracerebral hemorrhage, thromboembolic strokes, and paraplegia from spinal cord damage) and to dissecting and saccular aneurysms of the aorta and intercostal arteries. Although resection of the coarctation and its attendant lowering of blood pressure would be expected to, and probably does, decrease the frequency of these complications, it does not eliminate them.[27] Finally, because of long-standing hypertension, coronary atherosclerosis is probably more prevalent in these patients than in the general population. The data of Maron et al[27] suggest that the prognosis after operation for "uncomplicated" coarctation is better in those operated on before 25 years of age. Thus, early diagnosis is essential. Continued careful follow-up of all patients after operative repair is also mandatory, because most have further cardiovascular problems.

# Hemodynamics and Intracardiac Conduction After Operative Repair of Tetralogy of Fallot

DOLORES TAMER, MD, GRACE S. WOLFF, MD, PEDRO FERRER, MD, ARTHUR S. PICKOFF, MD, ALFONSO CASTA, MD, ASHOK V. MEHTA, MD, OTTO GARCIA, MD, and HENRY GELBAND, MD

**Electrophysiologic studies were performed in 47 children aged 3 to 18 years, 15 of whom had cardiac arrhythmias 1 to 15 years after repair of tetralogy of Fallot. Six exhibited sinus or atrioventricular nodal dysfunction, 8 had ventricular extrasystoles, and 1 had supraventricular tachycardia. Hemodynamic and electrophysiologic data were obtained at postoperative catheterization. Although electrophysiologic responses were abnormal in a proportion of both the children with and those without arrhythmia, hemodynamic values were similar. Three of 6 children with impaired sinus impulse generation or atrioventricular nodal conduction had a prolonged A-H interval, and in 3 Wenckebach heart block developed at low pacing rates. Ventricular ectopic rhythm was not associated with any particular abnormality of basic intracardiac conduction intervals. Thus, arrhythmias and conduction abnormalities are not consistently related to residual right ventricular hypertension. Abnormalities in electrophysiologic function are common after repair of tetralogy of Fallot in patients with sinus rhythm and may have prognostic implications for these patients.**

Tetralogy of Fallot is a common congenital heart defect for which reparative open heart surgery has been performed in thousands of patients over the past 2 decades. The immediate risk of the surgery has steadily declined; however, a small but alarming incidence of late sudden unexpected deaths represents a continuing source of concern. Bifascicular block,[1–4] transient complete heart block,[4,5] ventricular ectopic rhythm,[6] especially with right ventricular hypertension,[7–9] and late development of left axis deviation[10] have been associated with sudden unexpected death.

This investigation attempts to determine whether intracardiac hemodynamics relate to the intracardiac conduction properties in children after repair of tetralogy of Fallot. Also, because arrhythmias have been implicated in late mortality, it was hoped to determine whether those children with arrhythmias have specific conduction abnormalities that may serve to identify those requiring increased surveillance. The study was begun in 1975 to collect electrocardiographic information and to correlate this with postoperative hemodynamics and electrophysiologic functions at cardiac catheterization.

From the University of Miami School of Medicine, Department of Pediatrics, Miami, Florida. This study was supported in part by Grant HL07436 from the National Institutes of Health, Bethesda, Maryland. Manuscript received December 9, 1981; revised manuscript received August 19, 1982, accepted August 20, 1982.

## Methods

Forty-seven children were studied after operative repair of tetralogy of Fallot. None had arrhythmia preoperatively on standard electrocardiography. In 13 children the indications for admission included findings of residual heart disease or electrocardiographic abnormality; the remaining 34 were admitted electively. There were 24 male and 22 female patients, aged 3 to 18 years. Surgery had been performed 1 to 15 years previously (average 4.3). All children had a routine 12-lead electrocardiogram.

After informed consent had been obtained, cardiac catheterization was performed and included hemodynamics, cineangiography, and determination of basic intracardiac conduction intervals, right ventricular activation time, and sinus node recovery time to rapid atrial pacing. Thirty-one patients had programmed atrial extrastimulation studies, and 21 had programmed ventricular stimulation. Thirty patients also had

ambulatory electrocardiographic monitoring and 29 had exercise stress testing using the modified Bruce protocol.

The materials and methods used for catheterization and electrode placement have previously been described.[11] Agents used for sedation included Demerol®, Phenergan®, Thorazine®, and pentobarbital sodium. Basic intervals and apical activation were compared with those of age-matched preoperative children studied in this laboratory.[12] Sinus node recovery time was measured from the last paced atrial deflection to the first spontaneous atrial beat and then divided by the resting sinus cycle length and expressed as a percentage. The majority of preoperative children have values for this percentage <160% in our laboratory.[12] The response to rapid atrial pacing was monitored for development of Wenckebach heart block. The cycle length at which Wenckebach periodicity occurred was compared with the reference distribution for our laboratory.[12] Values for Wenckebach periodicity were considered abnormal if they fell outside this reference. Definitions of basic intervals, right atrial effective refractory period, atrioventricular nodal effective refractory period, right ventricular effective refractory period, and right ventricular apical activation time have been cited[13] previously.

## Results

**Electrocardiographic findings:** Various arrhythmias were discovered by scalar electrocardiography (11 cases), ambulatory monitoring (3 cases), or exercise stress testing (1 case), The arrhythmias are listed in Table I and characterize Group A. Six children had various manifestations of sinus or atrioventricular nodal dysfunction, including sinus arrest, spontaneous Mobitz type I or II atrioventricular block, and junctional bradycardia (Table I). One child had supraventricular tachycardia and 8 had ventricular ectopic rhythm, which consisted of uniform single ectopic beats or bigeminy that were suppressed or unaffected by exercise. There were 32 children without arrhythmia and these comprise Group B (Table III). The average age of children in Group A was 8.9 years, of Group B 7.7 years, and of the study group as a whole 8.1 years. Twelve-lead scalar electrocardiograms revealed right bundle branch block in 96% of all cases and in all 15 cases in Group A.

LAD = left axis deviation; ND = not done; PRBBB = proximal right bundle branch block; other abbreviations as in Tables I and II.

Four children in Group A and 4 in Group B had left axis deviation that was not present preoperatively.

**Hemodynamic findings:** The majority of children had good hemodynamics postoperatively (Tables I and III), although mild pulmonary valve stenosis or pulmonary insufficiency, or both, were common. Four children in Group A and 4 in Group B had severe pulmonary stenosis, with right ventricular pressure ≥60 mm Hg. Two children in Group A and 1 in Group B required reoperation after these studies. Tricuspid valve regurgitation was found on right ventricular cineangiography in 4 children each in Groups A and B. Right atrial mean pressure was increased >8 mm Hg in 1 child in Group A (Case 11) and 2 in Group B. Right ventricular end-diastolic pressure was increased (>8 mm Hg) in 3 children in Group A and 10 children in Group B, and may reflect residual pulmonary insufficiency, right ventricular dysfunction, or decreased right ventricular compliance. Right ventricular aneurysm was defined angiographically by dilatation of the right ventricular outflow area to twice the diameter of the main pulmonary artery as visualized on the frontal view and was present in 2 children in Group A and 9 in Group B. Pulmonary stenosis was considered mild to moderate when right ventricular pressure was <60 mm Hg. Significant pulmonary insufficiency was defined by at least a grade 2/6 diastolic murmur at the pulmonary area. Three children had small residual ventricular septal defects. The residual cardiac defects are summarized in Table IV.

* p = 0.05 (chi-square).

**Electrophysiologic data:** These data are similar to conduction studies reported previously[14–16] after operative repair of tetralogy of Fallot. In addition, similar percentages of abnormal electrophysiologic findings were present in Group A as a whole and Group B (Tables II, III, and V). However, when the subgroup of cases of arrhythmia with impaired sinus or atrioventricular nodal conduction was analyzed separately, a higher aggregate number of cases had abnormal conduction values as compared with cases with ventricular ectopic rhythm or patients in Group B. There was no single pattern or abnormal measurement of conduction in the 6 children with impaired function (cases 1 to 6), although each had at least 1 abnormal value in the studies performed (Table II). Three children had a prolonged A-H interval of atrioventricular nodal dysfunction (cases 1, 4, and 5). One had a prolonged H-V interval consistent with His-Purkinje disease (case 2). In 3 children Wenckebach heart block developed at abnormally low paced rates (cases 3, 4, and 6) and in case 3 the block occurred below the His bundle. Only 2 of the 4 children (cases 2 and 5) suspected of having sinus node dysfunction had prolongation of the sinus node recovery time, suggesting either that this measurement is not sensitive, that vagal slowing may account for the observed bradycardia, or that the circumstances of the study did not reflect the clinical situation because of sedation or other factors.

## Discussion

Fifteen of 47 patients with postoperative tetralogy of Fallot manifested significant cardiac arrhythmias. In the 6 children with impaired sinus generation or atrioventricular nodal conduction, various electrophysiologic abnormalities were noted including prolonged A-H or H-V interval, increased sinus node recovery time, atrioventricular nodal effective refractory period, or appearance of Wenckebach periodicity at low pacing rates. Atrial and ventricular effective refractory periods were normal in these children. More children in Group A had a prolonged A-H interval (p = 0.05); however, the frequency of the other abnormalities was not statistically different in Groups A and B. Specifically, H-V interval, sinus node recovery time, Wenckebach periodicity, and atrial, ventricular, and atrioventricular nodal effective refractory periods were found in similar proportions in patients with and without overt arrhythmias.

Children with ventricular ectopic rhythm had no consistent abnormality of basic conduction intervals. In 5 of 6 cases in Group B in which comparison was possible, the right ventricular effective refractory period was longer at the outflow region of the right ventricle than at the apex. Only 2 of the 8 children cases with extrasystoles had ventricular stimulation. Provocative measures such as multiple stimuli or burst ventricular pacing might have uncovered more abnormalities. Ventricular tachycardia was reported after repair of tetralogy of Fallot[17] which used a reentry circuit around the margin of the ventriculotomy. Kavey et al[18] noted that fewer patients in their series of cases of ventricular tachycardia had outflow patches. One may speculate that the interposition of fabric may tend to interrupt a potential ventricular reentrant pathway. The difference we observed in ventricular refractoriness may be potentially arrhythmogenic. Other potentially arrhythmogenic factors such as prolonged effective refractory period, presence of dual atrioventricular nodal pathways, and split His potentials (reported previously)[11,19] are of uncertain prognostic significance. In addition, the large proportion of children in Group B who had sinus rhythm and abnormal intracardiac conduction values may have latent conduction disease and will require continued medical follow-up to determine whether impaired conduction or ventricular arrhythmia appears.[20]

Despite the findings of other investigators that ventricular extrasystoles were more frequent when right ventricular hypertension persisted,[7–9] our data show no consistent relation. Two patients with impaired conduction and 2 with ventricular extrasystoles had a right ventricular systolic pressure >60 mm Hg, but the majority of patients with arrhythmia had good hemodynamic results. Although a direct relation between the rate of pacemaker depolarization and myocardial stretch was demonstrated in vitro,[21] the present findings do not support a mechanical factor as the likely mechanism in clinical cases of postoperative rhythm disturbances. Furthermore, the reported series of ventricular tachycardia[17,18,22] occurred in cases with no significant residual pulmonary stenosis. The increase in ventricular arrhythmias noted by James and co-workers[22] after exercise may represent increased ventricular excitability

due to sympathetic discharge in patients who have a latent reentry circuit around the ventriculotomy. The observation that several patients with ventricular extrasystoles and right ventricular hypertension had sudden death[7-9] may reflect the poor tolerance of patients with impaired hemodynamic function to the circulatory effects of arrhythmias. Ventricular ectopic rhythm or conduction impairment, residual hemodynamic stress, and myocardial injury may combine to bring about sudden death. Furthermore, the incidence of ventricular arrhythmia was increased in older patients especially in those with tetralogy of Fallot followed up 10 years or more,[2,6,9,10,22-24] suggesting a relation to late fibrosis in the myocardium. Recent methods of myocardial preservation during surgery and the practice of operating at an earlier age may change the future incidence of ventricular arrhythmias.

Conclusions from these data are threefold: (1) children with evidence of Mobitz type I or II atrioventricular block usually have electrophysiologic abnormalities; (2) right ventricular hypertension or residual heart disease does not correlate well with the occurrence of arrhythmias or with electrophysiologic abnormalities; (3) a large number of children after repair of tetralogy of Fallot have conduction abnormalities and normal sinus rhythm. Although the arrhythmias and the electrophysiologic findings were well tolerated in this series and in others,[15,23] a longer period of observation is necessary before the prognostic significance of these findings is known.

# Terminal Cardiac Electrical Activity in Pediatric Patients

CHRISTINE KULL WALSH, MD and EHUD KRONGRAD, MD

**Ventricular fibrillation (VF) is a frequently reported terminal cardiac electrical activity in adults. Such data are unavailable for pediatric patients. Terminal cardiac electrical activity determined in 100 pediatric patients was bradycardic arrest throughout the death process in 88% of newborns, 67% of infants, and 64% of children. Although bradycardic arrest was more common, the incidence of ventricular tachyarrhythmias was higher in patients who had congenital heart disease, who had received cardiopulmonary resuscitation, who were beyond the neonatal period, and/or who weighed >2.23 kg. No definite associations could be established between arterial blood gases, electrolyte values, and type of terminal cardiac electrical activity. The development of VF may be related to cardiac mass and the developing autonomic nervous system and therefore is less likely to occur in patients with a small heart.**

Cardiac arrest is defined as the sudden cessation of cardiac output. The electrical phenomena associated with cardiac arrest include VF and bradycardic arrest. The latter term refers to ventricular standstill or asystole, in which mechanical and electrical activity have ceased, and to agonal rhythm, in which there are wide, bizarre ventricular complexes but no myocardial contractions, palpable pulse, or heart sounds. Terminal cardiac electrical activity may differ with different patient populations. The most common cause of cardiac arrest associated with anesthetic induction and surgical procedures is asystole, probably precipitated by marked vagal stimulation.[1] Medical and surgical patients admitted for cardiac disease and persons who die suddenly most often die in VF.[2,3] The final mechanism of cardiac arrest may be complex and may be affected by various additive events, such as electrolyte imbalance, metabolic acidosis, hypothermia, intrinsic cardiac electrical abnormalities, intrinsic or drug-induced autonomic activity, disturbances of central nervous system function, and myocardial ischemia.[4,5]

No information is available about the terminal electrical events in children who die suddenly or who are expected to die. Indeed, reported studies of the terminal cardiac electrical activity in adults who die suddenly may bear no relation to that in children who die suddenly or who are expected to die. Therefore, this study was undertaken to determine the types of terminal cardiac electrical activity that occur in hospitalized pediatric patients and to determine if there is any association with conditions that might facilitate the development of VF or bradycardic arrest, or both, such as acid-base and electrolyte disturbances.

## Methods

**Patient population:** The prospective study population included 100 hospitalized pediatric patients, 56 boys and 44 girls, who died at Babies Hospital in New York (Table I). The patients were divided into 3 age groups: 54 newborn infants aged 1 to 28 days (median 3), 24 infants aged 28 days to 1 year (median 3 months), and 22 children aged 1 to 18 years (median 6.6).

In the newborn group, 18 patients (33%) had congenital heart disease and 17 patients (31%) had severe respiratory distress syndrome. Five patients had sepsis, 4 had intracranial hemorrhage, 3 had meconium aspiration, and 7 had other causes of death. Of the 54 newborns, 28 were premature. The infant group contained 13 patients (54%) with congenital heart disease. Others had renal failure (3 patients), bronchopulmonary dysplasia (2 patients), or various other causes of death (6 patients). Fifteen (68%) of the 22 children had congenital heart disease. Two patients died from Reye's syndrome and 5 from different causes. Digitalis blood levels were not obtained. No patient was receiving digitalis at the time of death, because patients dying from congenital heart disease either had restricted pulmonary blood flow or were postoperative. Digitalis was routinely discontinued 2 days before surgery, and postoperative congestive heart failure and low output were treated with pressor agents such as dopamine or isoproterenol.

**Recording of terminal cardiac electrical activity:** A 1-lead (usually lead II) electrocardiogram was obtained from cardiac monitors or portable recorders, or both. Recording was usually precipitated by deterioration of clinical status or by an arrhythmia and was terminated with cessation of all cardiac electrical activity. The electrocardiographic recording was continued throughout the entire death process and during cardiopulmonary resuscitation when applied. The duration of recordings was 20 to 90 minutes during resuscitation and another 5 to 15 minutes after blood pressure, respiration, and pulse were absent.

**Laboratory studies:** The last arterial pH and partial pressure of oxygen and carbon dioxide values obtained in patients were recorded. These results were divided into 3 groups: (1) those obtained <1 hour before death, (2) those obtained 1 to 4 hours before death, and (3) those obtained 4 to 24 hours before death. The same classification was applied to the last sodium, potassium, and chloride values.

**Statistical analysis:** Statistical analysis of the data was performed using a chi-square test or Fisher's exact test.

## Results

**Types of terminal cardiac electrical activity:** Two basic types of terminal cardiac electrical activity were observed. In 1, bradycardic arrest occurred without ventricular tachyarrhythmia. Electrical activity included a gradual slowing of the heart rate with deterioration of AV conduction and QRS, S-T, and T wave configuration until complete cessation occurred. In the other, ventricular tachycardia or VF, or both, were prominent.

Figure 1 depicts bradycardic arrest which occurred throughout the terminal electrical activity of a child who died from smoke inhalation. The sequence of electrical events was sinus tachycardia followed by ST-T wave changes increasing atrioventricular block with QRS and Q-T prolongation, and finally wide, bizarre QRS complexes at an extremely slow, irregular rate until complete standstill occurred.

In the other type of observed terminal cardiac electrical activity, ventricular tachycardia or VF occurred during the death process. The final electrical event was either bradycardic arrest or deteriorating VF until standstill. Figure 2 depicts recurrent VF in a 1 month old infant with congenital heart disease.

The terminal cardiac electrical activity in all 100 patients is summarized in Figure 3. Bradycardic arrest was present throughout the death process in 78% of patients. Ventricular tachycardia or VF was seen during terminal electrical activity in 22 patients, 16 of whom had bradycardic arrest as the final electrical event. Six

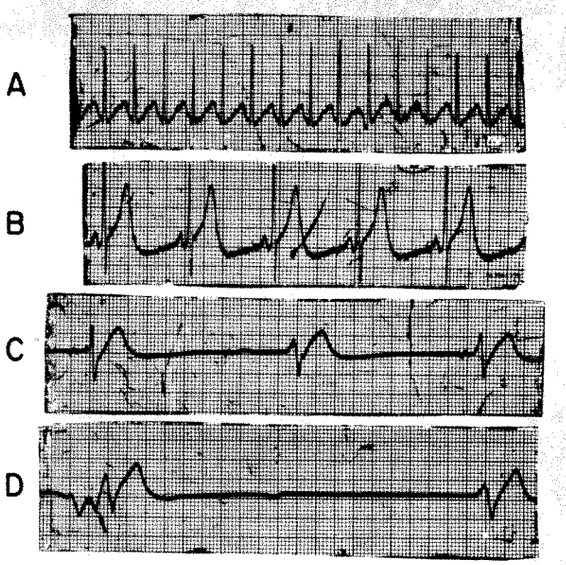

**FIGURE 1.** Successive electrocardiograms of a 5-year-old child who died from smoke inhalation. **A,** sinus tachycardia at a rate of about 200 beats/min. **B,** progressive sinus bradycardia with ST-T wave changes. **C,** atrioventricular dissociation with an idioventricular rhythm. **D,** a very slow terminal idioventricular rhythm with abnormally wide, bizarre QRS complexes.

patients had deteriorating and unremitting VF as the final electrical activity in the death process.

**Effect of age:** Bradycardic arrest was the most frequent terminal cardiac electrical activity in all groups (Fig. 4). Of the 54 newborns, 88% had bradycardic arrest throughout, whereas 67% of the 24 infants and 64% of the 22 children had this type of terminal activity. The difference in the terminal cardiac electrical activity of

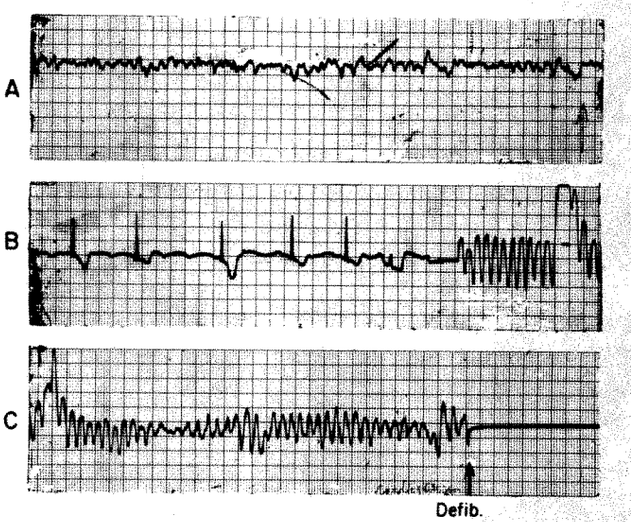

**FIGURE 2.** Successive rhythm strips obtained during prolonged cardiopulmonary resuscitation in a 1-month-old infant with cyanotic congenital heart disease. VF is evident in **A. B,** irregular ventricular contractions after cardioversion. The rhythm deteriorates to VF towards the end of this strip. **C,** continuation of VF with cardioversion (Defib.) to asystole.

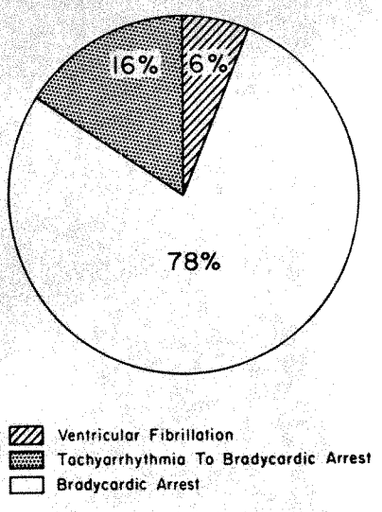

**FIGURE 3.** Summary of the terminal cardiac electrical activity in 100 patients. Bradycardic arrest occurred throughout the death process in 78% of patients. Sixteen percent had episodes of ventricular tachycardia or VF, with bradycardic arrest as the final electrical event. Unremitting VF was seen in 6%.

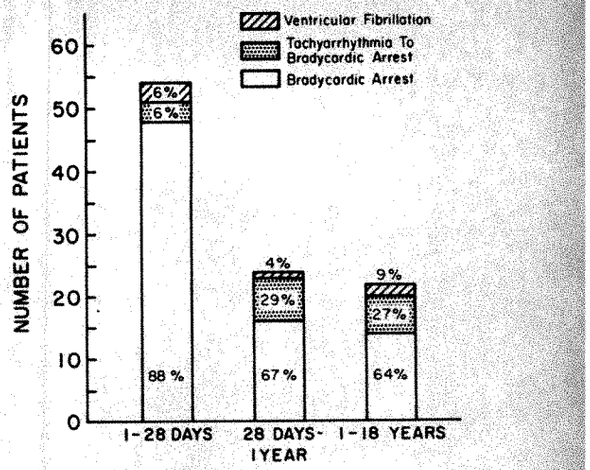

**FIGURE 4.** Terminal cardiac electrical activity among newborns aged <28 days, infants aged 28 days to 1 year, and children aged >1 year. Bradycardic arrest was the most common pattern in all age groups.

newborns versus that in older pediatric patients is statistically significant ($p < 0.01$), but no significant difference exists between the 2 older groups. Thus, 12% of newborns and 35% of the combined older groups had ventricular tachyarrhythmias, suggesting an increased tendency to develop ventricular tachyarrhythmias after the newborn period.

**Relation to patient weight:** The relation of weight to terminal cardiac activity also was examined. Because autopsies were performed in only a small number of children, cardiac mass could not be obtained directly. Patients' weight ranged from 630 g to 45 kg (median 3.25 kg). Ventricular tachycardia and VF did not occur in the 32 patients weighing <2.23 kg. Only 3 (9%) of these patients had congenital heart disease.

**Relation to congenital heart disease:** Forty-six patients had congenital heart disease and 54 patients had other terminal diseases (Fig. 5). Bradycardic arrest was the most common terminal cardiac electrical activity, but ventricular tachyarrhythmias were seen in 35% of patients with and 11% of those without congenital heart disease. Three of the 6 patients with congenital heart disease and VF died in the operating room. No patient without congenital heart disease had VF as the final cardiac electrical event.

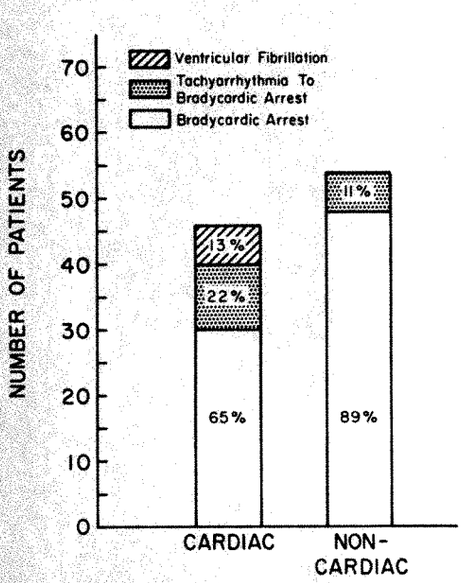

**FIGURE 5.** Relation of congenital heart disease to terminal cardiac electrical activity. Although bradycardic arrest was most common in both groups, ventricular tachyarrhythmia occurred more frequently in patients with congenital heart disease than in those with other diagnoses ($p < 0.01$).

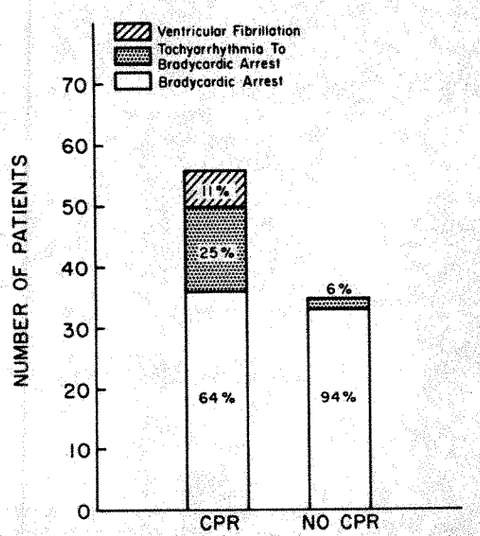

**FIGURE 6.** Relation of cardiopulmonary resuscitation (CPR) to terminal cardiac electrical activity. Bradycardic arrest occurred most frequently in both groups, but ventricular tachyarrhythmias were seen more often in patients who experienced resuscitative efforts ($p < 0.005$).

| 4–24 | 7.21–7.70 | 7.40 (6) | 27–69 | 44 (6) | 50–140 | 78 (6) |

* Figures in parentheses represent number of values obtained.
$pCO_2$ and $pO_2$ = partial pressure of carbon dioxide and oxygen, respectively.

**Relation to cardiopulmonary resuscitation:** Among 56 patients who had cardiopulmonary resuscitation, 64% died with bradycardic arrest, 25% had a transient tachyarrhythmia, and 11% had VF as the terminal cardiac electrical activity (Fig. 6). In contrast, 94% of patients with end-stage terminal illness or brain death who did not experience resuscitative efforts died with bradycardic arrest.

**Arterial blood gases and electrolytes:** Arterial blood gas and serum electrolyte values are given in Tables II and III. No definite associations could be established between pH, partial pressure of oxygen and carbon dioxide, sodium, potassium, and chloride values and the type of terminal cardiac electrical activity. Ventricular tachyarrhythmias were observed infrequently in acidotic patients, but because these patients were most often neonates, this relation could not be separated from the possible additive effects of age and weight.

## Discussion

Bradycardic arrest was the most common terminal cardiac electrical activity in all pediatric patients studied irrespective of diagnosis, resuscitative efforts, or acid-base and electrolyte status. No comparable data are available for terminal hospitalized adult patients. The data were most striking among newborns, 88% of whom had bradycardic arrest as the terminal rhythm.

The propensity to develop tachyarrhythmias increased with age. The percentage of patients dying from congenital heart disease also increased with age. Cardiac patients were 3 times more likely to have tachyarrhythmias than were noncardiac patients (35 versus 11% of each group). In addition, deteriorating VF did not occur as the terminal cardiac electrical activity in any patient without congenital heart disease. Nevertheless, when the noncardiac patients are considered by themselves, the tendency to develop tachyarrhythmias increases with age (Fig. 7). Moreover, the same trend also is evident within cardiac patients after they are analyzed alone. Therefore, age and not the mere presence of congenital heart disease appears to be a dominant factor in determining the propensity to develop a certain kind of terminal electrical activity.

Our clinical observations support electrophysiologic data suggesting that induction and maintenance of VF is related to cardiac mass and therefore less likely to occur in smaller hearts. In 1887, McWilliams[6] found that VF could exist more easily in larger hearts than

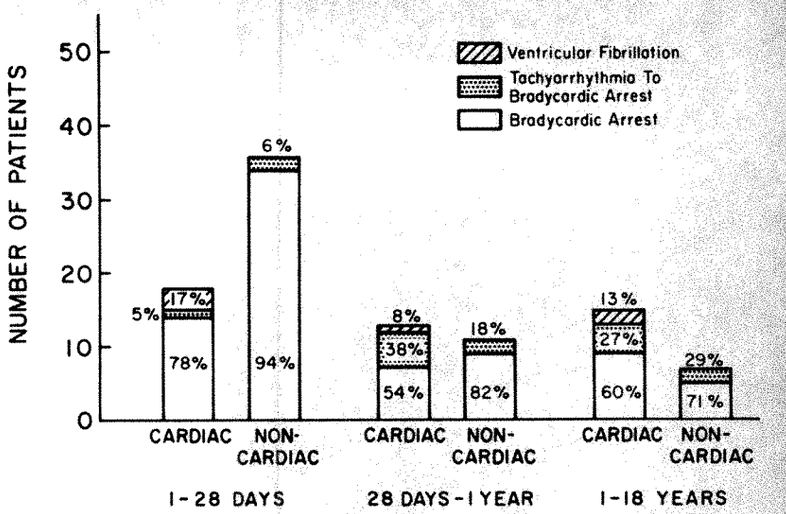

**FIGURE 7.** Terminal cardiac electrical activity in cardiac versus noncardiac patients, in newborn, infant, and child groups. The tendency to develop tachyarrhythmia increased similarly with age in both cardiac and noncardiac patients.

smaller ones. In 1914, Garrey[7] showed that pieces of muscle from a fibrillating left ventricle of a dog stopped fibrillating when the surface area was reduced to less than 4 $cm^2$. When only one fourth of the ventricular mass remained, it too stopped fibrillating. If fibrillation is more difficult to initiate and maintain in the small heart of young animals, the same may be true for the relatively small heart of infants and children. The possible effects of a critical cardiac mass on the development of VF is most evident when the relation of weight to terminal cardiac electrical activity is investigated. Although ventricular tachyarrhythmias occurred in patients as young as 1 day of age, none occurred in any of the 32 patients <2.23 kg.

The developing autonomic nervous system may play an important role in the age-related changes in cardiac rhythm. Studies[8] show that parasympathetic and alpha-adrenergic activity is dominant at an early period of gestation. Beta-adrenergic activity in the myocardium matures much later. Rosen et al[9] demonstrated that there are age-related changes in alpha- and beta-adrenergic responsiveness of the heart that may influence the occurrence of a particular arrhythmia. The late development of beta-adrenergic effects will cause a decrease in the VF threshold that would alter ventricular vulnerability to VF.[10] The fact that alpha- and beta-adrenergic activities are opposite in nature and mature asynchronously suggests that they may strongly influence the mechanism and type of arrhythmia that occurs in the neonate, infant, or child. The early dominance of the parasympathetic system and alpha-adrenergic activity may further explain why bradycardic arrest is the most common terminal cardiac electrical activity in infants. Such consideration cannot be applied when maturation of the autonomic nervous system has already been completed.

In contrast to adult medical and surgical patients hospitalized for cardiac disease, most of whom have VF as the terminal rhythm,[2] most children with congenital heart disease still had bradycardiac arrest as the terminal cardiac electrical activity. In our patient population, ventricular tachyarrhythmias were seen more often with congenital heart disease than with other terminal diseases. The increased muscle mass and cardiac hypertrophy associated with congenital heart disease may contribute to the increased tendency to develop a terminal cardiac tachyarrhythmia.

Many variables may contribute to the development of a certain type of terminal cardiac electrical activity.[4-13] These abnormalities are seldom found in isolation and their interrelationship is extremely complex and cannot be ascertained by clinical observations alone. Nevertheless, terminal tachyarrhythmias were seen more often in patients with congenital heart disease and in those who received cardiopulmonary resuscitation. Catecholamine administration during cardiopulmonary resuscitation may also contribute to the development of tachyarrhythmias. All 6 patients who died in unremitting VF had congenital heart disease and received unsuccessful cardiopulmonary resuscitation.

# Percutaneous Transluminal Angioplasty of Congenital Coarctation of the Aorta

DONALD R. SPERLING, MD, THOMAS J. DORSEY, MD, MARSHALL ROWEN, MD, and ALAN B. GAZZANIGA, MD

**Two cases of successful dilatation of congenital coarctation of the aorta using the Grüntzig technique are reported. In a 3-week-old boy and an 11-month-old girl, systolic gradients across the narrowed areas were lowered from 50 to 8 mm Hg and from 23 to 8 mm Hg. Although the femoral pulses later disappeared in the younger patient, surgery was avoided. The second patient's gradient has remained minimal for 8 months and no surgery has been performed.**

The use of catheters to dilate vascular obstructions has increased since the original description by Dotter and Judkins[1] in 1964. Coaxial dilatation was followed by the use of balloon-tipped catheters in 1973 and 1974.[2,3] Grüntzig and Hopff[4] reported their initial experience with coronary arterial dilatation in 50 patients in 1979. The same technique also has been used to dilate a constriction in the distal abdominal aorta[5] and has been applied to relief of stenosis of the renal artery in a 3-year-old girl.[6] These catheters have been used to dilate artificially created branch pulmonary arterial stenoses in newborn lambs.[7] This study describes the use of the Grüntzig technique to dilate congenital coarctation of the aorta in 2 patients.

## Methods

A 5Fr Grüntzig dilatation catheter was inserted percutaneously into the femoral artery. This catheter has an inflatable balloon 5 mm in diameter and 2 cm in length. The catheter was passed across the coarctation into the ascending aorta for pressure recording and injection of contrast material through the end hole of the catheter (Fig. 1 and 2). The gradient across the coarctation was measured just before the balloon was placed across the area of narrowing (Fig. 3). The 2 radiopaque clips inherent in the catheter were used to delineate the limits of the balloon for orientation. The balloon was inflated by hand over a 3-second period with half-strength Renografin® to 75 lb/in$^2$ measured with use of a gauge. Full inflation time was 10 seconds and deflation time was 3 seconds. This was repeated 3 times over a 10 to 15 minute period. Postdilatation angiograms and pressure measurements were obtained (Fig. 2, 3, and 4). No complications occurred during or after the procedure.

## Comments

The 2 patients described in Table I and Figures 1 to 5 clearly demonstrate that acute dilatation of coarctation of the aorta is possible. Whether relief of the constriction will persist is unknown, although the pressure differential by cuff measurement has remained decreased for 5 and 8 months, respectively, after the procedure in these patients. The absence of femoral pulses with an 18 mm Hg sphygmomanometer pressure gradient between the right arm and left leg indicates persisting or recurrent obstruction in Patient 1, but early surgery was avoided. Dilatation in the moribund neonate with acute congestive heart failure secondary to the coarctation syndrome in conjunction with prostaglandin $E_1$[8] also is to be considered and may avoid early coarctation surgery. The 8-month success in our second patient suggests that the procedure may obviate surgery completely in some cases.

| Patient | Age | | Cardiac Catheterization Pressure (mm Hg) Above Coarctation | Below Coarctation | Femoral Pulses | Cuff Blood Pressure (mm Hg) Right Arm | Left Leg |
|---|---|---|---|---|---|---|---|
| 1 | 17 days | Before D | 124/68 | 74/59 | 0 | 100/80 | 40/Flush |
| | | After D | 122/72 | 114/72 | 0 (late) | 120/77 | 102/67 |
| 2 | 1 year | Before D | 98/60 | 75/60 | 0 | 110/70 | 50/Flush |
| | | After D | 89/53 | 81/53 | + | 93/83 | 97/78 |

D = dilatation.

The use of balloon dilatation of other congenital heart conditions must be considered. Postsurgical applications may be dilatation of a narrowed Blalock-Taussig shunt or a narrowed aorta after coarctectomy or patch angioplasty.[9] Artificially created peripheral pulmonary stenoses have been relieved in lambs[7]; perhaps this will also be possible in humans. A narrowly obstructed area in an anomalous pulmonary vein is a potential application. Dilatation of isolated pulmonary valvular stenosis or the pulmonary valve in tetralogy of Fallot are also potential applications of this procedure.

**Acknowledgment:** We thank Patrick Poon, MD, and Jet Black, MD, for patient referrals, the Special Procedures laboratory personnel at Childrens Hospital of Orange County for invaluable technical help, and Marion Sheppard for manuscript preparation.

# NOW IT'S HERE... ONCE-A-DAY 24-HOUR ANGINA PROPHYLAXIS

# TRANSDERM®-NITRO

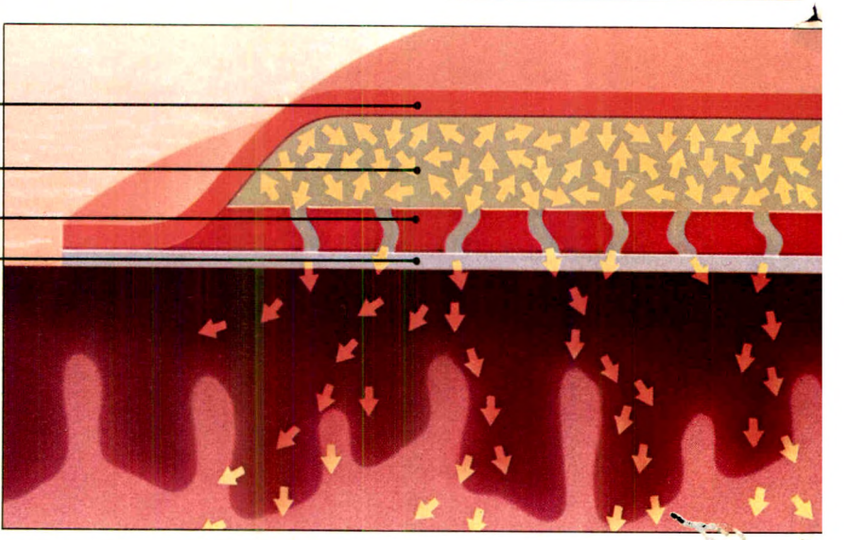
nitroglycerin

# once-a-day

# Transderm-Nitro®

## nitroglycerin

**Exclusive rate-controlling membrane delivers hour-by-hour precision dosage**



- Specially designed copolymer membrane governs, and limits, rate at which drug diffuses from the system to the skin.
- Similar to an intravenous *infusion*, Transderm-Nitro delivers medication at a constant rate.
- Patients are protected against extremely high concentrations being reached even where skin is unusually permeable.

(actual size)

(approx. thinness)

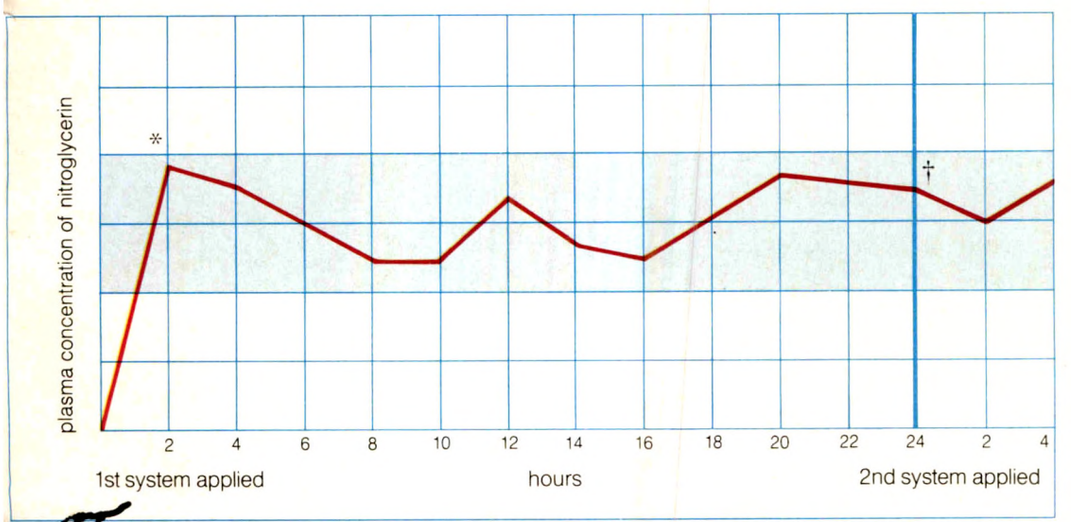
**Magnified cross section of Transderm-Nitro system**

Contains an initial dose of medication to saturate skin-binding sites so that absorption begins immediately

# Precision dosage system assures 24-hour angina protection

## Steady, sustained 24-hour nitroglycerin levels

- Constant protection against angina attacks assured by uninterrupted plasma concentrations of nitroglycerin: Transderm-Nitro 5 rated to release 5 mg/24 hours; Transderm-Nitro 10 rated to release 10 mg/24 hours.



Orthostatic hypotension may indicate nitroglycerin overdosage; reduce dosage if symptoms occur. Nitrates are contraindicated in patients with increased intraocular pressure. Withdrawal should be gradual if treatment is terminated. Do not apply to distal parts of the arms and legs.

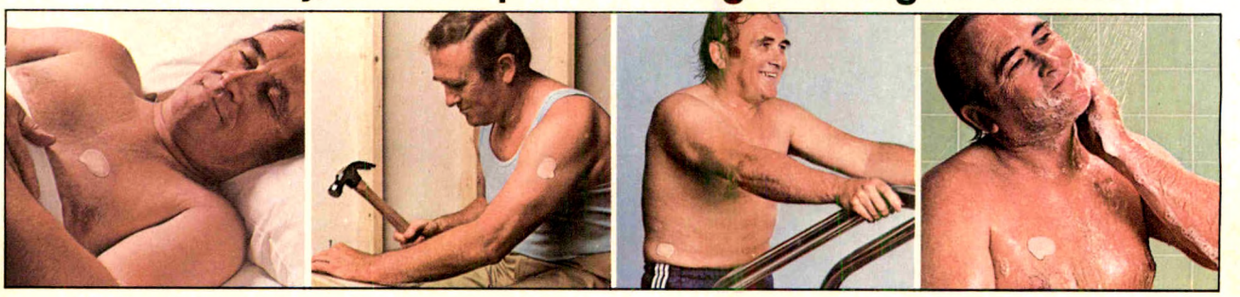
## System is simple and easy to use

- Every 24 hours the old system is removed and the new one applied.
- Therapeutic effect can be anticipated 30 minutes after application and maintained for 30 minutes following removal.
- Can be applied anywhere on the body except the distal extremities.

## An advance beyond tablets and ointments

- 24-hour sustained therapeutic blood levels of nitroglycerin
- Precise dosage control
- Ease of administration...avoids mess and inconvenience of ointments
- Once-a-day dosage to enhance compliance
- May be worn while swimming, bathing and showering

*First measurement in this study was taken at 2 hours. However, a therapeutic effect can be anticipated 30 minutes after application of the system, and will be maintained for 30 minutes after its removal.



†After 24 hours, system is removed and a new one is applied to another site. Renewal of the system does not result in any significant alteration in the plasma levels, as long as the change is made without delay.

CIBA

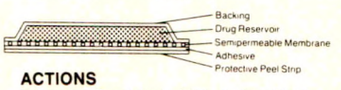
*For full details, please see the prescribing information on the next page.*

# Transderm®-Nitro nitroglycerin

## Once-a-day, 24-hour protection against angina attacks

System can be applied anywhere except distal extremities. Doesn't compromise daily activities.

**Transderm®-Nitro**
(nitroglycerin)
**Transdermal Therapeutic System**



### DESCRIPTION

Transderm-Nitro (nitroglycerin) transdermal therapeutic system is a flat unit designed to provide controlled release of nitroglycerin through a semipermeable membrane continuously for 24 hours following application to intact skin. Nitroglycerin (glyceryl trinitrate) is a prompt-acting vasodilator for the relief and prevention of anginal attacks. Systems are rated to release *in vivo* 5 and 10 mg nitroglycerin over 24 hours and are in sizes of 10 and 20 $cm^2$ respectively.

One-fifth of the total nitroglycerin in the system is delivered transdermally to the patient over 24 hours; the remainder serves as the thermodynamic energy source to release the drug and remains in the system. The rated release of drug is dependent upon the area of the system; 0.5 mg nitroglycerin is delivered *in vivo* for every $cm^2$ of system size.

The Transderm-Nitro system comprises four layers as shown below. Proceeding from the visible surface toward the surface attached to the skin, these layers are: 1) a tan-colored backing layer (aluminized plastic) that is impermeable to nitroglycerin; 2) a drug reservoir containing nitroglycerin adsorbed on lactose, colloidal silicon dioxide, and silicone medical fluid; 3) an ethylene/vinyl acetate copolymer membrane that is permeable to nitroglycerin; and 4) a layer of hypoallergenic silicone adhesive. Prior to use, a protective peel strip is removed from the adhesive surface.

Cross section of the system:

### ACTIONS

When the Transderm-Nitro system is applied to the skin, nitroglycerin is absorbed continuously through the skin into the systemic circulation. This results in active drug reaching the target organs (heart, extremities) before being inactivated by the liver. Nitroglycerin is a smooth muscle relaxant with vascular effects manifested predominantly by venous dilatation and pooling. The major beneficial effect of nitroglycerin in angina pectoris is a reduction in myocardial oxygen consumption secondary to vascular smooth muscle relaxation and consequent reduced cardiac preload and afterload. In recent years there has been an increasing recognition of a direct vasodilator effect of nitroglycerin on the coronary vessels.

In clinical studies transdermal absorption of nitroglycerin from a nitroglycerin system occurred in a continuous and well-controlled manner, for a minimum of 24 hours. Therapeutic effect can be anticipated 30 minutes after application of the system and to be maintained for 30 minutes after its removal.

### INDICATIONS AND USAGE

Transderm-Nitro system is indicated for the prevention and treatment of angina pectoris due to coronary artery disease.

### CONTRAINDICATIONS

Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

### WARNINGS

In patients with acute myocardial infarction or congestive heart failure, Transderm-Nitro system should be used under careful clinical and/or hemodynamic monitoring.

In terminating treatment of anginal patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

### PRECAUTIONS

Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension, may be due to overdosage. When these symptoms occur, the dosage should be reduced or use of the product discontinued.

Transderm-Nitro system is not intended for immediate relief of anginal attacks. For this purpose occasional use of the sublingual preparations may be necessary.

### ADVERSE REACTIONS

Transient headaches are the most common side effect, especially when higher doses of the drug are used. These headaches should be treated with mild analgesics while Transderm-Nitro therapy is continued. When such headaches are unresponsive to treatment, the nitroglycerin dosage should be reduced or use of the product discontinued.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. These symptoms are attributable to the known pharmacologic effects of nitroglycerin, but may be symptoms of overdosage. When they persist the dose should be reduced or use of the product discontinued.

### DOSAGE AND ADMINISTRATION

Therapy should be initiated with application of one Transderm-Nitro 5 system to the desired area of skin. Many patients prefer the chest; if hair is likely to interfere with system adhesion or removal, it can be clipped prior to placement of the system. Each system is designed to remain in place for 24 hours, and each successive application should be to a different skin area. Transderm-Nitro system should not be applied to the distal parts of the extremities.

The usual dosage is one Transderm-Nitro 5 system every 24 hours. Some patients, however, may require the Transderm-Nitro 10 system. If a single Transderm-Nitro 5 system fails to provide adequate clinical response, the patient should be instructed to remove it and apply either two Transderm-Nitro 5 systems or one Transderm-Nitro 10 system. More systems may be added as indicated by continued careful monitoring of clinical response.

The optimal dosage should be selected based upon the clinical response, side effects, and the effects of therapy upon blood pressure. The greatest attainable decrease in resting blood pressure that is not associated with clinical symptoms of hypotension, especially during orthostasis, indicates the optimal dosage. To decrease adverse reactions, the size and/or number of systems should be tailored to the individual patient's needs.

Do not store above 86°F (30°C).

### PATIENT INSTRUCTIONS FOR APPLICATIONS

A patient leaflet is supplied with the systems.

# Subepicardial Adipose Tissue Producing Echocardiographic Appearance of Pericardial Effusion

## Documentation by Computed Tomography and Necropsy

JEFFREY M. ISNER, MD, BARBARA L. CARTER, MD, WILLIAM C. ROBERTS, MD, and MARK S. BANKOFF, MD

**An isolated anterior echo-free space is generally regarded as a false-positive echocardiographic finding for pericardial effusion. Even when an anterior echo-free space is accompanied by a posterior echo-free space, the echo-free spaces have been occasionally reported to be falsely positive for pericardial effusion, principally in patients with cardiac neoplasms. The basis for these findings has never been adequately explained. In the present study, evaluation by computed tomographic imaging or necropsy examination of 5 patients in whom there was either an anterior or posterior echo-free space or both demonstrated that subepicardial adipose tissue is the echocardiographic imitator of pericardial effusion.**

The presence by cardiac ultrasound of an anterior echo-free space in the absence of a posterior echo-free space represents a combination of findings known to imitate, but seldom indicate, a pericardial effusion.[1,2] Although speculated to result from subepicardial adipose tissue,[1,3,4] an isolated anterior echo-free space has never been established with certainty to result from subepicardial fat. The present report documents by necropsy examination in 1 patient and computed tomographic imaging of the chest in 2 other patients that subepicardial adipose tissue is the basis for the finding of an isolated anterior echo-free space. Furthermore, necropsy findings and results of computed tomography in 2 additional patients suggest that subepicardial adipose tissue is the basis for echocardiograms previously reported as being falsely positive for pericardial effusion in patients with a cardiac neoplasm.

From the Departments of Medicine (Cardiology) and Radiology, Tufts-New England Medical Center, Boston, Massachusetts; and the Pathology Branch, National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland. Manuscript received and accepted August 13, 1982.

Address for reprints: Jeffrey M. Isner, MD, Box 70, New England Medical Center, 171 Harrison Avenue, Boston, Massachusetts 02111.

## Methods

**Computed tomographic imaging** of the chest was performed on a Siemen's Somatom-2 whole body scanner that utilizes a rotating gantry. A complete section scan with a slice thickness of 8 mm was performed in 5 seconds using 125 kV and 46 mA. At least 2 separate windows of varying contrast were viewed at each level. The scale for transparency was −1,000 Hounsfield Units (HU) for air, 0 for water, and +1,000 HU for bone; the attenuation coefficient for any given site was determined by multiple cursor sampling.

**M-mode echocardiography** was performed on either a Smith-Kline or Unirad ultrasonoscope with a 2.55 MHz transducer. Particular care was taken to prevent directing the ultrasonic beam too far medially. A switched-gain ("damping") mechanism[5] was used to evaluate the pericardial space in each patient. Two-dimensional real-time echocardiography was performed with either a mechanical (Hoffrel 201) or phased array (Hewlett-Packard) sector scanner.

Pertinent clinical and necropsy findings in the 4 patients are summarized in Table I and in Figures 1 to 6.

## Discussion

Although the finding of an echo-free space *posterior* to the left ventricular free wall has come to represent the echocardiographic sine qua non for pericardial effusion, the initial description of the use of ultrasound for diagnosing pericardial effusion involved an isolated echo-free space *anterior* to the right ventricular free

+ = present; 0 = absent; – = not done; Ant = anterior; F = female; Ht = height; M = male; NI = normal; Peri = pericardial; Post = posterior; Pt = patient; Sm = small; Wt = weight.

**FIGURE 1.** M-mode echocardiogram from Patient 1 shows an isolated anterior echo-free space (Ant EFS) anterior to the right ventricular free wall (RVFW). Chest computed tomogram shows that the echo-free space is due to subepicardial fat interposed between the pericardium (Peri) and right ventricle (RV). AML = anterior mitral leaflet; Ant = anterior; Ao = aorta; ecg = electrocardiogram; L = left; LVFW = left ventricular free wall; Post = posterior; R = right; VS = ventricular septum.

wall.[6] Subsequently, Feigenbaum et al[7,8] demonstrated that the extent of pericardial fluid accumulation must be quite large before an anterior echo-free space is observed, so that it is nearly always associated with a posterior echo-free space. In fact, an anterior echo-free space in the *absence* of a posterior echo-free space was one of the earliest patterns to be recognized as a false-positive finding in the echocardiographic diagnosis of pericardial effusion.[1]

Horowitz et al[2] suggested that such an isolated anterior echo-free space might result from either fibrous tissue or lung interposed between the heart and anterior chest wall. Teichholz[9] suggested that in addition to connective tissue and lung, adipose tissue might be responsible for separating the anterior wall of the right ventricle from the chest wall. Feigenbaum[3] agreed that epicardial fat was the most likely basis for the finding of an anterior echo-free space. While the admonitions of these and other investigators established that the finding of (1) an anterior echo-free space in the absence of a posterior echo-free space is an inadequate diagnostic criterion for the presence of a pericardial effusion, and (2) that the basis for such an isolated anterior

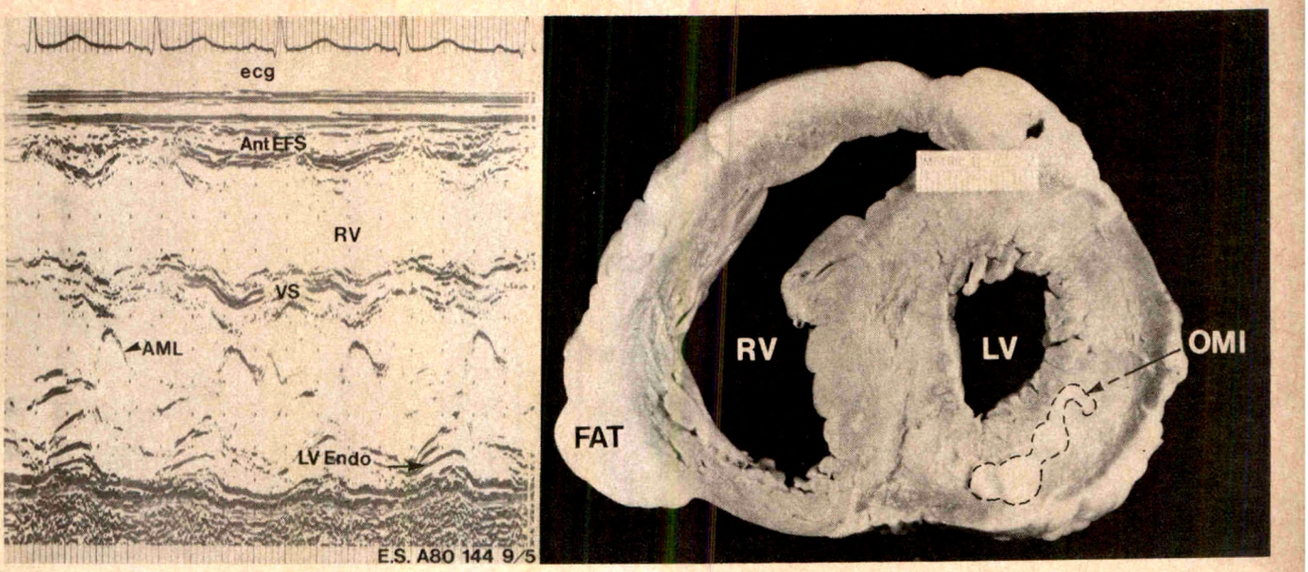

**FIGURE 2.** Patient 2. The anterior echo-free space on an M-mode echocardiogram was due to extensive subepicardial adipose tissue, greater over the anterior right ventricle (RV) than the posterior left ventricle (LV). AML = anterior mitral leaflet; Ant EFS = anterior echo-free space; ecg = electrocardiogram; Endo = endocardium; OMI = old myocardial infarction; VS = ventricular septum.

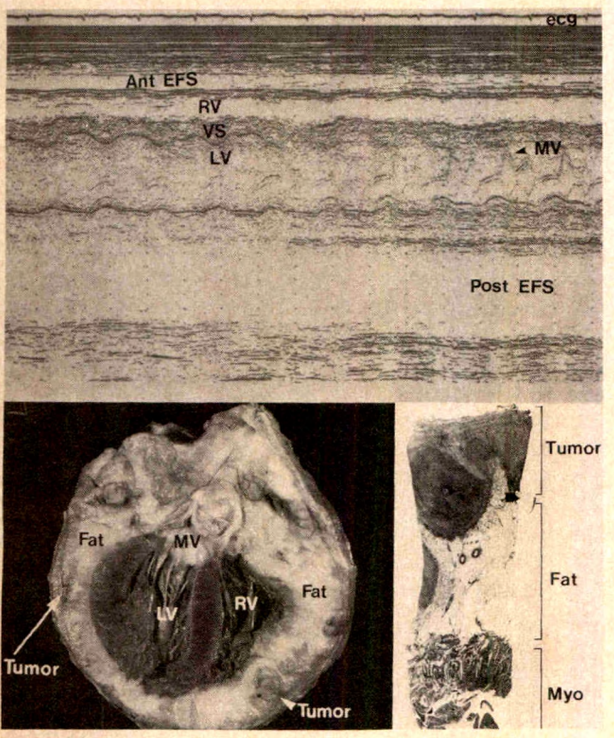

**FIGURE 3.** M-mode echocardiogram (**top panel**) from Patient 3 shows anterior (Ant) and posterior (Post) echo-free space (EFS). A "sweep" from left ventricle to left atrium showed no echo-free space posterior to the left atrium. At necropsy, gross examination of the heart (**bottom left panel**) disclosed no pericardial fluid. Instead, extensive subepicardial fat was interposed between underlying myocardium and metastatic bronchogenic carcinoma. The latter encased the heart in a nearly circumferential manner. Photomicrograph (**bottom right panel**) shows tumor, fat, and underlying myocardium (Myo). (Movat's pentachrome stain; original magnification × 6), reduced 38%. ecg = electrocardiogram; LV = left ventricle; MV = mitral valve; RV = right ventricle; VS = ventricular septum.

echo-free space was likely to be epicardial fat, documentation of the latter has not been previously established. The present study establishes by computed tomographic imaging and necropsy examination that the isolated anterior echo-free space is in fact due to the anterior epicardial fat.

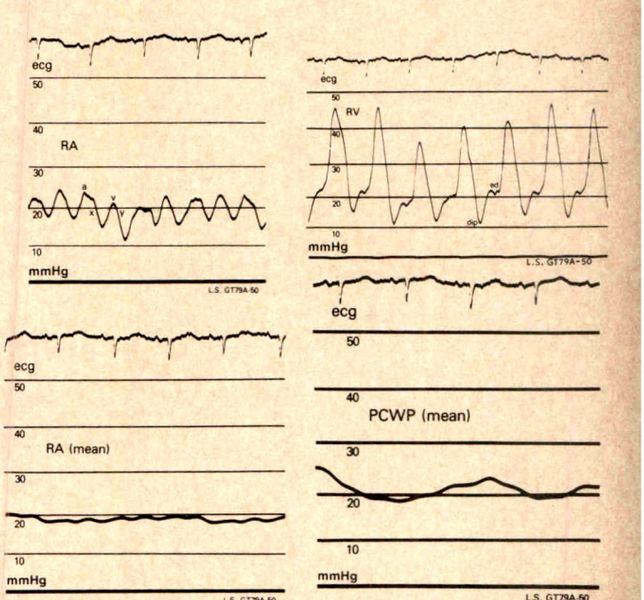

**FIGURE 4.** Hemodynamic recordings from Patient 3. The mean right atrial (RA), right ventricular (RV) end-diastolic, and mean pulmonary capillary wedge (PCWP) pressures are equal. The RA phasic trace (**top left**) has an M-shaped contour with a steep *y* descent. The RV pressure contour has an initial dip, followed by a short end-diastolic (ed) plateau. These hemodynamic findings documented constrictive/restrictive physiology secondary to tumor encasement of the heart. ecg = electrocardiogram.

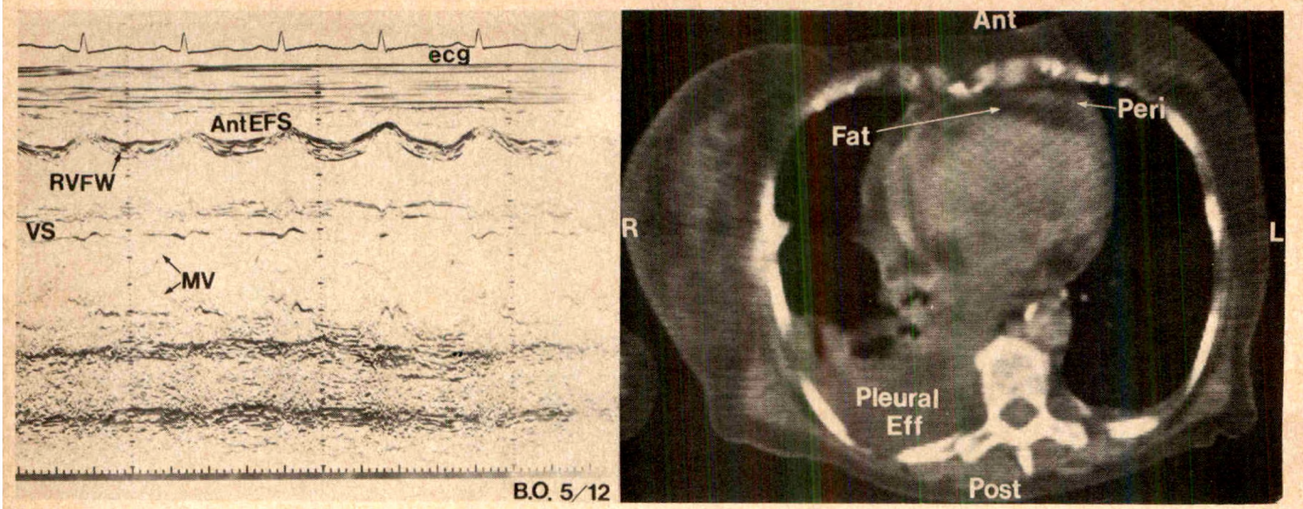

**FIGURE 5.** M-mode echo and computed tomographic scan from Patient 4. The M-mode echocardiogram shows an anterior relatively echo-free space (Ant EFS). Chest computed tomogram shows this to be due to fat underlying the pericardium (Peri); the pericardium itself is thickened by presumed metastatic bronchogenic carcinoma. The posterior echo-free space was related to the pleural effusion (Pleural Eff) seen on computed tomography. Ant = anterior; ecg = electrocardiogram; L = left; MV = mitral valve; Post = posterior; R = right; RVFW = right ventricular free wall; VS = ventricular septum.

The amount of subepicardial fat generally increases with age.[10] These deposits are characteristically most extensive over the anterior portion of the heart—in contrast to the *posterior* heart—a fact which explains the propensity for extensive subepicardial fat to produce an *anterior* echo-free space in the absence of a *posterior* echo-free space. While the extent of the fat is not necessarily related to the adipose content of other body tissues, the extent of subepicardial fat tends to be greater in obese individuals; 4 of our 5 patients were in fact obese (Table I). Endogenous or exogenous steroid excess (for example, long-term administration of high-dose steroid therapy) constitutes another setting in which an increased amount of subepicardial fat is commonly seen.[11] This factor may have played a role in the excessive amount of subepicardial adipose tissue in Patients 2 and 5 (Table I).

The unique capabilty of computed tomography to identify relative tissue density makes this diagnostic technique ideal for determining the basis of relatively sonolucent spaces visualized by cardiac ultrasound.[12] The relatively low attenuation coefficient of fat (−60 to −100 HU) established with certainty that the isolated anterior echo-free space in Patients 1 and 5 was due to subepicardial fat. A similar echocardiographic finding in Patient 2 was confirmed at necropsy. Although necropsy examination in the latter patient was performed over 1 year after the last M-mode echocardiogram, the absence of any posterior echo-free space on any of the multiple echocardiograms recorded and the finding at necropsy of normal visceral and parietal pericardia suggest that the anterior echo-free space resulted from the excessive amount of fat seen at necropsy rather than a transient pericardial effusion. In Patients 1, 2, and 5, the characteristically greater distribution of fat over the anterior, as opposed to the posterior, surface of the heart resulted in an isolated anterior echo-free space by cardiac ultrasound. In Patients 2 and 5, a small amount of posteriorly located fat appeared to result in a small posterior echo-free sliver with the boundary lines moving in parallel during systole and diastole. The finding of an anterior echo-free space that is out of proportion to an associated posterior echo-free space is therefore a valuable clue to the possibility that such echo-free spaces represent fat rather than fluid.

In contrast to the finding of an isolated anterior echo-free space, the finding of an isolated posterior echo-free space, provided it persists through ventricular diastole as well as systole, has been shown to be a reliable indicator of pericardial effusion.[2] As mentioned above, the finding of an anterior echo-free space in combination with a posterior echo-free space generally indicates a large effusion.[2,7,8] Even in the situation in which both an anterior and posterior echo-free space are observed together, however, echocardiograms may be falsely positive for a pericardial effusion, particularly as the result of a cardiac neoplasm.[13–16] The explanation for this association is poorly understood. In the patient reported by Lin et al,[15] the false-positive echo-free space seen anteriorly and posteriorly was attributed to the type of neoplasm encasing the heart (angiosarcoma with a rich vascular component). Millman et al[13] described 3 patients with metastatic carcinoma or lymphoma in whom a sonolucent space posterior to the left ventricle was unassociated with pericardial effusion at operation or necropsy. These authors also attributed the echo-free space to the neoplasm itself, suggesting that the acoustic impedence of the neoplasm might be the same as that of pericardial fluid. Come et al[16] reported 3 patients with metastatic tumor involving the pericardium. All 3 had a posterior echo-free space and 2 had both anterior and posterior echo-free spaces. In 1 patient, a 62-year-old man with lymphoma encasing the heart in whom there was both an anterior and posterior echo-

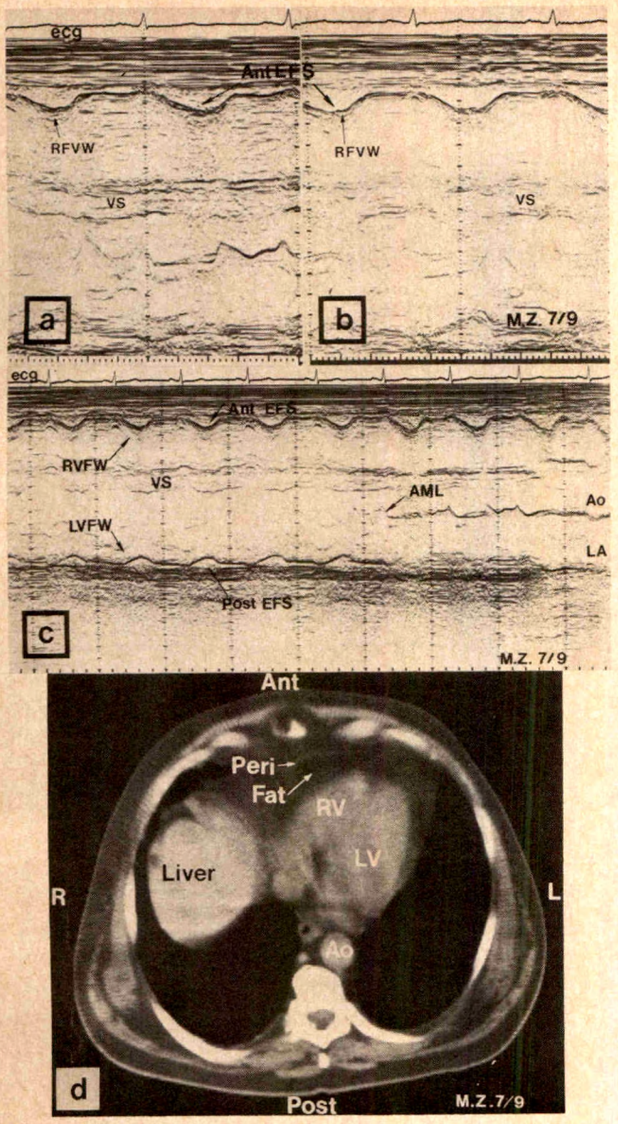

**FIGURE 6.** M-mode echocardiogram and computed tomographic scan from Patient 5. **a and b,** M-mode echocardiograms at 2 different gain settings each show an anterior (Ant) relatively echo-free space (EFS) anterior to the right ventricular free wall (RVFW). **c,** M-mode echocardiographic "sweep" from the left ventricular free wall (LVFW) to the left atrium (LA) shows a small posterior (Post) echo-free space in addition to an anterior echo-free space. **d,** computed tomographic scan shows that an anterior space on the M-mode echocardiogram is due to extensive subepicardial fat anterior to the right ventricle (RV), while a small posterior echo-free space is due to a small amount of fat posterolateral to the left ventricle (LV). AML = anterior mitral leaflet; Ao = aorta; ecg = electrocardiogram; L = left; Peri = pericardium; R = right; VS = ventricular septum.

free space, ". . . the epicardial fat pad was seen to lie several centimeters within the anterior heart border on the lateral film." In a second patient with metastatic squamous cell carcinoma, the posterior echo-free space ". . . was seen only at the junction of the left atrium and left ventricle . . .," that is, the atrioventricular sulcus where deposits of adipose tissue are generally extensive.

Necropsy findings and examination by computed tomographic imaging in Patients 3 and 4, respectively, demonstrate that subepicardial fat is the basis for the ability of neoplasms encasing the heart to simulate pericardial effusion on cardiac ultrasound. In Patient 3, generalized obesity was associated with extensive subepicardial fat that completely encased the heart, before superimposed encasement by metastatic bronchogenic carcinoma. The nearly circumferential deposits of subepicardial adipose tissue and the obliteration of the nonfluid filled pericardial cavity at necropsy demonstrate that fat was the basis for the echo-free space on this patient's echocardiogram. The tumor in this patient further simulated pericardial heart disease by causing physiologic constriction, a finding observed previously in patients with cardiac encasement by metastatic neoplasm.[14] In Patient 4, the capability of computed tomography to accurately identify tissue density again demonstrated that subepicardial adipose tissue interposed between encasing metastatic bronchogenic carcinoma and underlying myocardium was the basis for the echo-free space in this patient's M-mode and 2-dimensional echocardiograms.

Finally, the results of this computed tomographic and necropsy study suggest that caution must be observed in evaluating relatively sonolucent spaces in elderly obese patients who have no clinical evidence of pericardial heart disease. Findings in Patients 1, 4, and 5 also underscore the utility of computed tomography in clarifying the basis of an apparent echo-free space on cardiac ultrasound examination in patients in whom the finding is either unexpected or contrary to available clinical information.

# Exercise-Induced Cardiac Dysfunction in Sickle Cell Anemia

## A Radionuclide Study

WESLEY COVITZ, MD, CASIMIR EUBIG, PhD, IAN C. BALFOUR, MD, RAJINDER JERATH, BS, BRUCE S. ALPERT, MD, WILLIAM B. STRONG, MD, and ROBERT H. DuRANT, MA, *With the technical assistance of* BONNIE G. HADDEN

**Cardiac performance was studied by radionuclide angiography at rest and during exercise in 22 adolescents with sickle cell (SC) anemia and the results were compared with those in 12 control subjects. At rest, cardiac contractility was normal; cardiac output and end-diastolic volume were increased. At maximal exercise, heart rate, cardiac output response, and work capacity were reduced; the reduction was related to the degree of anemia. Left ventricular end-diastolic volume decreased with exercise most markedly in patients with ischemic exercise electrocardiograms. An abnormal ejection fraction response to exercise occurred in 4 patients; electrocardiographic signs of ischemia developed in all 4, and wall motion abnormalities in 2. Those patients who had electrocardiographic signs of ischemia had a significantly lower heart rate, ejection fraction, and cardiac output response to exercise, and a lower hematocrit level than subjects with normal results on exercise electrocardiography. The increase in cardiac output was not sufficient to maintain a normal level of exercise. The decrease in end-diastolic volume suggests that diastolic function was abnormal during exercise. Cardiac dysfunction was manifested by an abnormal ejection fraction response, wall motion abnormalities, and incomplete left ventricular filling during exercise.**

Sickle cell anemia is associated with cardiomegaly,[1] left ventricular hypertrophy,[2] and decreased work capacity.[3] Controversy exists as to whether there is a specific pathologic process involving the myocardium which is associated with SC anemia. Despite pathologic data which suggest that there is no myocardial abnormality specific for SC disease,[4] there is mounting evidence of a functional abnormality. Rees et al[5] found decreased left ventricular contractility with echocardiography in one third of children tested. Alpert et al[3] demonstrated an ischemic electrocardiographic response in 15% of SC patients undergoing exercise testing. Cardiac dysfunction secondary to hemosiderosis has been demonstrated in thalassemic patients,[6] but no study of cardiac function has been reported for a large group of children with other types of anemia for comparison with the SC population. This study was undertaken to further characterize the functional abnormality seen in children and young adults with SC anemia.

### Methods

Eleven male and 11 female adolescents and young adults with homozygous SC anemia were studied. Their ages ranged from 10 to 22 years (mean 15.3). No patient had had a crisis or transfusion in the 3 weeks before testing. Exercise testing without radionuclide evaluation had been performed in the past in 21 of 22. Eleven patients had previously abnormal or equivocal exercise electrocardiogram findings[3]; 10 had normal exercise electrocardiographic results previously. The patient who had not been exercised had an atrial septal defect and left ventricular aneurysm in addition to SC anemia. The current study was performed 5 to 6 years after the initial exercise test in 17 patients and 1 year after in 4 (Table I).

Extensive data are available from our laboratory for physical work capacity and heart rate response to exercise in healthy black children.[7] Radionuclide measurements for *normal children* during upright exercise are unavailable. For

this reason normal values were established for our laboratory. The control group included 12 adolescents referred to cardiac catheterization. The diagnoses included chest pain of undetermined cause, postoperative study after repair of a congenital heart defect, and mild valvular stenosis or insufficiency. All children were demonstrated to have normal left ventricular function at catheterization and had normal exercise test results. Six were black and 6 were white. No significant differences were noted in radionuclide measurements by race.

A continuous, graded *nuclear stress test* was performed with the subject sitting on a mechanically braked cycle ergometer (Monarch). Patients pedaled against a constant resistance during 3-minute stages, maintaining a speed of 60 to 70 rpm. Work loads were based by weight on those expected of normal subjects as described by Strong et al.[7] Subjects weighing <30 kg performed work loads of 75, 150, and 300 kg-m/min if they completed stages I to III, respectively. Those subjects weighing 30 to 40 kg performed work loads of 150, 300, and 450 kg-m/min. The larger subjects weighing 41 to 60 kg performed work loads of 300, 450, and 600 kg-m/min. Patients were exercised to exhaustion. Leads $V_5$, $V_1$, and aVF were monitored continuously. Myocardial ischemia was assessed by use of the P-R isoelectric line because of the low incidence of false-positive results with this method in previous studies on healthy black children.[8] A definitely ischemic test consisted of a downsloping S-T segment during the initial 60 to 80 ms with or without J-point depression, or a flat S-T segment (zero slope) with J-point depression. A borderline ischemic test consisted of a flat S-T segment without J-point depression, or an upsloping S-T with J-point depression. One test was interrupted (Patient 22) due to concern about the subject's condition. She had 2 mm J-point depression at the time in lead $V_5$ at a work load nearly equal to the maximal work performed during a previous exercise test.

Radionuclide studies were performed with a portable gamma camera (Technicare Sigma 420), interfaced with a portable computer (Medical Data Systems). A Brattle physiologic gate was used to trigger the system. Gated equilibrium radionuclide studies (MUGX) were performed at rest and

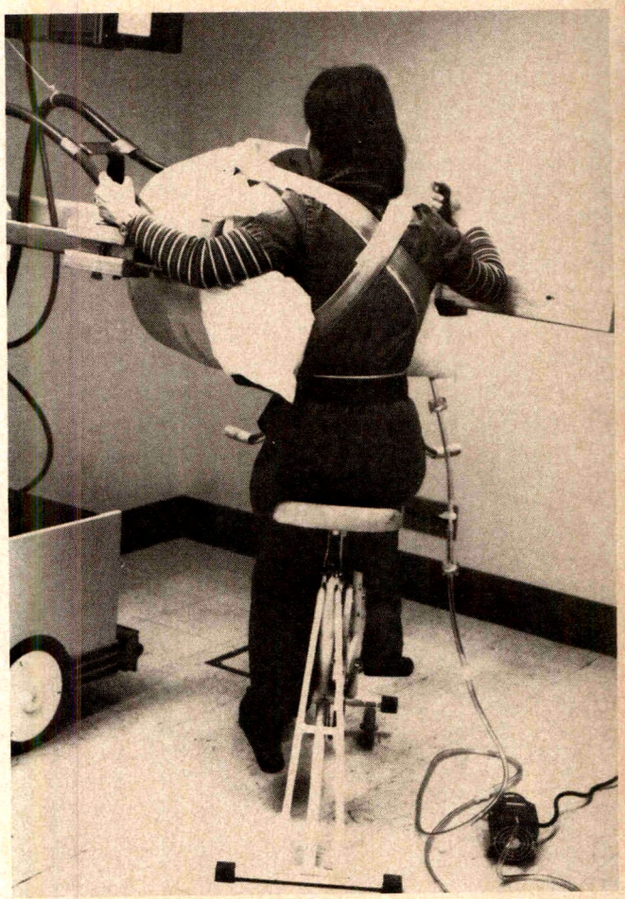

**FIGURE 1.** The adjustable wedge mold and harness permits appropriate positioning of the gamma camera and eliminates patient-detector motion. The mold is a plastic pillow filled with polystyrene beads which becomes hard in the molded configuration when a vacuum is applied. Three straps form the harness.

during the last 2 minutes of each 3-minute exercise stage. Technetium-99m albumin (0.3 mCi/kg) was administered intravenously just before positioning the patient on the bicycle (approximately 20 minutes before exercise). A high sensitivity, parallel hole collimator was placed within 2 cm of the chest wall. Zoom mode was not utilized. The patients were maintained in the proper left anterior obliquity (where the collimator was perpendicular to the interventricular septum), and motion was eliminated by using an adjustable wedge mold and harness (Fig. 1). Previous studies in our laboratory using radioopaque markers on exercising volunteers confirmed the elimination of motion with this device.[9] Left ventricular areas and background were automatically selected with the MUGX program.[10] This method was successfully applied to 96% of ejection fraction measurements. Ejection fraction and end-diastolic counts were determined at rest and during each exercise stage. Changes in end-diastolic counts from rest were assumed to reflect changes in ventricular volume, and changes in counts ejected/minute to reflect changes in cardiac output.[11] Cardiac cycles were divided into 14 frames. Count rates were adjusted to take into account varying times/frame and number of cycles processed as heart rate increased. Left ventricular end-diastolic volume and cardiac index at rest were expressed as unity, and volume and output during exercise were expressed as multiples of resting values. Wall motion abnormalities were detected by viewing the cineangiographic format of the equilibrium studies in a blinded fashion without knowledge of the ejection fraction data and subsequently by overlaying edge images from end-systole and end-diastole.

M-mode echocardiograms were obtained with an Irex echocardiograph just before exercise to assess left ventricular volume. Standard echocardiographic techniques were used.[12] Left ventricular volume was calculated from the end-diastolic dimension as described by Meyer et al.[13] Values derived from echocardiograms were compared with those performed in our laboratory of healthy black children of comparable body surface area.

**Statistical analysis:** Selected exercise and physical measurements were correlated with one another using Pearson's product moment correlation coefficient (r). Exercise data for the nonischemic SC group, the ischemic group, and the control group were compared using a $t$ test for 2 independent means. The null hypotheses that were tested were that the means did not differ, requiring a 2-tailed test significance. Changes in serial exercise data were tested with paired $t$ tests using 2-tailed tests of significance. The values shown represent the mean ± standard deviation.

## Results

**Resting measurements:** The mean upright resting radionuclide left ventricular ejection fraction was 0.60 ± 0.08 (control values 0.67 ± 0.08, p = NS). Resting heart rates (85 ± 9 beats/min) were normal.[7] Echocardiography revealed left ventricular enlargement in all patients (volume 114 ± 35 ml/m$^2$, normal for our laboratory 58 ± 25 ml/m$^2$). Since resting heart rates and ejection fractions were normal, the marked left ventricular volume overload would of necessity result in abnormally high stroke volumes and cardiac outputs. Though the elevated cardiac outputs and dilated ventricles were likely due to the anemia, these measurements did not correlate significantly with hematocrit.

**Serial exercise data (Table I):** A 5 to 6 year interval between tests in 17 patients, and 1 year interval in 4 revealed a significant decrease in maximal heart rate (p = 0.02). Maximal heart rate continued to be abnormally low, compared with values from our laboratory in normal black children (Table II) reported previously (previous exercise 176 ± 14 beats/min, nuclear exercise 170.5 ± 16). Though no change was noted in work capacity when all 21 studies were reviewed, a significant decrease was noted (p = 0.034) when only those with a

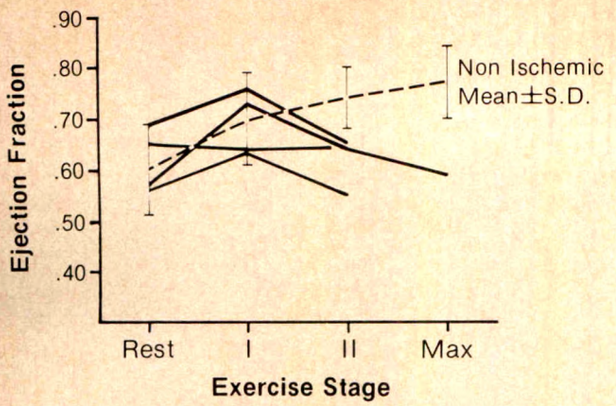

**FIGURE 2.** Ejection fraction response to exercise. The SC patients with electrocardiographic signs of ischemia during exercise are plotted individually. The **dashed line** represents the mean ± standard deviation (SD) for the SC patients with normal exercise electrocardiograms.

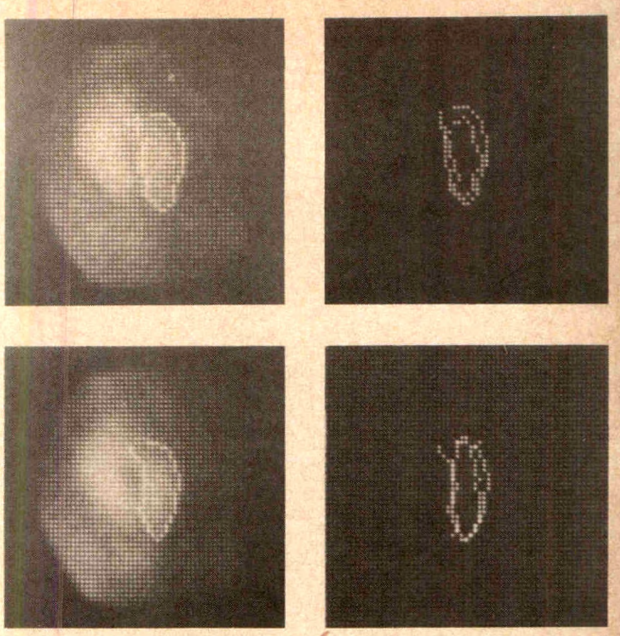

**FIGURE 3.** Gated equilibrium images at rest (**top panels**) and on maximal exercise (**bottom panels**) to demonstrate wall motion abnormalities. **Left panels,** the end-diastolic image is shown with the left ventricular edge, as defined by the automated edge detection program, superimposed. Note the decrease in diastolic chamber size from rest to maximal exercise. **Right panels,** the diastolic and systolic edge images are superimposed. Note that symmetrical contraction results in a concentric appearance at rest. At maximal exercise the apex is akinetic, resulting in a lack of separation of edges.

5 to 6 year follow-up were included. Though these were statistically significant changes, they were not clinically significant. Work capacity defined as kg-m/min/kg was decreased when compared with values in normal black children (before exercise in males 10.8 ± 2.7, females 10.4 ± 4.9; nuclear exercise in males 10.2 ± 1.9, females 8.2 ± 2.3). Work capacity was correlated with hematocrit ($r = 0.50$, $p < 0.02$).

The exercise electrocardiographic results during the radionuclide study showed definite ischemia in 5 and equivocal ischemia in 1, and was normal in 16 subjects. The exercise electrocardiogram of only 1 patient of 21 became abnormal during the 4.6 years (mean) study period, while 7 improved (Table I). It is unclear why 2 of 7 abnormal tests were subsequently normal, but the 5 borderline tests that became normal demonstrate the lack of reliability of the borderline category.

**Radionuclide data:** The exercise response of subjects without evidence of ischemia on their exercise electrocardiograms consisted of a stepwise increase in ejection fraction. The mean increase from rest to maximum was 0.14 ± 0.08. Maximal exercise was reached during stage II by 17 patients; 3 reached stage III and 2 reached stage IV. There were no significant differences in ejection fraction between subjects with normal and abnormal exercise electrocardiograms at rest and stage I of exercise. Subsequently, in 3 of 4 patients with electrocardiographic evidence of ischemia, ejection fraction decreased >5% in the presence of an increasing heart rate and effort. Ejection fractions were essentially unchanged from resting values at maximal exercise in these 4 patients (Fig. 2). The fifth ischemic test (Patient 22) was interrupted due to concern about the subject's condition before the ejection fraction could be obtained. Patients with electrocardiographic signs of ischemia had significantly lower heart rate, ejection fraction, and cardiac output responses to exercise as well as lower work capacity and hematocrit (Table II).

Observation of the cineangiographic mode of the gated equilibrium scans revealed wall motion abnormalities in 2 of the patients with ischemic tests. Patient 3 had a dyskinetic apical area at rest. Patient 10 had normal wall motion at rest; an akinetic area was identified at maximal exercise in the left anterior oblique projection (Fig. 3).

Cardiac output achieved was significantly correlated with heart rate ($r = 0.67$, $p < 0.003$). Work capacity was related to the percent increase in cardiac output from rest ($r = 0.50$, $p < 0.05$). The cardiac output response was most severely impaired in those patients with the lowest hematocrit levels ($r = 0.52$, $p < 0.03$). Though resting outputs were high, performance was related to the relative increase in output from rest, which was significantly less than expected (Table II).

Left ventricular end-diastolic volume (based on end-diastolic counts) was unchanged from resting values to stage I of exercise, but decreased from stage I to maximal exercise (assume resting volume = 1, stage I = 1.0 ± 0.10, maximal exercise = 0.91 ± 0.12) (Table III). Normally no change in diastolic volume is seen in our laboratory at maximal exercise. A decrease in end-diastolic volume at maximum was associated with a reduced cardiac output response ($r = 0.57$, $p < 0.02$). At maximum, the decrease in left ventricular volume was even more marked in the ischemic group than in the SC patients with normal exercise electrocardiographic results (Table II).

## Discussion

This study was designed to document and further define the cardiac dysfunction associated with SC anemia. Although Gerry et al[14] found no evidence of left

* Excluded from data analysis due to additional abnormalities.
† Electrocardiographic evidence of ischemia.
CO = cardiac output expressed as a multiple of resting output; EF = radionuclide ejection fraction; HCT = hematocrit (%); HR = heart rate (beats/min); LVV = left ventricular diastolic volume expressed as a multiple of resting volume; PWC = physical work capacity (kg-m/min/kg).

ventricular dysfunction in an echocardiographic study of adult patients with SC disease and no myopathic changes in an autopsy series,[4] we have previously reported echocardiographic evidence for left ventricular dysfunction in children with SC anemia.[5] We have also noted a decreased working capacity and heart rate response to sitting bicycle exercise.[3] Electrocardiographic signs of ischemia were identified during exercise in 15% of children tested.[3]

In the current study, no progression in exercise electrocardiographic abnormalities was found in the 4.6 year follow-up period. Electrocardiographic signs of ischemia were, however, related to a specific cardiac dysfunction (abnormal ejection fraction response). This provided nonelectrocardiographic confirmation of an exercise-induced abnormality. The consistent association of ischemia and abnormal ejection fraction response supports the validity of the P-R isoelectric line method of defining electrocardiographic ischemia. Use of the P-Q junction to P-Q junction would have resulted in a greater number of electrocardiograms being interpreted as ischemic in the absence of an abnormal ejection fraction response. The cardiac dysfunction was associated with wall motion abnormalities in 2 of our patients.

The data presented provide insight into the hemodynamic response to exercise in a group of patients with SC anemia. At maximal exercise a normal adult should be able to triple resting cardiac output.[15] The patients with SC anemia had high resting outputs and were unable to raise their outputs to the extent that normal subjects do. Their working capacity was related to the relative increase in cardiac output from rest to maximum, rather than the absolute output. This is understandable since the high resting outputs were due to a reduced oxygen-carrying capacity seen with hemoglobins in the 7 to 8 g/100 ml range.[16] Meeting the increased demands of maximal exercise would logically require a tripling of the already high cardiac outputs. Work capacity and the relative increase in cardiac output with exercise were dependent on the degree of anemia.

Of interest is that those persons with the most severe anemia, poorest performance (reduced heart rate and cardiac output response and work capacity), and electrocardiographic signs of ischemia had a decrease in left ventricular end-diastolic volume at maximal exercise. In coronary disease[16] and in aortic stenosis,[17] when ejection fractions decrease during maximal exercise, left ventricular diastolic volume increases due to the reduced stroke volume and high residual volume. In aortic insufficiency left ventricular volume decreases, but this has been interpreted as being due to a lessening of regurgitation.[18] The decrease in left ventricular diastolic volume at maximum in our patients is likely to be due to incomplete left ventricular filling. Whether the incomplete ventricular filling is related either to diastolic unloading of the left ventricle or due to an abnormality of ventricular relaxation is not known.

We have documented cardiac dysfunction in the form of abnormal ejection fraction responses and wall motion abnormalities in association with electrocardiographic signs of ischemia in young patients with SC anemia. The dysfunction which is related to the severity of the anemia may also be associated with an abnormality of ventricular filling.

METHODS

# Variability of Digitized Echocardiography: Size, Source, And Means of Reduction

CHARLES POLLICK, MB, MRCP (UK), FRCP (C), PETER J. FITZGERALD, MSEE, and RICHARD L. POPP, MD

**Digitization of M-mode echocardiograms provides useful information on left ventricular function, but its variability has been assessed rarely. Inter- and intraobserver (technical) variability of readers digitizing the same cardiac cycles, and variability between beats, days, and subjects (biologic) was determined. Technical variability was small for both standard dimensions (correlation coefficient r values 0.82 to 1.00) and rates of change (r values 0.70 to 0.98). Biologic variability was large with expected normal differences between 2 measurements (95% confidence limits) of 11 to 55% and 37 to 106% for standard dimensions and rates of change, respectively. By averaging measurements of 5 beats from each of 2 days, the expected normal differences are reduced to 6 to 32% and 23 to 63% for standard dimensions and rates of change.**

**This study emphasizes the large biologic variability in rates of change of digitized left ventricular measurements. Normal variation between studies can be reduced and real physiologic or pathologic changes perceived best if many beats from more than 1 day are measured.**

M-mode echocardiography, by virtue of the high repetition rate of 1,000 pulses/second, displays cardiac structures "continuously" throughout the cardiac cycle. The method of digitization of M-mode records takes advantage of this excellent frequency response, and provides information on left ventricular function beyond that given by standard dimensions.[1]

Despite the more widespread use of digitization, the variability and reproducibility of measurements has been assessed rarely. Such information is needed to differentiate between normal random variation and a true physiologic or pathologic change in the derived measurements. We performed this study to explore the magnitude of technical variability between and within observers of digitized M-mode echocardiograms, and normal biologic variability between subjects, days, and beats.

## Methods

For the assessment of inter- and intraobserver variability (technical variability or reproducibility) 3 to 5 cardiac cycles from patients with various cardiac physiology were independently analyzed by 2 "readers," and were reanalyzed by 1 of these readers several weeks later. There were a total of 35 cycles for analysis from 10 patients: 3 normal subjects, 2 normal subjects during a drug infusion (done for other purposes), 2 patients with mitral regurgitation, 2 patients with hypertrophic cardiomyopathy, and 1 patient with a congestive cardiomyopathy (Group 1). The same 35 cycles were analyzed by both observers.

To assess variability between subjects, days, and beats (biologic variability), we studied 10 normal healthy male

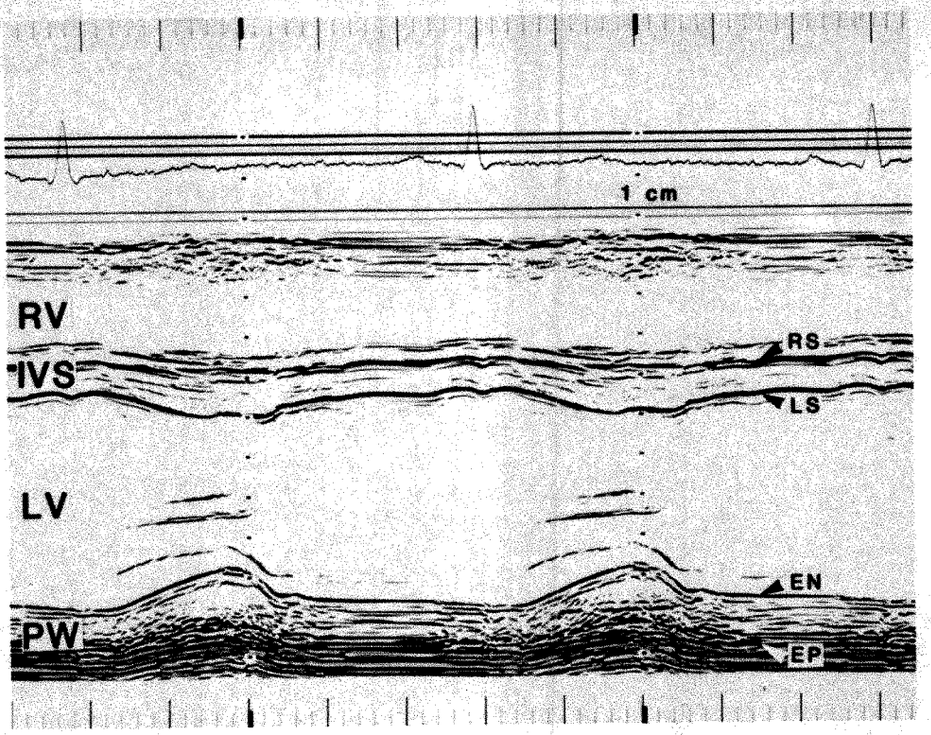

**FIGURE 1.** M-mode echocardiogram of the left ventricle in a normal subject. EN = posterior wall endocardium; EP = posterior wall epicardium; IVS = interventricular septum; LS = left side of septum; LV = left ventricular cavity; PW = posterior wall; RS = right side of septum; RV = right ventricle.

volunteers, all hospital personnel aged 21 to 30 years (mean 24), on 3 separate occasions several days apart (Group 2).

**Echocardiographic studies:** M-mode echocardiograms at the level of the left ventricular minor axis[2] were obtained using an Irex System II echocardiograph with a 2.25 MHz medium focus transducer and were recorded at 100 mm/s. Echocardiographic studies of the left ventricle were chosen for digitization if there were continuous echoes of the right and left sides of the septum and the endocardial and epicardial surfaces of the posterior wall throughout the cardiac cycle. In Group 2, 5 to 15 beats/day (12 ± 4, mean ± standard deviation) were analyzed on each of 3 separate days.

**Digitization:** The studies were digitized by tracing echoes from the right and left sides of the septum and the endocardial and epicardial surfaces of the posterior wall (Fig. 1) using a Hewlett-Packard 9874A digitizing table, interfaced with a Hewlett-Packard 2100 computer. The data were analyzed at 10 ms intervals with a moving average filter using a 3 point smoothing algorithm.[1] Each cardiac cycle was identified by 2 successive electrocardiographic Q waves and up to 5 cycles could be digitized. Each strip chart was calibrated by time (2 seconds) and depth (3 cm), which also ensured axis alignment of the strip chart with respect to the digitizing pad. From the digitized echocardiogram, the following standard left ventricular dimensions (in centimeters) were obtained in diastole (d) and systole (s): left ventricular internal dimension (LV), interventricular septal thickness (IVS), and posterior wall thickness (PW). Standard dimensions in diastole were taken at the onset of the electrocardiographic Q wave. Systolic dimensions were taken at the time that left ventricular dimensions were smallest. The peak rates of change of the left ventricle, interventricular septum, and posterior wall (in centimeters/second) were obtained as follows: peak left ventricular filling and emptying rates (d/dt LVd, d/dt LVs), peak interventricular septal and posterior wall diastolic thinning, and systolic thickening rates (d/dt IVSd, d/dt PWd, d/dt IVSs, d/dt PWs).

**Conceptual analysis and statistical methods:** A single measurement of a cardiac dimension is affected by the following factors: (1) *The subject:* There is a "normal" variability between subjects with normal hearts reflecting body size, sex, heredity, and so on. (2) *The day:* The same subject may show variability on different days. This may be due to several factors, including body position during the examination and different levels of autonomic tone. (3) *The beat:* Dimensions may differ between beats due to respiration, sinus arrhythmia, and so on. (4) *The reader* ("personality" factor): There will be variability between different readers digitizing the same tracing. This may be due to different types of style in moving the digitizing cursor, for example. (5) *The tracing* ("jitter" factor): There will be a difference in the measurements made by the same reader digitizing the same tracing on ≥2 occasions. This difference reflects the human interaction such as fine motor and eye-hand coordination required to digitize the tracing.

The purpose of this study was to estimate the magnitude of effects from these different variability factors in digitized echocardiographic measurements. The estimates cannot be derived simply by subtraction since only their combined effect is observed in any 1 observation. For instance, let us consider 1 normal subject whose mean left ventricular end-diastolic dimension of 10 beats on Day 1 is 5.2 cm, and measured by a different reader is 5.0 cm on Day 2. The difference between the mean values on the 2 separate days simultaneously embody normal differences due to reader variability, tracer variability, and normal variability between beats, as well as

any true difference in dimensions on the different days. The 10 beats on the 2 separate days may be truly identical (and thus the difference of 0.2 cm between the means does not represent day-to-day difference); on the other hand the reader, tracing, and beat factors may have cancelled out true day-to-day difference and the day-to-day difference may actually be much larger than 0.2 cm.

The separate variability factors were "teased out" using standard statistical methods[3] by a *variance components analysis* based on the following concept:

Consider 1 cardiac cycle of a left ventricular echocardiogram. Let us assume that the true value for end-diastolic cavity dimension (LVd) of this beat is X cm.

1. Reader A digitizes the cardiac cycle obtaining a value of $Y_1$ cm. He redigitizes it 9 times and obtains $Y_2$-$Y_{10}$ cm, with an average of $\overline{Y}$cm. The average jitter (*tracer variability*) could be estimated from the average of the differences between each Y measurement and $\overline{Y}$. (The applicable standard statistical methods actually use the root-mean-square rather than the arithmetic mean.)

2. Reader B digitizes the same tracing and obtains value $Z_1$ cm. Nine other readers digitize the same tracing and obtain values $Z_2$-$Z_{10}$. These readings will differ from one another partly because each contains "jitter," but additionally because various readers may systematically tend to provide somewhat higher or lower readings than do others. This possibility (checkable from the data) represents variability due to "personality" (*reader variability*).

3. Reader A digitizes 2 separate cardiac cycles from the same day and obtains two values $A_{b1}$ and $A_{b2}$. The difference between the values may represent jitter or true *interbeat variability*. Reader B digitizes the 2 cardiac cycles to obtain values $B_{b1}$ and $B_{b2}$. The difference between $A_{b1}$ and $B_{b1}$ embodies, in combination, jitter, personality, and possible true interbeat differences.

4. Similarly, if reader A digitizes a cycle from Day 1 and reader B a cycle from Day 2 then the difference reflects jitter, personality, and beats, as well as *interday variability*.

5. Finally, if reader A digitizes a cycle from normal subject M and reader B digitizes a cycle from normal subject N then the differences reflect jitter, personality, interbeat, and interday, as well as *intersubject variability*.

In summary, the variance components analysis works in the following way: In Group 1, the variance* between measurements made by the same observer of the same tracing was calculated (tracer variance – $\sigma^2$T). This component of variance estimates variability due to jitter. It was then suitably removed from the variability recorded between measurements of 2 different observers of the same tracing to obtain an estimate of reader variance ($\sigma^2$R). Both these factors were then suitably removed from the variability of beats recorded in Group 2 on any 1 day to obtain beat variance ($\sigma^2$B). $\sigma^2$T, $\sigma^2$R, and $\sigma^2$B were then all suitably removed from the variability recorded between days to obtain day variance ($\sigma^2$D). All 4 factors were then suitably removed from the variability recorded between subjects to obtain subject variance ($\sigma^2$S). (The details of "suitably removing" are made more specific later.)

**Variance components analysis equations:** An individual digitized measurement of a cardiac cycle of a given subject represents the true value for that given cycle ± the total variability due to each of the 5 factors. If several observations are averaged together, than that average will contain variability from all factors, and the *amount* of that variability for any factor will be related to how many different values of that factor enter into the average. Thus, if we estimate a cardiac dimension for a particular subject by recording 5 beats, on each of 3 days, each read twice by 4 readers, then the average of the $3 \times 5 \times 2 \times 4 = 120$ readings contains 120 jitter components averaged together, and 3 day components, 4 reader components, and 15 beat components. The variability of the average of the 120 readings we call $\sigma^2$, and it has the form:

$$\sigma^2 = \frac{\sigma^2 D}{3} + \frac{\sigma^2 B}{15} + \frac{\sigma^2 R}{4} + \frac{\sigma^2 T}{120}.$$

More generally, if $\overline{N}$ denotes the average of the D × B × R × T tracings (where on each of D days B beats are recorded and read by each of R readers T times), then the average has variance:

$$\sigma^2\overline{N} = \frac{\sigma^2 D}{D} + \frac{\sigma^2 B}{DB} + \frac{\sigma^2 R}{R} + \frac{\sigma^2 T}{DBRT}.$$

From this equation (equation 1), we may see that if we take the average value of an infinite number of tracings by an infinite number of readers of an infinite number of beats and on an infinite number of days we may arrive at a true number for that subject, as the total variability would be zero. If this were repeated for another subject, the difference between the true numbers would represent true intersubject variability, having eliminated the differences due to day, beat, reader, and tracing.

**Statistical significance of different measurments:** The difference between M1 and M2, 2 averaged measurements obtained by the same B, R, and T pattern from the same subject on 2 different days, will have variance equal to $2\sigma^2\overline{N}$ (since the difference involves the random error of 2 averages, each with variance $\sigma^2\overline{N}$). This standard error for (M1 – M2), the difference between the 2 average readings, permits deciding how large a value (M1 – M2) must be in order to be regarded as showing a real change, rather than merely exhibiting statistical fluctuation. *The argument is: If, indeed, no real change has occurred between the 2 days, then there is a 95% chance that (M1 – M2) will not exceed 1.96* $\sqrt{2\sigma^2\overline{N}}$ *= 2.8* $\sigma^2\overline{N}$*, and so if the difference in the 2 measurements exceeds that amount, it may be taken (with 95% confidence, or p <0.05) to indicate a real difference. For 99% confidence (p <0.01), the difference must be at least 2.58* $\sqrt{2\sigma^2\overline{N}}$ *= 3.64* $\sigma^2\overline{N}$.

## Results

**Technical variability:** Correlations between repeated readings of 1 reader, and between 2 readers, were high both for standard dimensions and peak rates of change as tabulated in Table I.

The variance attributable to the reader and tracing factors is shown in Table II. The variance is larger for peak rates of change than standard dimensions.

**Biologic variability:** The variance attributable to the subject, day, and beat factors is shown in Table III. Biologic variability is much larger than technical variability. As with technical variability, the variance of the peak rates of change was larger than for standard dimensions (Fig. 2). There was no significant correlation between cycle length and either dimensions or rates of change within the same subject or between different subjects.

**Estimated total variance:** From the individual components, $\sigma^2$D, $\sigma^2$B, $\sigma^2$R, and $\sigma^2$T, we estimated (from equation 1) the total variance for the mean of d/dt LVd derived from 20 observations, taken in various patterns (Table IV). Days and beats reduce the variance more

* Variance ($\sigma^2$) is a measure of variability, and represents the average squared deviation from the mean.

The estimated variance attributable to the subject ($\sigma^2$S), day ($\sigma^2$D), and beat ($\sigma^2$B) are shown for peak rates of change and standard dimensions. These data were derived from Group 2 after taking into account the estimated variance attributable to the reader and tracing derived grom Group 1 data. Mean values from Group 2 are shown.

than the number of readers or tracings. Table V shows the precision obtainable on the standard dimensions using 2 patterns, and Table VI shows the corresponding information for the peak rates of change.

**Statistical significance:** The difference between 2 averaged measurements for standard dimensions and peak rates of change for 2 patterns of B, R, and T to occur beyond 95 and 99% confidence limits were calculated and are shown in Tables VII and VIII. Differences of 46.5 and 37.2% in d/dt LVd (peak filling rate) and d/dt LVs (peak emptying rate) are required for 95% confidence with 1 day, 1 beat, 1 reader, and 1 tracing. With 2 days, 5 beats, 1 reader, and 2 tracings, these differences are reduced to 27.1 and 23.4%, respectively, for 95% confidence.

## Discussion

Biologic variability due to the subject, day, and beat is greater than technical variability due to the reader and the tracing he or she makes. Among biologic factors, the subject variance is the highest for standard dimensions and peak left ventricular filling rate, indicating, as might be expected, that intersubject variation is greater than intrasubject variation due to different days or beats for these measurements. For the other measurements, subject-to-subject variance is equal to or less than day-to-day or beat-to-beat variance, which may be a reflection of the homogeneity of Group 2; subject variance would have been greater for these measurements if Group 2 had been composed of patients with larger differences in these peak rates of change rather than normal young persons.

There is large beat-to-beat variation both for standard dimensions and peak rates of change as has been described previously.[4–6] There are several possible reasons for this variation. In a study of normal subjects paced at heart rates of 50 to 150 beats/min, there was a significant correlation between heart rate and left ventricular size and function.[7] However, in another study, no correlation between heart rate and left ventricular performance was found within the normal variation in heart rate of resting subjects.[4] We also did not find a significant correlation between heart rate and left ventricular performance. Shapiro et al[8] recently reported striking differences between rates of change recorded in different regions of the left ventricle; we also observed this (Fig. 2). Finally, beat-to-beat variation is likely to reflect variation due to respiration.[9] Day-to-day variation is less than beat-to-beat variation and may be due to a change in body position of the subject,[10] or different transducer angulation, or both.[4,10,11]

Guiding the digitizer over the recording of the septum and posterior wall throughout the cardiac cycle requires fine eye-hand coordination which is within most people's capabilities; however, mastering this takes a few sessions. There was more technical variability of septal

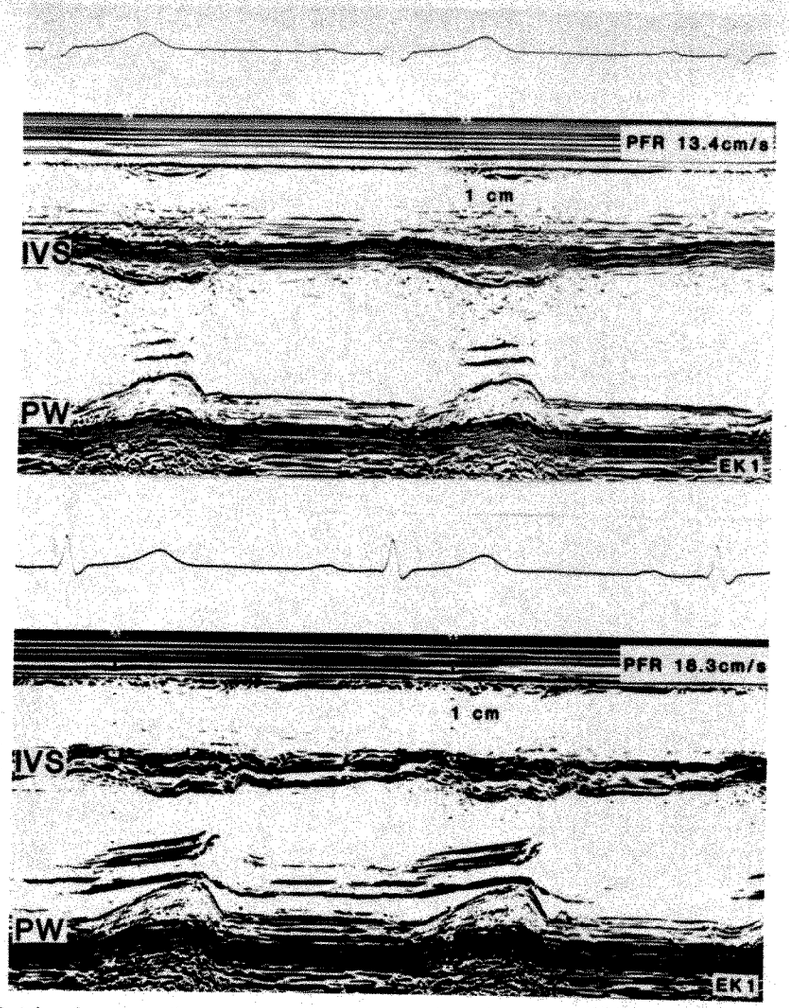

**FIGURE 2.** Two pairs of beats taken from a continuous recording (on the same day in the same subject) showing a large difference in peak filling rate. The part of the mitral valve apparatus recorded for each pair is quite different, indicating different transducer positions between beats. IVS = interventricular septum; PFR = peak filling rate (mean measurement for both beats at each level of the ventricle is shown); PW = posterior wall.

and posterior wall measurements than of left ventricular cavity measurements, as described previously,[12,13] and this is likely due to the difficulty often encountered in demarcating both the right side of the septum and epicardium. There was little technical variance in standard dimensions compared to peak rates of change, which showed relatively large biologic and technical variance. The extra element of eye-hand coordination involved in tracing the often rapid slopes of the septum and posterior wall probably explains the larger technical variability of peak rates of change compared with technical variability of standard dimensions.

Our results of the variance components of the standard dimensions are similar to a previous study in which the measurements were made directly by hand without digitizing the records.[13] This suggests that the technical variability of standard dimensions is not reduced by deriving these by digitization. Using 2-dimensional images to localize the area for M-mode sampling has been reported not to improve reproducibility of standard dimensions.[14] The effect of different sonographers performing the study has been shown to add little variability above the other components.[13]

By analyzing the contribution of each variance component, we were able to estimate the total expected variance for the combinations of different numbers of days, beats, readers, and tracings. In the comparison of measurements made at different times, large differences of $\geq 100\%$ are required in some of the peak rates of change to be beyond 99% confidence limits ($p < 0.001$) with only 1 day, 1 beat, 1 reader, and 1 tracing. Smaller differences are statistically significant with a combination of 2 days, 5 beats, 1 reader, and 2 tracings. Thus, by using such combinations, biologic variation is reduced and real physiologic or pathologic changes will be perceived best.

It is appreciated that our assessment of biologic variability refers to normal subjects. The biologic

variability of patients with stable heart disease may be different, although 2 studies[15,16] have shown that day-to-day variability of standard dimensions measured manually was similar to previous studies of normal subjects.[14]

**Implications:** Digitized M-mode echocardiograms provide information on left ventricular function beyond that given by standard dimensions. However, there is much biologic and technical variability in derived peak rates of change. Variance components for each variable

**TABLE IV Estimated Total Variance of Peak Left Ventricular Filling Rate for 20 Observations on the Same Subject (for Various Patterns of Taking the 20 Observations)**

| D | B | R | T | $\sigma^2\bar{N}$ |
|---|---|---|---|---|
| 1 | 1 | 1 | 20 | 5.20 |
| 1 | 1 | 2 | 10 | 5.00 |

# Left Ventricular Isovolumic Pressure Decay and Diastolic Mechanics After Postextrasystolic Potentiation and During Exercise

JOHN D. CARROLL, MD, RENÉ WIDMER, BA, OTTO M. HESS, MD, HEINZ O. HIRZEL, MD, and HANS P. KRAYENBUEHL, MD

**Left ventricular contraction, relaxation, and diastolic mechanics were examined in subjects after postextrasystolic potentiation and compared with results during supine bicycle exercise. Twelve patients had ventricular extrasystoles induced during biplane left ventricular cineangiography (PES Group). Six patients with no or minimal cardiovascular disease underwent exercise (Exercise Group). From simultaneous high-fidelity pressure curves the time constant of relaxation (T), a theoretical baseline for isovolumic pressure decay ($P_B$), and the lowest diastolic pressure ($P_L$) were determined. Frame-by-frame volume analysis was completed in 6 patients from the PES Group and 4 in the Exercise Group to quantitate filling rates and to construct diastolic pressure-volume relations.**

**In the PES Group, the ejection fraction increased from 65 to 74% ($p < 0.001$) and end-systolic volume decreased from 38 to 29 ml/m$^2$ ($p < 0.001$). Pressure decay was altered with maximal negative first derivative of left ventricular pressure (dP/dt), decreasing from −1,553 to −1,273 mm Hg/s ($p < 0.001$), T increasing from 51 to 74 ms ($p < 0.001$), and $P_B$ decreasing from −6 to −19 mm Hg ($p < 0.001$). While $P_L$ occurred later in diastole (138 to 177 ms after maximal negative dP/dt, $p < 0.001$), it remained at the same level (8 versus 7 mm Hg). Peak filling rate was unaltered in the diastole after postextrasystolic potentiation, and no upward shift in the diastolic pressure-volume relation occurred.**

**In the Exercise Group, the ejection fraction increased from 65 to 75% ($p < 0.001$) and end-systolic volume decreased from 35 to 26 ml/m$^2$ ($p < 0.001$). With exercise, maximal negative dP/dt increased from −1,566 to −2,650 mm Hg/s ($p < 0.001$), T decreased from 50 to 26 ms ($p < 0.001$), and $P_B$ was unchanged. As a result, $P_L$ occurred earlier in diastole (120 to 96 ms, $p < 0.001$), achieved a lower value (9 to 4 mm Hg, difference not significant [NS]), and the peak filling rate increased from 588 to 1,107 ml/s, $p < 0.001$). At $P_L$, relaxation was complete during exercise but incomplete after postextrasystolic potentiation (3.7 versus 2.4 T elapsed, $p < 0.001$).**

**Postextrasystolic potentiation, like dynamic exercise, enhances shortening and augments restoring forces by producing a smaller end-systolic chamber. Yet, postextrasystolic potentiation delays inactivation and prolongs relaxation. Diastolic mechanics (early diastolic pressure, filling, pressure-volume relation) are not subsequently altered, suggesting that enhanced restoring forces counterbalance the delayed inactivation. With exercise, diastolic filling is enhanced both by more rapid pressure decay and by increased restoring forces. Thus, diastolic mechanics can be dissociated from systolic and are determined by the nature of the inotropic stimulus.**

Diastolic mechanics have been characterized by the predominant effect of left ventricular passive chamber properties. Diastolic mechanics are also determined by the preceding systole. The end-systolic volume produced by contraction may contain stored elastic energy which promotes restoration of the ventricle to its precontraction configuration. Similarly, pressure decay from systole may play an important role in determining diastolic pressures, filling rates, and pressure-volume relations.[1–5] We examined these influences on relaxation and diastolic function in man after 2 interventions producing distinctive alterations in cardiovascular function. Postextrasystolic potentiation is a positive inotropic intervention with enhanced shortening, producing a smaller end-systolic chamber capable of augmenting restoring forces. Yet, isolated muscle studies and animal studies have shown that postextrasystolic potentiation delays relaxation probably by delaying muscle inactivation.[6,7] Dynamic exercise also is a positive inotropic intervention producing a smaller end-systolic chamber with enhanced restoring forces available. In human subjects pressure decay is greatly aug-

mented during dynamic exercise, and in isolated muscle and animal studies catcholamines promote inactivation and pressure decay.[6-10] Thus, the 2 interventions produce an increase in restoring forces but opposite effects on muscle inactivation. In our subjects, we assessed the net effect of these 2 common cardiovascular interventions on pressure decay and diastolic function as represented by diastolic pressures, filling dynamics, and pressure-volume relations.

## Methods

A total of 17 patients (16 men, 1 woman) were included in the study. Twelve patients participated in the postextrasystolic potentiation part of the study. Ten had significant coronary artery disease (>50% diameter narrowing: 8 with 3-vessel and 2 with 2-vessel disease) and 2 patients with atypical chest pain had no cardiovascular abnormalities. All 12 had normal resting ejection fractions (>57%), although 8 had mild to moderate regional wall motion abnormalities on the resting angiogram, which improved in 5 after postextrasystolic potentiation. The response to postextrasystolic potentiation was similar in all types of patients; they will be referred to as 1 group, the PES Group.

Five additional patients and 1 patient from the PES Group (Case 1) underwent supine bicycle exercise. In all the ejection fraction increased by >5%, and none had angina. All underwent catheterization to evaluate atypical chest pain (4 had no cardiovascular abnormalities, 1 had minimal coronary artery disease, and 1 had minimal mitral valve prolapse without mitral regurgitation). These patients comprise the Exercise Group.

**Catheterization and cineangiography:** Premedication consisted of 10 mg of chlordiazepoxide given orally 1 hour before catheterization. In the Exercise Group, 4 patients were receiving long-term administration of beta-adrenergic blockers; 4 patients, calcium antagonists; and 2 patients, long-acting nitrates. In the PES Group, 11 were taking beta-adrenergic blockers, 7 took calcium antagonists, and 11 took long-acting nitrates. Cardiovascular medications were withheld for 12 to 24 hours before study. Left ventricular pressure was measured with a Millar pigtail angiographic micromanometer introduced from the femoral artery. The pressures were recorded at a paper speed of 250 mm/s (Electronics for Medicine, VR16) with the dP/dt, dP/dt/P, and an intracardiac electrocardiogram from a right-sided catheter. Before both resting and exercise recordings, the pressure was calibrated against a fluid-filled system.

Biplane left ventricular cineangiography was performed in the right anterior oblique (30°) and left anterior oblique (60°) projections at a filming rate of 50 frames/s. Volumes were calculated using the area-length method. Each angiographic frame had a digital time which corresponded to time marks on the pressure recordings.

**Postextrasystolic potentiation protocol:** In 7 of the 12 patients in the PES Group, a single premature contraction was produced by right ventricular electrical stimulation with a right-sided pacing catheter. The extrasystole occurred immediately after the second well-opacified beat during cineangiography. Coupling interval was adjusted before the angiogram to insure systolic potentiation (as judged from maximal positive dP/dt) of the postextrasystolic beat. In the additional 5 patients, spontaneous extrasystoles (in 3 single, in 2 triplets) occurred during cineangiography with adequate visualization of a nonpotentiated and a potentiated beat to permit analysis. In 6 of the 12 patients, both the nonpotentiated and potentiated beats were evaluated from end-diastole to the next end-diastole to assess alterations in filling and diastolic pressure-volume relations (see later). All 12 patients had their feet in a semi-elevated position, attached to a bicycle device, as part of a separate study. For this reason, in part, end-diastolic pressures were increased due to the augmented preload.

**Exercise protocol:** All 6 patients in the Exercise Group had precatheterization bicycle exercise testing to determine achieved work load and exercise limitations. At catheterization, pressures were recorded before and after attaching the patients' feet to the bicycle device. Left ventricular end-diastolic pressure subsequently increased from 12 to 20 mm Hg ($p < 0.01$). The increase in preload and bradycardia in several patients account for the elevated end-diastolic pressures. All resting data presented here are during the first angiogram with the legs in this elevated position. After the resting angiogram and a subsequent 12- to 15-minute pause, exercise was begun at a low level. Patients underwent progressively higher work loads until limiting symptoms (fatigue in legs, no angina) occurred or until they achieved a predicted submaximal heart rate according to sex, age, and height. At the point of peak exercise pressure was again recorded and simultaneous cineangiography was completed. Coronary arteriography was performed after exercise using the Judkins technique.

**Data analysis:** Rest, postextrasystolic, and exercise data were derived from beats selected during simultaneous pressure measurement and left ventricular cineangiography. All beats analyzed were well opacified and within 5 seconds of the beginning of contrast injection. In the PES Group, a control, unpotentiated beat was compared with a potentiated beat. In the Exercise Group, all beats analyzed were sinus beats, and postextrasystolic beats were excluded. Resting beats were from midinspiration and exercise beats were average if any respiratory-related pressure changes were noted.

Pressure tracings were digitized for an entire cardiac cycle by an electronic digitizer (Numonics Corporation) interfaced with a digital computer (PDP 11/10). A previously described program produced a printout of pressure and dP/dt values with a time interval between 3 and 10 ms depending on the heart rate (each cycle being divided into 130 time intervals).[11] The time constant of relaxation (T, in milliseconds) was calculated as the negative reciprocal of the slope of the linear regression of pressure and dP/dt coordinates.[12] These coordinates were taken from the isovolumic relaxation period defined as from immediately after maximal negative dP/dt to the time pressure had decreased to 5 mm Hg above left ventricular end-diastolic pressure. The linear regression of pressure and dP/dt coordinates was also characterized by its pressure axis intercept. This extrapolated baseline pressure—$P_B$—was calculated at dP/dt = 0.

To study the completeness of relaxation in early diastole we used the technique of Weisfeldt et al,[1] which assumes pressure decay to be 97% complete at 3.5 times constants (T) after maximal negative dP/dt. The number of time constants elapsed was computed at the time of lowest diastolic pressure ($P_L$) in the rest and exercise states and also for control and postextrasystolic potentiated beats.

In order to assess the effects of postextrasystolic potentiation and exercise on diastolic dynamics, ventricular filling was quantitated using frame-by-frame angiographic volumes from mitral valve opening to end-diastole in 10 patients with adequate data (6 with postextrasystolic potentiation and 4 with exercise). The time of mitral valve opening was 20 ms before the time of the first frame showing the entry of unopacified blood into the left ventricle. The time of end-diastole was noted as the beginning of the rapid rise in left ventricular pressure immediately after the onset of the QRS complex. The time of mitral valve opening to end-diastole is the left ven-

LVP = left ventricular pressure; LVEDP = end-diastolic pressure; SD = standard deviation; T = time constant of relaxation; $P_L$ = lowest diastolic pressure; * $p < 0.05$; † $p < 0.01$; ‡ $p < 0.001$. All probabilities are for intervention (I) versus control (C) comparisons.

tricular filling time. This filling time was divided into a first and second half, the middle being mid-diastole. The average filling rate was calculated for the first half of diastole. In addition, instantaneous filling rates were calculated every 40 ms after mitral valve opening. The greatest value opening occurring early in diastole was termed the peak filling rate. End-diastolic volume index, end-systolic volume index, and ejection fraction were calculated in the usual fashion.

The left atrial-left ventricular pressure gradient is a major determinant of ventricular filling.[13] Since left atrial pressure was not measured, we noted the pressure at the time unopacified blood first entered the ventricle. This is termed the *driving pressure* and is an index of the pressure responsible for mitral valve opening.

Prolonged relaxation during ischemia has been implicated as a cause of the upward shift in the diastolic pressure-volume relation.[4] We assessed the possible influence of prolongation of relaxation induced by postextrasystolic potentiation on the diastolic pressure-volume relation in 6 patients. Angiographic biplane volumes every 20 ms were time-matched to simultaneous left ventricular pressures and the data graphically displayed.

**Statistics:** All tabular data are presented as means ±1 standard deviation. Figure data are means ±1 standard error. The statistical significance of differences between control and PES data and between rest and exercise data was tested with a paired *t* test. Differences between the PES and Exercise Groups were assessed with an unpaired *t* test.

## Results

Left ventricular pressure results are shown in Table I, volume data in Table II, and derived relaxation parameters in Table III. Figures 1 and 2 show representative pressure tracings.

Systolic performance was augmented in both postextrasystolic and exercise beats (Fig. 3). Postextrasystolic potentiation increased maximal positive dP/dt from 1,514 to 1,679 mm Hg/s ($p < 0.01$), ejection fraction increased from 65 to 74% ($p < 0.001$), and end-systolic volume decreased from 38 to 29 ml/m$^2$ ($p < 0.001$). Exercise increased heart rate from 66 to 118 beats/min and maximal positive dP/dt increased from 1,468 to 2,939 mm Hg/s ($p < 0.001$), which was greater than the level achieved by postextrasystolic potentiation ($p < 0.05$). Exercise increased ejection fraction from 65 to 75% ($p < 0.001$) and decreased end-systolic volume from 35 to 26 ml/m$^2$ ($p < 0.001$), nearly identical compared with postextrasystolic potentiation. With exercise, there was an insignificant increase in end-diastolic volume (99 to 105 ml/m$^2$) and end-diastolic pressure (20 to 21 mm Hg). With postextrasystolic potentiation, there was a small increase in end-diastolic volume (107 to 112 ml/m$^2$, $p < 0.001$) and pressure (21 to 23 mm Hg, NS). Peak left ventricular pressure increased with exercise from 133 to 154 mm Hg ($p < 0.05$) but decreased slightly with postextrasystolic potentiation (141 to 133 mm Hg, $p < 0.05$).

Relaxation was altered in opposite directions by postextrasystolic potentiation and exercise (Fig. 4). With postextrasystolic potentiation, maximal negative dP/dt decreased from −1,553 to −1,273 mm Hg/s ($p < 0.001$), T increased from 51 to 74 ms ($p < 0.001$), and $P_B$ decreased from −6 to − 19 mm Hg ($p < 0.001$). Exercise caused an increase in maximal negative dP/dt from −1,566 to −2,650 mm Hg/s ($p < 0.001$), T de-

creased from 50 to 26 ms ($p < 0.001$), and $P_B$ was unchanged. These changes in pressure decay are portrayed in Figure 5.

Early diastolic pressures were also different after postextrasystolic potentiation and exercise. In the diastole after the potentiated beat, the minimal diastolic pressure, $P_L$, occurred later after maximal negative dP/dt (138 to 177 ms, $p < 0.001$), relaxation was less complete at $P_L$ (2.7 to 2.4 T elapsed, NS), but the absolute value of $P_L$ was unchanged (8 to 7 mm Hg). Exercise caused $P_L$ to occur earlier (120 to 96 ms, $p < 0.001$), relaxation was completed at $P_L$ (2.4 to 3.7 T elapsed, $p < 0.05$), and $P_L$ decreased in 5 of 6 patients (9 to 5 mm Hg, NS).

Despite a prolonged T, the diastolic filling after the potentiated beat was not diminished in the 6 patients studied. The mean filling rate for the first half of diastole increased insignificantly (377 ± 163 ml/s to 409 ± 123 ml/s, NS) and early peak filling rate was unaltered (829 ± 325 ml/s to 829 ± 394 ml/s). There was no change in the other key determinant of early diastolic filling, the driving pressure. The pressure at mitral valve opening was 17 ± 8 mm Hg in the control beats and unchanged after the potentiated beats at 18 ± 8 mm Hg.

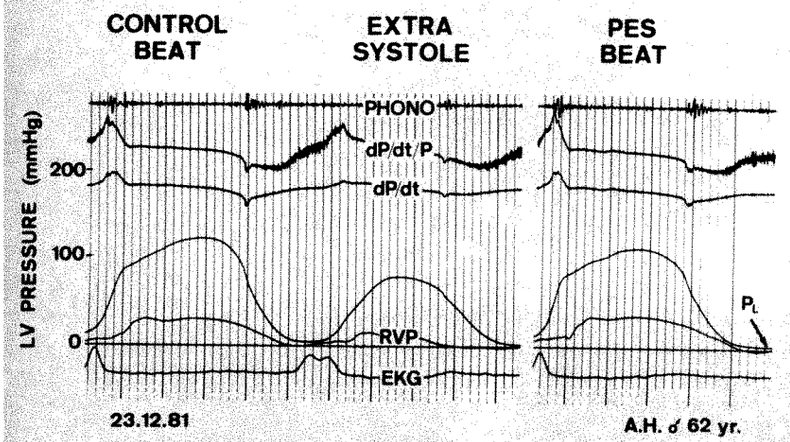

**FIGURE 1.** Patient 5. Left ventricular (LV) pressure tracing for a control beat and a postextrasystolic potentiated beat. An extrasystole was produced by a right ventricular pacing (RVP) catheter. The postextrasystolic beat had an increase in maximal positive dP/dt but a reduction in maximal negative dP/dt. The time constant of relaxation (T) was prolonged from 58 to 101 ms. $P_L$, the lowest diastolic pressure was not affected by this delay, but occurred later in diastole. EKG = electrocardiogram.

$P_B$ = baseline pressure, $P_L$ = lowest diastolic pressure. T = time constant of relaxation; * $p < 0.001$; † $p < 0.05$. All probabilities are for intervention (I) versus control (C) comparisons.

During exercise, all 4 patients with data had an increase in mean filling rate for the first half of diastole (360 ± 120 ml/s to 684 ± 157 ml/s, NS) and early peak filling rate (586 ± 174 ml/s to 1,094 ± 350 ml/s, $p < 0.05$). There was no change in the driving pressure (13 ± 8 mm Hg to 15 ± 12 mm Hg, NS).

Pressure-volume relations from the diastole after the potentiated beat are presented for 6 patients in Figure 6. No upward shifts occurred despite the prolongation of T by an average of 50%. In 1 patient (Case 9) who did not have a prolonged T after postextrasystolic potentiation, but in whom end-systolic volume was reduced, there was a downward shift of the pressure-volume relation.

## Discussion

In humans, left ventricular relaxation is slower and prolonged after postextrasystolic potentiation, but accelerated and shortened during dynamic exercise. Relaxation, that is, pressure decay or force dissipation, is dependent upon a complex interplay of 2 major controlling systems, as described by Brutsaert et al.[14] The first is related to inactivation, which is the energy-requiring process of calcium reuptake by the sarcoplasmic reticulum. The second, load dependency, is determined by the nature and magnitude of the load, its timing relative to the contraction-relaxation sequence, its duration, and the uniformity of its distribution. Loads produced by acute aortic cross-clamping in experi-

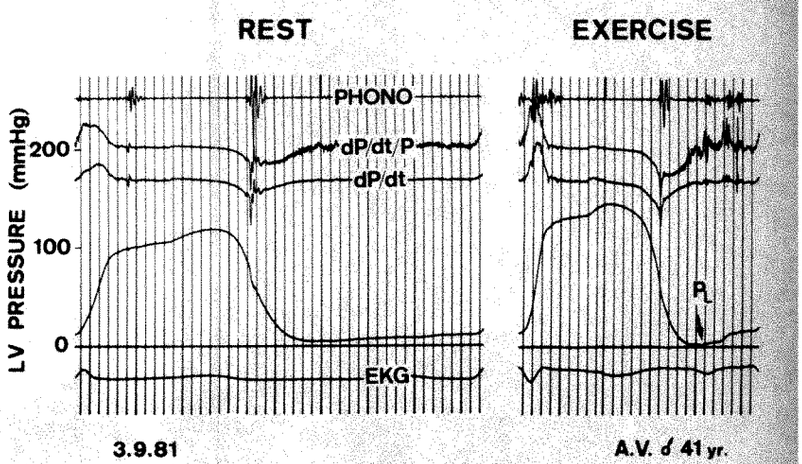

**FIGURE 2.** Patient 2. An example of the left ventricular (LV) pressure tracing at rest and during maximal supine bicycle exercise. The exercise beat had a greater maximal positive and negative dP/dt. The time constant of relaxation (T) decreased from 60 to 23 ms. The lowest diastolic pressure ($P_L$) occurred earlier after maximal negative dP/dt (87 versus 120 ms) and was lower. EKG = electrocardiogram; PHONO = phonocardiogram.

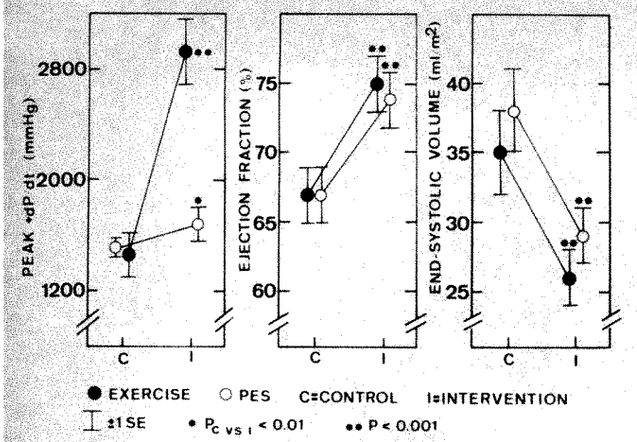

**FIGURE 3.** Systolic performance was augmented during exercise beats (**solid circles**) and postextrasystolic potentiated beats (PES) (**open circles**). Control data (C) and after the intervention (I: exercise or PES) are presented as means ±1 standard error. Maximal positive dP/dt and ejection fraction increased after both positive inotropic interventions. Both exercise and postextrasystolic potentiation caused a similar reduction in end-systolic volume and thus augmented restoring forces. * p <0.01; ** p <0.001. SE = standard error.

mental animals are applied throughout systole and appear to slow relaxation.[15] Loads applied in late systole on partially relaxed muscle may increase the rate of relaxation.[16] Relaxation, as assessed by both T and maximal negative dP/dt, is accelerated during dynamic exercise. Probably most important is the direct effect of catecholamines on the inactivation process, resulting in more rapid uptake of calcium by the sarcoplasmic reticulum. Augmented restoring forces, increased coronary blood flow, and enhanced synchrony of contraction probably contribute further to more rapid relaxation. The subsequent rapid inflow of blood early in diastole may further accelerate the return of the left ventricle to its precontraction configuration.[14]

Pressure decay is decelerated after postextrasystolic potentiation. Parmley and Sonnenblick[6] have suggested that the prolongation of tension decay after postextrasystolic potentiation in isolated muscle is probably due to a change in the uptake and the removal of activating calcium. The increase in the intracellular active calcium pool after an extrasystole potentiates contraction yet may saturate the system responsible for its removal. While the inactivation process is altered so as to prolong relaxation, loading conditions appear chiefly altered to produce the opposite. As with exercise, postextrasystolic potentiation augments restoring forces, and left ventricular systolic pressure is slightly lower. The increase in T occurs despite this, suggesting that delayed inactivation has the predominant effect. In the canine left ventricle, Blaustein et al[7] previously reported that postextrasystolic potentiation increases T despite changes in loading conditions which should decrease T.

Elastic recoil and diastolic suction are being reconsidered as potentially important mechanical determinants of diastolic function. Sonnenblick[17] suggested that the smaller, more deformed end-systolic shape of the left ventricle during exercise produces restoring forces which may augment ventricular filling. Muscle fibers shortening below slack length may produce internal restoring forces while the deformation of the left ventricular wall at end-systole may produce external restoring forces.[14] Hori et al[18] showed that negative

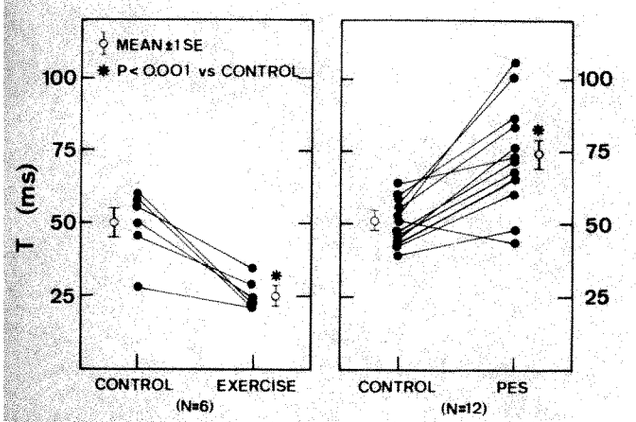

**FIGURE 4.** In the **left panel,** control (or rest) values of the time constant of relaxation (T) are compared with the exercise values. All 6 patients had more rapid pressure decay (50 to 26 ms, * p <0.001). The **right panel** compares control unpotentiated beats with postextrasystolic potentiated beats (PES) from 12 patients. All but 1 patient had a deceleration of pressure decay after PES. The mean T increased from 51 to 74 ms.

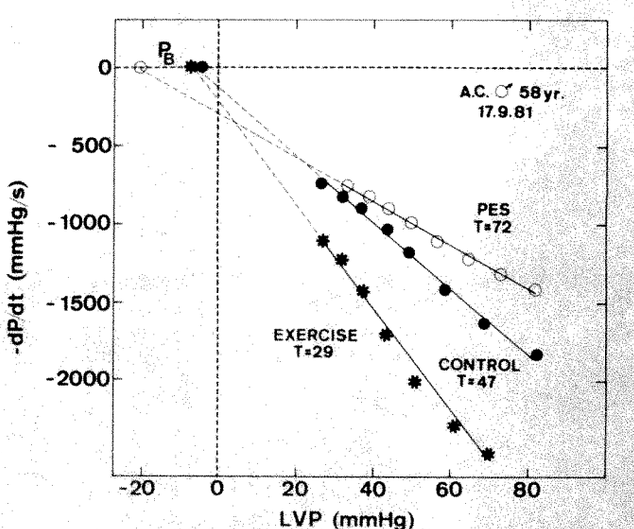

**FIGURE 5.** Left ventricular pressure and negative dP/dt coordinates from the isovolumic relaxation period are shown from the 1 patient who had both postextrasystolic potentiation (PES) and exercise studies. The time constant of relaxation (T) is the negative reciprocal of the slope of the linear regression between pressure and dP/dt coordinates. The **dotted lines** extend the linear regression to the left ventricular pressure axis intercept ($P_B$). During exercise (**asterisks**), T decreased to 29 ms from a control value (**solid circles**) of 47 ms. After PES, T prolonged to 72 ms and $P_B$ became more negative. Exercise and PES have different effects on left ventricular pressure decay despite their similar potentiation of systolic function.

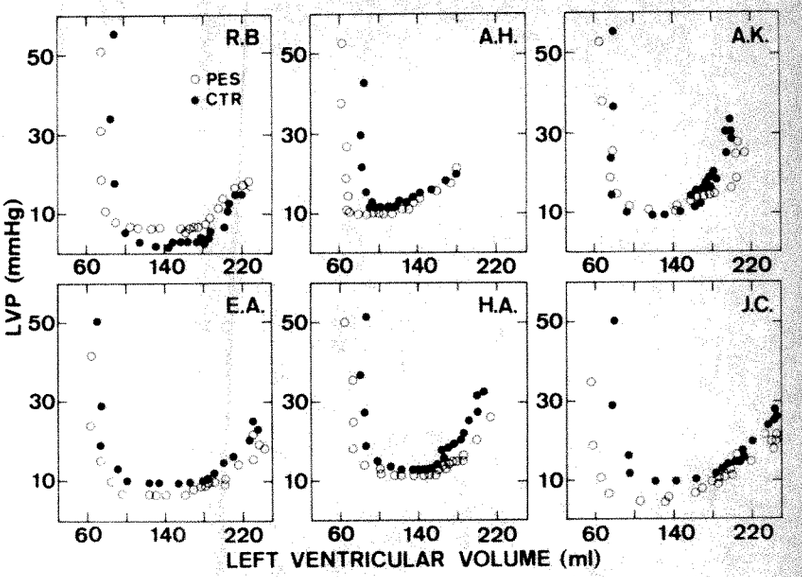

**FIGURE 6.** Six patients had diastolic pressure-volume relations constructed from simultaneous micromanometric left ventricular pressure recordings and biplane angiographic volumes every 20 ms. A control diastole (CTR) (**solid circles**) followed an unpotentiated beat, while the **open circles** represent the diastole immediately after a postextrasystolic potentiated beat (PES). Despite substantially increased T in 5 of the 6 patients, no upward shift of the pressure-volume relation occurred after postextrasystolic potentiation. The 1 patient (J.C.) without an increase in T appeared to have a slight downward shift early in diastole. This probably reflects enhanced elastic recoil from a smaller end-systolic volume. In other patients, the prolonged T apparently balances the enhanced elastic recoil so that pressure-volume relations are not altered.

intraventricular pressures occur in the canine left ventricle if filling is prevented by acute mitral orifice occlusion. Both catecholamines and postextrasystolic potentiation produced smaller end-systolic volumes which relaxed to more negative baseline pressures when filling was prevented. In certain states in humans associated with small end-systolic volumes, negative intraventricular pressures have been reported.[19,20] It appears that negative pressures are not more commonly seen because of the simultaneous occurrence of rapid filling which increases pressure proportional to volume increase. In mitral stenosis, in which rapid early filling is limited, pressure may be negative early in diastole.[19,20] Both during dynamic exercise and after postextrasystolic potentiation we have documented that end-systolic volume decreases. This parameter probably provides a fairly accurate reflection of directional changes in restoring forces. An augmentation of restoring forces could both promote faster relaxation and result in pressure decay to a lower, negative baseline if filling did not occur. Postextrasystolic potentiation is unique in that the rate of pressure decay from the small end-systolic volume is clearly prolonged. The effect of this unusual combination of factors is that filling and pressure-volume relations in the following diastole are unaltered. The significant prolongation of pressure decay may otherwise be expected to reduce early filling and shift upward the pressure-volume relation during early diastole. The lack of such changes suggests that the smaller end-systolic volume counterbalances the effect of delayed pressure decay.

The extrapolated baseline pressure, $P_B$, is derived from isovolumic data and theoretically represents the pressure attained at infinity (when $dP/dt = 0$). Our previous work with exercise-induced ischemia in human subjects revealed an upward shift in $P_B$ paralleling the increase in end-systolic volume and predicting elevated early diastolic pressures.[3] The present study further expands this concept and shows some of its limitations. While postextrasystolic potentiation reduces end-systolic volume and $P_B$ becomes more negative, the normal exercise-induced reduction of end-systolic volume does not produce a more negative $P_B$. In addition, it is apparent that in chronic heart failure with large end-systolic volumes and prolonged time constants, $P_B$ is forced mathematically to an illogical, very negative value (unpublished data). It appears that $P_B$ does not always have the same physiologic meaning as the baseline pressure measured by Hori et al when filling is prevented. $P_B$ does help in characterizing pressure decay which is not adequately described by a time constant alone. During exercise-induced ischemia in human subjects, the time constant did not distinguish those with grossly elevated diastolic pressures from those with normal pressures.[3] In humans, pressure decay cannot be assumed to always decrease to a zero baseline pressure. Quantification of relaxation requires a method allowing for variations in baseline pressure.[21]

Other methods for quantitating pressure decay have subdivided the isovolumic period and calculated several time constants.[22] Rousseau et al[22] showed that these 2 time constants move in the same direction after intracoronary nifedipine.[22] While this method of quantifying relaxation was not completed for our data, it is unlikely that our results would have been affected since postextrasystolic potentiation and exercise produce such directionally opposite effects on pressure decay.

Despite medications being held for the day before catheterization, persistent medication effects are possible. Beta-adrenergic blocking agents may attenuate the heart rate response and do slow pressure decay.[10] We observed no different response to postextrasystolic potentiation in those taking calcium antagonists.

Contrast dye has no known effect on isovolumic relaxation although no specific studies have been reported. Since we analyzed beats occurring early in contrast injection, significant hemodynamic alterations due to contrast were avoided.

The coupling interval for the extrasystole was not systematically altered in this study. In the canine left ventricle, Blaustein et al[7] failed to find a significant effect of coupling interval or compensatory pause on either maximal negative dP/dt or T, even though maximal positive dP/dt was altered. In the present study, the coupling interval was between 400 and 600 ms in all patients but no clear effect of coupling interval on T was noted.

The $P_L$ occurring typically early in diastolic represents a crossover point of 2 major processes: pressure decay from relaxation and pressure rise from filling. After an extrasystolic potentiated beat, pressure decay is slower while filling is unaltered. As predicted, the minimal diastolic pressure is achieved later in diastole. During exercise, pressure decay is accelerated and filling is augmented and the minimal diastolic pressure is earlier in diastole. Maintaining low diastolic pressures with augmented filling should be beneficial during exercise when diastole is significantly abbreviated.

Exercise and postextrasystolic potentiation are commonly occurring events in humans and knowledge regarding their effects on systolic and diastolic dynamics may be useful in several clinical situations. Hypertrophic cardiomyopathy is characterized by a hypercontractile state with an elevated time constant of relaxation.[22,23] The abnormal diastolic mechanics appear to be a consequence not only of the passive properties of the hypertrophied muscle, but also of abnormal relaxation.[22–24] When modifying diastolic function with pharmacologic agents, one must also consider effects on contraction-relaxation. Verapamil may "uncouple" contraction from relaxation since it depresses contractility and decreases the time constant of relaxation in dogs.[25] Thus, it is increasingly apparent that diseases, drugs, and the nature of inotropic stimuli may dissociate diastolic from systolic mechanics.

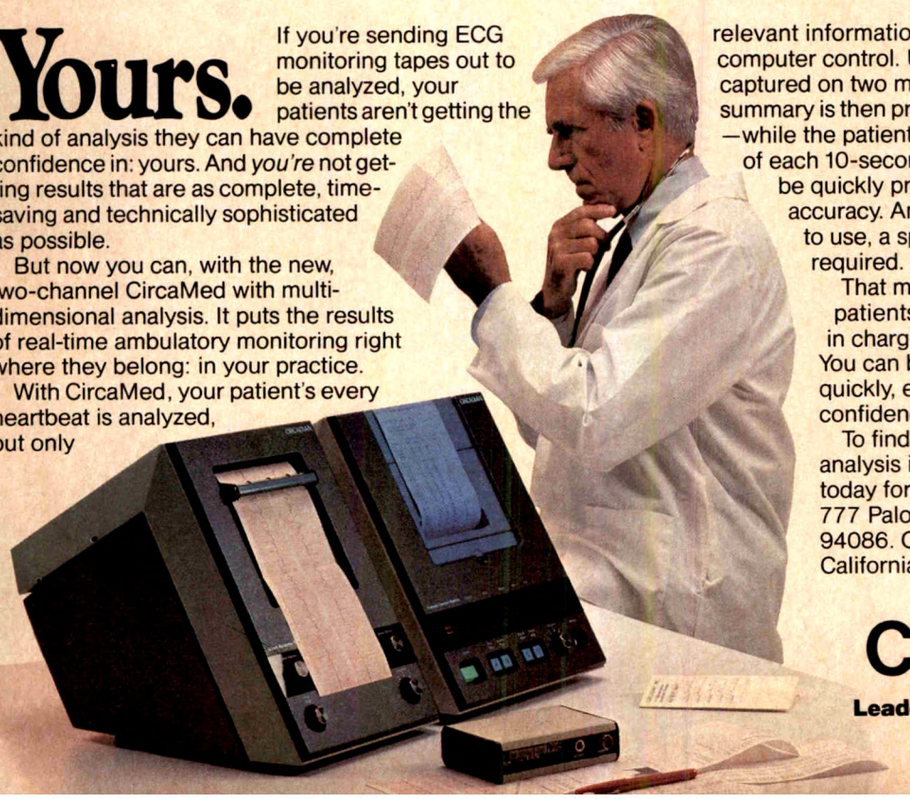
# Your patients deserve the best ECG analysis they can get.

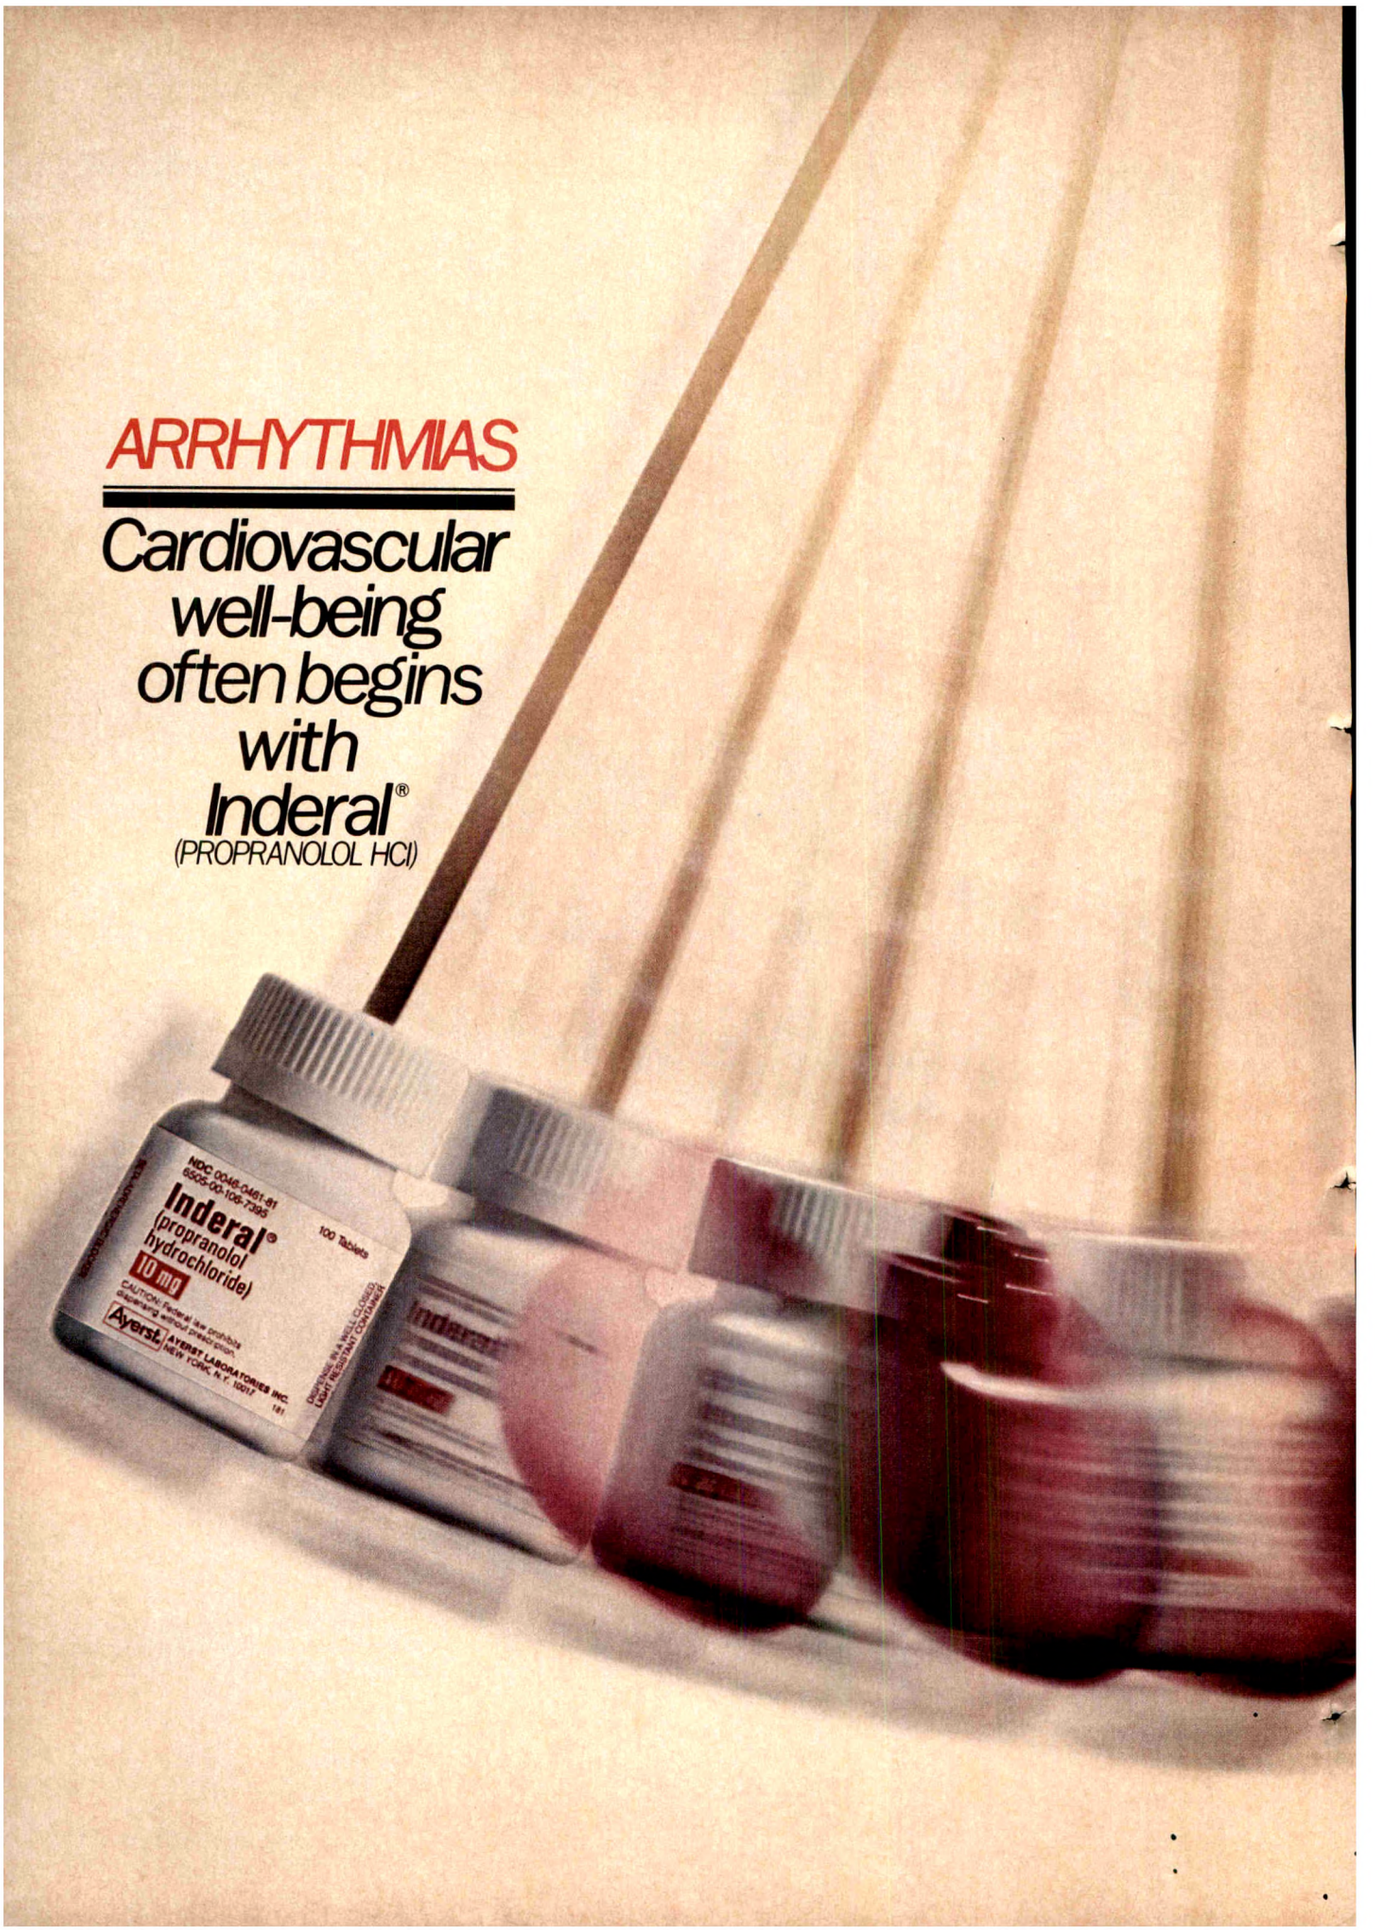
## Yours.



If you're sending ECG monitoring tapes out to be analyzed, your patients aren't getting the kind of analysis they can have complete confidence in: yours. And *you're* not getting results that are as complete, time-saving and technically sophisticated as possible.

But now you can, with the new, two-channel CircaMed with multi-dimensional analysis. It puts the results of real-time ambulatory monitoring right where they belong: in your practice.

With CircaMed, your patient's every heartbeat is analyzed, but only relevant information is recorded, under micro-computer control. Up to two days of patient data are captured on two multi-dimensional channels; a summary is then printed in your office within minutes —while the patient is still there. A strip chart record of each 10-second ECG measurement can also be quickly produced for further diagnostic accuracy. And because CircaMed is simple to use, a specially trained technician isn't required.



That means now neither you nor your patients have to worry about who's in charge of their ECG analysis: you are. You can both count on getting results quickly, economically and with complete confidence.

To find out how easy it is to bring ECG analysis into your practice, write us today for a brochure or demonstration: 777 Palomar Avenue, Sunnyvale, CA 94086. Or call: (800) 538-1772. In California (408) 738-8550.

## CIRCADIAN

**Leaders in real-time ECG analysis.**

ARRHYTHMIAS
Cardiovascular well-being often begins with Inderal®

DISPENSE IN A WELL CLOSED LIGHT RESISTANT CONTAINER

No agent offers a better risk/benefit profile in arrhythmias than INDERAL (propranolol HCl). INDERAL works to reduce heart rate and contractility, lengthen A-V conduction time, and suppress automaticity[1]—helping to restore the heart rate to normal in many patients with a wide variety of arrhythmias.

Consider INDERAL for arrhythmias early—to restore cardiovascular well-being as soon as possible.

*BRIEF SUMMARY (FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE CIRCULAR.)*
**Inderal®** (propranolol hydrochloride)

BEFORE USING INDERAL (PROPRANOLOL HYDROCHLORIDE), THE PHYSICIAN SHOULD BE THOROUGHLY FAMILIAR WITH THE BASIC CONCEPT OF ADRENERGIC RECEPTORS (ALPHA AND BETA), AND THE PHARMACOLOGY OF THIS DRUG.

### CONTRAINDICATIONS

1) bronchial asthma; 2) allergic rhinitis during the pollen season; 3) sinus bradycardia and greater than first degree block; 4) cardiogenic shock; 5) right ventricular failure secondary to pulmonary hypertension; 6) congestive heart failure (see WARNINGS) unless it is secondary to a tachyarrhythmia treatable with propranolol; 7) in patients on adrenergic-augmenting psychotropic drugs (including MAO inhibitors), and during the two week withdrawal period from such drugs.

### WARNINGS

CARDIAC FAILURE: In congestive heart failure, inhibition with beta-blockade carries the potential hazard of further depressing myocardial contractility and precipitating cardiac failure. In patients already receiving digitalis, propranolol may reduce the positive inotropic action of digitalis and may have an additive depressant effect on AV conduction.

IN PATIENTS WITHOUT A HISTORY OF CARDIAC FAILURE, in rare instances, cardiac failure has developed during propranolol therapy. At the first sign of impending cardiac failure, patients should be fully digitalized and/or given a diuretic, and observed closely: a) if cardiac failure continues, despite adequate digitalization and diuretic therapy, propranolol should be immediately withdrawn; b) if tachyarrhythmia is being controlled, patients should be maintained on combined therapy and closely followed until threat of cardiac failure is over.

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following *abrupt* discontinuation of INDERAL therapy. Therefore, when discontinuance of INDERAL is planned the dosage should be gradually reduced and the patient carefully monitored. In addition, when INDERAL is prescribed for angina pectoris, the patient should be cautioned against interruption or cessation of therapy without the physician's advice. If INDERAL therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute INDERAL therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease, who are given propranolol for other indications.

IN PATIENTS WITH THYROTOXICOSIS, possible deleterious effects from long term use have not been adequately appraised. Give special consideration to propranolol's potential for aggravating congestive heart failure. Propranolol may mask the clinical signs of developing or continuing hyperthyroidism or complications and give a false impression of improvement. Propranolol should be withdrawn slowly, since abrupt withdrawal may be followed by an exacerbation of symptoms of hyperthyroidism, including thyroid storm. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg propranolol.

IN PATIENTS UNDERGOING MAJOR SURGERY, beta-blockade impairs the ability of the heart to respond to reflex stimuli. Except in pheochromocytoma, propranolol should be withdrawn 48 hours prior to surgery. In case of emergency surgery, the effects of propranolol can be reversed by administration of beta-receptor agonists such as isoproterenol or levarterenol, but such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has been reported.

IN PATIENTS PRONE TO NONALLERGIC BRONCHOSPASM (*e.g.*, CHRONIC BRONCHITIS, EMPHYSEMA), administer with caution, since propranolol may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta-receptors.

DIABETICS AND PATIENTS SUBJECT TO HYPOGLYCEMIA: Propranolol may prevent the appearance of premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia, especially in patients with labile diabetes. A precipitous elevation of blood pressure may accompany hypoglycemic attacks.

USE IN PREGNANCY: Safe use in human pregnancy not established. Embryotoxic effects have been seen in animals at doses about 10 times the maximum recommended human dose.

### PRECAUTIONS

Patients receiving catecholamine depleting drugs such as reserpine should be closely observed if propranolol is administered, since it may occasionally produce hypotension and/or marked bradycardia resulting in vertigo, syncopal attacks, or orthostatic hypotension.

Observe laboratory parameters at regular intervals. Use with caution in patients with impaired renal or hepatic function.

### ADVERSE REACTIONS

*Cardiovascular:* bradycardia; congestive heart failure; intensification of AV block; hypotension; paresthesia of hands; arterial insufficiency, usually of the Raynaud type; thrombocytopenic purpura. *Central Nervous System:* lightheadedness; mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics. *Gastrointestinal:* nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation, mesenteric arterial thrombosis, ischemic colitis. *Allergic:* pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress. *Respiratory:* bronchospasm. *Hematologic:* agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura. *Miscellaneous:* reversible alopecia. Oculomucocutaneous reactions involving the skin, serous membranes and conjunctivae reported for a beta-blocker (practolol) have not been conclusively associated with propranolol. *Clinical Laboratory Test Findings:* Elevated blood urea levels in patients with severe heart disease; elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

### HOW SUPPLIED

TABLETS

—Each hexagonal-shaped, orange, scored tablet is embossed with an "I" and imprinted with "INDERAL 10," contains 10 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0421-81) and 1,000 (NDC 0046-0421-91). Also in unit dose package of 100 (NDC 0046-0421-99).

—Each hexagonal-shaped, blue, scored tablet is embossed with an "I" and imprinted with "INDERAL 20," contains 20 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0422-81) and 1,000 (NDC 0046-0422-91). Also in unit dose package of 100 (NDC 0046-0422-99).

—Each hexagonal-shaped, green, scored tablet is embossed with an "I" and imprinted with "INDERAL 40," contains 40 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0424-81) and 1,000 (NDC 0046-0424-91). Also in unit dose package of 100 (NDC 0046-0424-99).

—Each hexagonal-shaped, yellow, scored tablet is embossed with an "I" and imprinted with "INDERAL 80," contains 80 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0428-81) and 1,000 (NDC 0046-0428-91). Also in unit dose package of 100 (NDC 0046-0428-99).

The appearance of these tablets is a trademark of Ayerst Laboratories.

Store at room temperature (approximately 25° C).

INJECTABLE

—Each ml contains 1 mg of propranolol hydrochloride in Water for Injection. The pH is adjusted with citric acid. Supplied as 1 ml ampuls in boxes of 10 (NDC 0046-3265-10).

Store at room temperature (approximately 25° C).

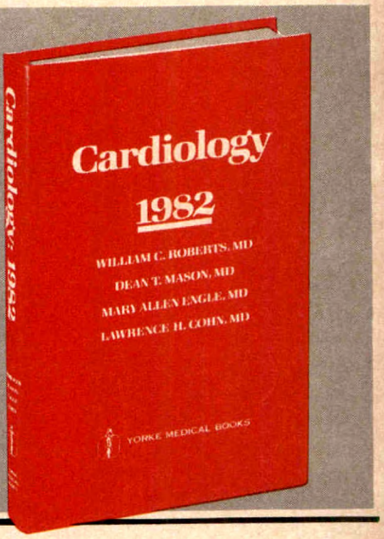
# CARDIOLOGY 1982



## The Second Issue of the New Annual providing a multidisciplinary approach to the latest, most important information on the state-of-the-art of cardiovascular medicine and surgery

*written by:*

- **William C. Roberts, M.D.**
  *Chief, Pathology Branch/National Heart, Lung & Blood Institute/National Institutes of Health/and Clinical Professor of Pathology & Medicine (Cardiology)/Georgetown University School of Medicine, Washington, D.C.*
- **Mary Allen Engle, M.D.**
  *Stavros S. Niarchos Professor of Pediatric Cardiology/Director of Pediatric Cardiology/The New York Hospital-Cornell University Medical College, New York*
- **Dean T. Mason, M.D.**
  *Professor of Medicine and Physiology, and Chief of Cardiovascular Medicine, University of California, Davis School of Medicine and University Medical Center, Davis and Sacramento, California*
- **Lawrence H. Cohn, M.D.**
  *Professor of Surgery/Harvard Medical School/Department of Surgery/Division of Thoracic & Cardiac Surgery/Brigham & Women's Hospital, Boston*

**ISBN 0-914316-27-3 approx. 500 pp., illus., April 1982, $45.00 ISSN 0275-0066**

## What is CARDIOLOGY 1982?

- The second in an annual series to be published in the SPRING each year
- A review of the year's newest and most important developments in cardiology — **665 papers**
- A multidisciplinary approach to clinical and applied research based on an exhaustive search of the year's literature
- A unique, cohesive summary of the state-of-the-art, written, not edited, by those making outstanding developments in the field
- A practical approach to a complicated and fast-moving subject designed to be read and used daily

## CARDIOLOGY:1982 is NOT

- A collection of unrelated reviews
- An abstracting service
- A rehash of materials readily available elsewhere

**CARDIOLOGY: 1982** provides in a concise and readable format and style fundamental and new information essential to understanding the current thinking on managing cardiovascular disease. It coordinates what's new with well-established data, arming the reader with a perspective on the field which is simply unavailable elsewhere. Its liberal use of illustrations and original tables condenses valuable information into instantly understandable knowledge.

### *Reviews of the first edition*

***"...recommend...to any reader interested in the literature of cardiology."***
Irwin R. Callen, M.D.
JAMA, November, 1981

***"It is more than merely a reference book, since it explains what to the average physician may be obscure....a treasure house of 1980 publications. It is highly recommended."***
Philip Reichert, M.D.
New York State Journal of Medicine, September, 1981

***"This is an excellent book, very well organized and written...should be on the shelf of the library, cardiologist, and internist."***

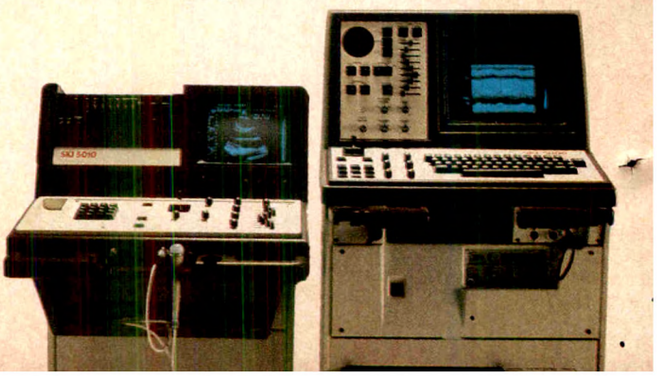
# EkoLine introduces

The SKI 5000 Ultrasound System.

The new super-portable SKI 5010 has the same advanced sector image as the SKI 5000- and less.



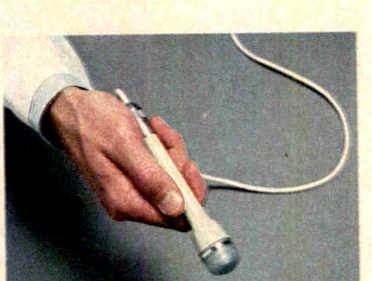
Less size.

Less weight.

Less cost.

Of course, it has a few less features than the SKI 5000. But it still has the same superior M-mode, manual TGC with nine separate slide controls, and a video tape recorder that produces compatible tapes with other recorders like the one in the SKI 5000.

In addition, the SKI 5010 will accommodate all new generation MICROPROBES™ for



# less of the same.

The new SKI 5010 Ultrasound System.

M-mode or sector imaging. For more information about the new SKI 5010 or the SKI 5000, send coupon today. Or call toll-free (800) 538-1556. In California, (408) 732-6010. EkoLine, Inc., 880 West Maude Avenue, Sunnyvale, CA 94086.

*New generation sector MICROPROBE.™*

# FOR ANGINA PROPHYLAXIS*

## ANNOUNCING

## SUSTAINED RELEASE

2.5, 6.5, 9.0 mg CAPSULES

# NITROSTAT® SR

# (nitroglycerin capsules)

■ complementary therapeutic effect: nitrates and beta-adrenergic blocking agents reduce myocardial oxygen demand by different mechanisms

**Mechanism I:** Nitrates reduce myocardial oxygen requirement by acting on systemic circulation. Their vasodilator action decreases venous return and systemic arterial resistance, thus improving the balance between the need and supply of oxygen. Reduction in the myocardial oxygen requirement appears to be the major action of nitrates in relieving typical angina. However, selective dilatation of large coronary vessels by nitrates may be the primary mechanism by which they benefit patients with angina due to coronary spasm.[1]

**Mechanism II:** In contrast, beta-blockers block the beta receptor sites in the heart itself. They work by reducing the heart rate and the force of contraction, thereby lowering oxygen demand. In addition to cardiac output and heart rate, blood pressure is also decreased.

Beta-blockers may reduce the oxygen requirement of the heart at any given level of effort by blocking catecholamine-induced increases in heart rate, systolic blood pressure, and the velocity and extent of myocardial contraction.

■ diminished side effects: some of the negative aspects of the effects of each drug are reduced. For example, concomitant nitrates oppose the increased ventricular size, filling pressure, and end-diastolic pressure caused by beta-adrenergic antagonists.[1]

**The effects of NITROSTAT® SR and a beta-blocker are complementary. The result can be improved therapy for angina prophylaxis.**

■ all day and all night prophylactic action with just two or three daily doses*

How Supplied: 2.5-mg and 6.5-mg strengths, in bottles of 60 and 100 capsules. Also, 9.0-mg strength, in bottles of 60 capsules.

Please see next page for brief summary of prescribing information.

**NITROSTAT® SR...Backed by the experience and reputation of PARKE-DAVIS**

*Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indication as follows: "Possibly" effective: For the management, prophylaxis or treatment of anginal attacks. Final classification of the less-than-effective indication requires further investigation.

**NITROSTAT® SR CAPSULES**
(nitroglycerin capsules)
SUSTAINED RELEASE

Before prescribing, please see full prescribing information. A Brief Summary follows:

**INDICATION:** Based on a review of this drug by the National Academy of Sciences–National Research Council and/or other information, FDA has classified the indication as follows.

"Possibly" effective: For the management, prophylaxis or treatment of anginal attacks.

Final classification of the less-than-effective indication requires further investigation.

**CONTRAINDICATIONS:**
Acute or recent myocardial infarction, severe anemia, closed-angle glaucoma, postural hypotension, increased intracranial pressure and idiosyncrasy to the drug.

**WARNINGS:**
Capsules must be swallowed. FOR ORAL, NOT SUBLINGUAL USE. Nitrostat SR Capsules are not intended for immediate relief of anginal attacks.

**PRECAUTIONS:**
Intraocular pressure may be increased; therefore, caution is required in administering to patients with glaucoma. Tolerance to this drug and cross-tolerance to other organic nitrites and nitrates may occur. If blurring of vision, dryness of mouth or lack of benefit occurs, the drug should be discontinued.

**ADVERSE REACTIONS:**
Severe and persistent headaches, cutaneous flushing, dizziness and weakness. Occasionally, drug rash or exfoliative dermatitis, and nausea and vomiting may occur; these responses may disappear with a decrease in dosage. Adverse effects are enhanced by ingestion of alcohol, which appears to increase absorption from the gastrointestinal tract.

**DOSAGE AND ADMINISTRATION:**
Administer the smallest effective dose 2 or 3 times daily, at 8- to 12-hour intervals, unless clinical response suggests a different regimen. Discontinue if not effective. 0883G010

# The Diagnosis and Treatment Oriented Approach to Rheumatology with the Primary Care Physician in Mind

# Rheumatology

## A Primary Care Approach

Written by:

**Bruce M. Rothschild, MD**

Director, Division of Rheumatology, University Health Sciences, The Chicago Medical School Chief, Section of Rheumatology, V. A. Medical Center North Chicago, Illinois

**ISBN 0-914316-33-8 430 pp., illus., November 1982, $39.50**

## What is Rheumatology: A Primary Care Approach?

- a succinct (approx. 450 pp.) yet comprehensive presentation of the latest techniques in diagnosis and therapeutic interventions of most use to the primary care physician
- a practical "how-to" desk reference to a difficult but common disease affecting over 35 million patients in the U.S. alone
- a book meant to be used regularly, not read once and stored away on a library shelf
- the primary care physicians' answer to the huge, weighty tomes on Rheumatology which offer too little on diagnosis and treatment and too much on etiology and mechanisms of disease

## Rheumatology: A Primary Care Approach is Not

- a research monograph filled with esoteric information of little use to the practicing primary care physician
- a difficult to follow, badly organized reference tool requiring a thorough knowledge of the subject matter before it can be used effectively
- a massive and verbose dissertation more useful as a door stop than a clinical reference

We know of no other book on rheumatic disease which covers the subject as exhaustively in terms of diagnosis and treatment while avoiding wasting the busy practitioner's time by including information of little interest to the primary care physician. This book emphasizes that information necessary to recognize basic disease processes and their natural history. It provides the reader with the information necessary for making a diagnosis and initiating a plan of treatment. Information on differential diagnosis from the point of view of characteristics which would not fit with a given diagnosis is also provided. It is especially strong on the interpretation of rheumatologic radiology and in its approach to joint examination and assessment of lab results. Rheumatic disease cannot be cured but proper intervention can reduce and sometimes eliminate the attendant disability. This book provides you with the means to diagnose, assess and decide for yourself the necessary intervention.

## From the Preface:

*"More than 15 million individuals in the United States suffer from arthritis, and there are only 3,000 physicians practicing rheumatology. It is evident that the majority of patients receive continuing care from the nonrheumatologist, i.e., the internist, family practitioner, pediatrician and other disciplines in medicine. Therefore, we require concise and authoritative clinical guidelines for the primary care physician. With this as motivation Dr. Bruce Rothschild has skillfully structured a text geared to the particular and immediate needs of the practitioner... This text... is an important contribution to continuing medical education of the clinician. It will be of immediate interest and value to clinicians in a wide variety of specialties and should be of great assistance to the faculties and student bodies of our medical schools. We have long needed this type of approach to primary care of patients with musculoskeletal diseases and we are indebted to the author for his accomplishments."*

**Alfred Soffer, MD**
Chief Editor Archives of Internal Medicine

## Table of contents

**Section 1 - Investigative Techniques** • Chapter 1 - The Rheumatologic History and Physical Examination • Chapter 2 - Arthrocentesis and Joint Fluid Evaluation • Chapter 3 - Laboratory Studies • Chapter 4 - Radiology of Joint Disease • **Section 2 - Patterns of Disease** • Chapter 5 - Infectious Agent Arthritis • Chapter 6 - Arthritis of Mechanical Derivation • Chapter 7 - Crystalline Arthritis • Chapter 8 - Rheumatoid Arthritis • Chapter 9 - Juvenile Rheumatoid Arthritis • Chapter 10 - Ankylosing Spondylitis • Chapter 11 - Reiter's Syndrome and Psoriatic Arthritis • Chapter 12 - Arthritis Associated with Gastrointestinal Disease • Chapter 13 - Endocrine, Metabolic, and Deposition Disease • Chapter 14 - Arthritis Associated with Hematologic Disease • Chapter 15 - Miscellaneous Causes of Arthritis • Chapter 16 - Nonarticular Rheumatism • Chapter 17 - Systemic Lupus Erythematosus, Polymyositis, and Sjogren's Syndrome • Chapter 18 - Scleroderma • Chapter 19 - Vasculitis/ Vasculopathy • **Section 3 - Management** • Chapter 20 - Approach to Diagnosis • Chapter 21 - Compliance and Quackery • Chapter 22 - Salicylate Pharmacodynamics • Chapter 23 -Medication Therapy • Chapter 24 - Rehabilitation Therapy • Chapter 25 - Surgical Intervention

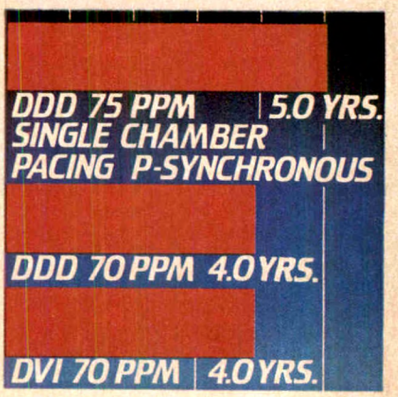
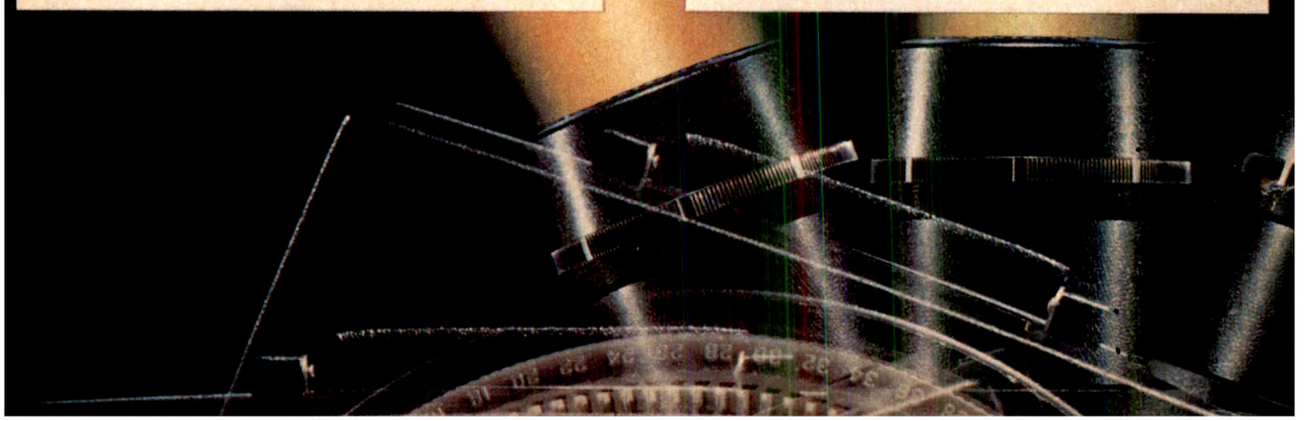
# TELECTRONICS AUTIMA

### *retrograde control prevents pacemaker induced tachycardias*

AUTIMA's Post-Ventricular Atrial Refractory Period (PVARP) prevents possible pacemaker inducement of tachycardias when a patient's retrograde conduction is less than the Atrial Refractory Period of the pacemaker.



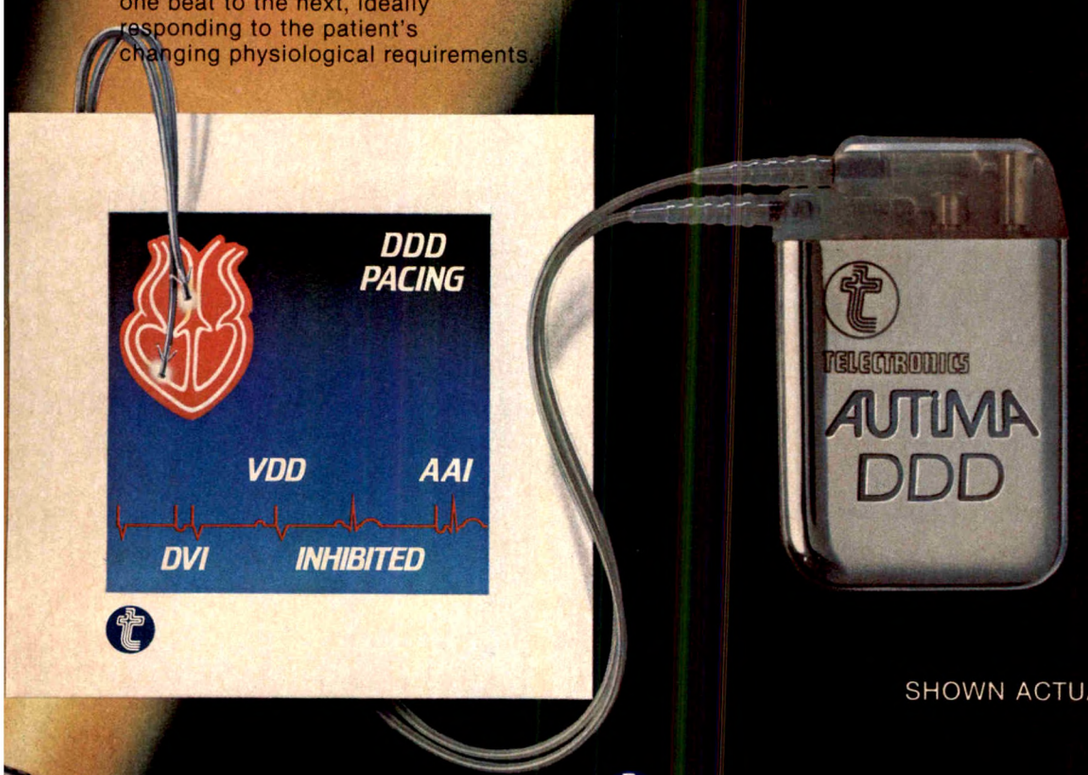
AUTIMA's Post-Ventricular Atrial Refractory Period (PVARP) provides your patient with this protection, nothing else counts in the control of retrogrades.



### *superior longevity from the thinnest "DDD" pacer*

AUTIMA utilizes a large battery capacity in a unique design to provide superior longevity in a compact "DDD" pacemaker.

AUTIMA is backed by a 4-year product lifetime warranty to protect you and your patient from required elective pacemaker replacement.



# DDD PACING SYSTEM: evaluates, diagnoses, and treats automatically

AUTIMA "DDD" pacemaker automatically evaluates, diagnoses, and treats your patients with the best pacing modality on a beat-to-beat basis.

The AUTIMA "DDD" pacemaker adjusts automatically in the DDD mode to AAI, VDD, or DVI, from one beat to the next, ideally responding to the patient's changing physiological requirements.

*IN CLINICAL TRIALS

## AUTIMA® , Model 2251
## Dual Chamber Pacemaker

**INDICATIONS**
**Indications include:**

1. Maintenance of critical atrial contribution to cardiac output in patients with ranging degrees of A-V block;
2. Generating an increased rate and atrioventricular (A-V) synchrony in cases of heart failure related to bradycardia;
3. Overdriving certain tachyarrhythmias by suppressing ectopic foci in both atrium and ventricle by improvement of cardiac output through A-V synchrony, by entering and blocking reentrant circus loops, and by maintenance of a fixed P-R interval.

**Such indications may include:**

- Symptomatic bradycardia
- Sinus bradycardia with A-V block
- Sick Sinus Syndrome
- Certain drug-resistant reentrant tachycardia
- Atrial and ventricular ectopic arrhythmias

**CONTRAINDICATIONS AND SIDE EFFECTS**
Patients suffering from either atrial fibrillation or atrial flutter, even when well controlled or intermittent, may be detrimentally affected by an atrial sensing mode. A dual chamber pacemaker may also be inappropriate for certain patients with retrograde conduction, as it can lead to a form of tachycardia that is related to the pacing system.

Muscle or nerve stimulation, body rejection phenomena, local tissue reaction, skin necrosis, or embolism and cardiac tamponade may occur as with any implantable pulse generator.

**PRECAUTIONS**
See physicians manual for the effects of electrical / magnetic interference, defibrillation, diathermy, random component failure, and battery depletion.

**For further information,** contact your Telectronics representative or call us toll free at (800) 525-7042. In Colorado call (303) 779-4670.

# NOSOCOMIAL INFECTIONS

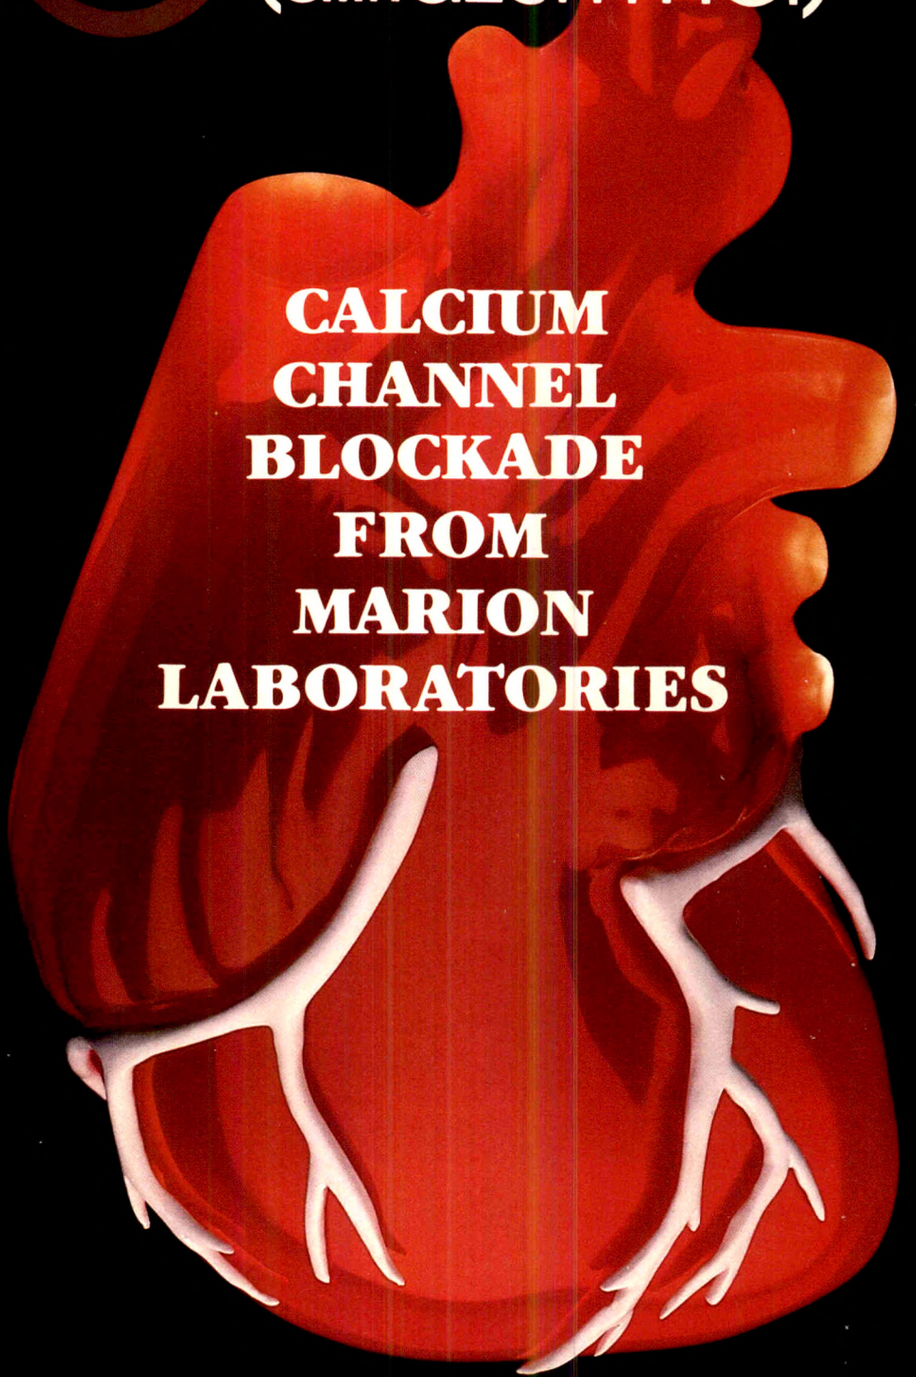
**edited by**
**Richard E. Dixon, M.D.**

**appx. 344p June 1981,**
**$29.50 hardbound**
**ISBN 0-914316-24-9**
**$19.50 softbound**
**ISBN 0-914316-29-X**

Based on the proceedings of the 2nd International Conference on Nosocomial Infections held August 5 - 8, 1980 in Atlanta, Georgia and sponsored by the Center for Disease Control, this book provides between two covers the most comprehensive, in-depth study of this international problem published in 10 years. This major reference is divided into 11 sections consisting of 50 chapters written by over 100 internationally known experts.

**The book includes:**

- An update of disease trends since the 1st International Conference held a decade earlier
- New information on the efficacy of specific approaches to infection control
- Discussions on how to implement effective infection surveillance and control programs
- Coverage of the increasing importance of antimicrobial resistance of nosocomial pathogens
- Information on the potential usefulness of antimicrobial prophylaxis in selected patient groups



***and many other topics.***

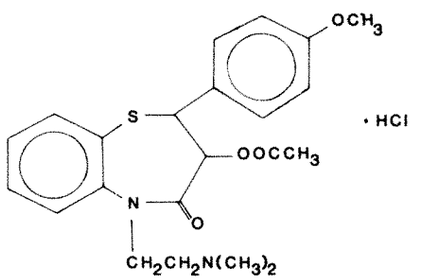
# Announcing NEW

# cardizem™ (diltiazem HCl)

## CALCIUM CHANNEL BLOCKADE FROM MARION LABORATORIES

Please see full prescribing information on next page.



# PROFESSIONAL USE INFORMATION

## cardizem™ (diltiazem HCl)

**30 mg and 60 mg tablets**

## ESCRIPTION

CARDIZEM™ (diltiazem hydrochloride) is a calcium ion influx inhibitor (slow channel blocker or calcium antagnist). Chemically, diltiazem hydrochloride is 1,5-Benzothiazepin-4(5H)one,3-(acetyloxy)-5-[2-(dimethylmino)ethyl]-2,3-dihydro-2-(4-methoxyphenyl)-.monohydrochloride,(+) -cis-. The chemical structure is:

Diltiazem hydrochloride is a white to off-white crystalline powder with a bitter taste. It is soluble in water, ethanol, and chloroform. It has a molecular weight of 450.98. Each tablet of CARDIZEM contains either 30 mg or mg diltiazem for oral administration.

## LINICAL PHARMACOLOGY

The therapeutic benefits achieved with CARDIZEM are believed to be related to its ability to inhibit the influx of lcium ions during membrane depolarization of cardiac and vascular smooth muscle.

**Mechanism of Action.** Although precise mechanisms of its antianginal actions are still being delineated, RDIZEM is believed to act in the following ways:

1. Angina Due to Coronary Artery Spasm: CARDIZEM has been shown to be a potent dilator of coronary arteries both epicardial and subendocardial. Spontaneous and ergonovine-induced coronary artery spasm are inhibited by CARDIZEM.
2. Exertional Angina: CARDIZEM has been shown to produce increases in exercise tolerance probably due to its ability to reduce myocardial oxygen demand. This is accomplished via reductions in heart rate and systemic blood pressure at submaximal and maximal exercise work loads.

In animal models, diltiazem interferes with the slow inward (depolarizing) current in excitable tissue. It causes citation-contraction uncoupling in various myocardial tissues without changes in the configuration of the action tential. Diltiazem produces relaxation of coronary vascular smooth muscle and dilation of both large and small ronary arteries at drug levels which cause little or no negative inotropic effect. The resultant increases in ronary blood flow (epicardial and subendocardial) occur in ischemic and nonischemic models and are companied by dose-dependent decreases in systemic blood pressure and decreases in peripheral resistance.

**Hemodynamic and Electrophysiologic Effects.** Like other calcium antagonists, diltiazem decreases sinoatrial d atrioventricular conduction in isolated tissues and has a negative inotropic effect in isolated preparations. In intact animal, prolongation of the AH interval can be seen at higher doses.

In man, diltiazem prevents spontaneous and ergonovine-provoked coronary artery spasm. It causes a decrease peripheral vascular resistance and a modest fall in blood pressure and, in exercise tolerance studies in patients h ischemic heart disease, reduces the heart rate/blood pressure product for any given work load. Studies to e, primarily in patients with good ventricular function, have not revealed evidence of a negative inotropic effect; diac output, ejection fraction, and left ventricular end diastolic pressure have not been affected. There are as yet data on the interaction of diltiazem and beta-blockers. Resting heart rate is usually unchanged or slightly luced by diltiazem.

Intravenous diltiazem in doses of 20 mg prolongs AH conduction time and AV node functional and effective fractory periods approximately 20%. In a study involving single oral doses of 300 mg of CARDIZEM in six normal unteers, the average maximum PR prolongation was 14% with no instances of greater than first-degree AV ck. Diltiazem-associated prolongation of the AH interval is not more pronounced in patients with first-degree rt block. In patients with sick sinus syndrome, diltiazem significantly prolongs sinus cycle length (up to 50% in ne cases).

Chronic oral administration of CARDIZEM in doses of up to 240 mg/day has resulted in small increases in PR erval, but has not usually produced abnormal prolongation. There were, however, three instances of second-gree AV block and one instance of third-degree AV block in a group of 959 chronically treated patients.

**Pharmacokinetics and Metabolism.** Diltiazem is absorbed from the tablet formulation to about 80% of a ference capsule and is subject to an extensive first-pass effect, giving an absolute bioavailability (compared to avenous dosing) of about 40%. CARDIZEM undergoes extensive hepatic metabolism in which 2% to 4% of the hanged drug appears in the urine. In vitro binding studies show CARDIZEM is 70% to 80% bound to plasma teins. Competitive ligand binding studies have also shown CARDIZEM binding is not altered by therapeutic ncentrations of digoxin, hydrochlorothiazide, phenylbutazone, propranolol, salicylic acid, or warfarin. Single f doses of 30 to 120 mg of CARDIZEM result in detectable plasma levels within 30 to 60 minutes and peak sma levels 2 to 3 hours after drug administration. The plasma elimination half-life following single or multiple g administration is approximately 3.5 hours. Desacetyl diltiazem is also present in the plasma at levels of 10% 0% of the parent drug and is 25% to 50% as potent as a coronary vasodilator as diltiazem. Therapeutic blood els of CARDIZEM appear to be in the range of 50 to 200 ng/ml. There is a departure from dose-linearity when gle doses above 60 mg are given; a 120-mg dose gave blood levels three times that of the 60-mg dose. There is information about the effect of renal or hepatic impairment on excretion or metabolism of diltiazem.

## DICATIONS AND USAGE

**Angina Pectoris Due to Coronary Artery Spasm.** CARDIZEM is indicated in the treatment of angina pectoris due to coronary artery spasm. CARDIZEM has been shown effective in the treatment of spontaneous coronary artery spasm presenting as Prinzmetal's variant angina (resting angina with ST-segment elevation occurring during attacks).

**Chronic Stable Angina (Classic Effort-Associated Angina).** CARDIZEM is indicated in the management of chronic stable angina in patients who cannot tolerate therapy with beta-blockers and/or nitrates or who remain symptomatic despite adequate doses of these agents. CARDIZEM has been effective in short-term controlled trials in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness is incomplete.

here are no controlled studies of the effectiveness of the concomitant use of diltiazem and beta-blockers or of safety of this combination in patients with impaired ventricular function or conduction abnormalities.

## NTRAINDICATIONS

ARDIZEM is contraindicated in 1) patients with sick sinus syndrome except in the presence of a functioning tricular pacemaker, 2) patients with second- or third-degree AV block, and 3) patients with hypotension (less 90 mm Hg systolic).

## RNINGS

**Cardiac Conduction.** CARDIZEM prolongs AV node refractory periods without significantly prolonging sinus node recovery time, except in patients with sick sinus syndrome. This effect may rarely result in abnormally slow heart rates (particularly in patients with sick sinus syndrome) or second- or third-degree AV block (4 of 959 patients for 0.42%). Concomitant use of diltiazem with beta-blockers or digitalis may result in additive effects on cardiac conduction. A patient with Prinzmetal's angina developed periods of asystole (2 to 5 seconds) after a single dose of 60 mg diltiazem.

**Congestive Heart Failure.** Although diltiazem has a negative inotropic effect in isolated animal tissue preparations, hemodynamic studies in humans with normal ventricular function have not shown a reduction in cardiac index nor consistent negative effects on contractility (dp/dt). Experience with the use of CARDIZEM alone or in combination with beta-blockers in patients with impaired ventricular function is very limited. Caution should be exercised when using the drug in such patients.

**Hypotension.** Decreases in blood pressure associated with CARDIZEM therapy may occasionally result in symptomatic hypotension.

**Acute Hepatic Injury.** There has been a single report in a patient receiving 120 mg of diltiazem t.i.d. of marked transaminase elevation (SGOT 4500, SGPT 2300) accompanied by hyperbilirubinemia (to 3 mg%), occurring after four days of treatment. The enzyme abnormalities resolved entirely and enzymes were nearly of viral hepatitis and received no other drugs but isosorbide dinitrate.

No other similar liver injury has been reported in clinical trials, but marketing experience in Europe ha resulted in a rechallenge confirmed instance of hepatocellular injury. However, it should be noted that ther have been further episodes of raised transaminases in the absence of diltiazem in this patient, so that th relationship to diltiazem of the abnormalities is not completely clear. Other instances of transaminas elevation have been reported in Europe, but their relationship to drug is uncertain.

## PRECAUTIONS

**General.** CARDIZEM is extensively metabolized by the liver and excreted by the kidneys and in bile. As with an new drug given over prolonged periods, laboratory parameters should be monitored at regular intervals. The dru should be used with caution in patients with impaired renal or hepatic function. In subacute and chronic dog an rat studies designed to produce toxicity, high doses of diltiazem were associated with hepatic damage. In speci subacute hepatic studies, oral doses of 125 mg/kg and higher in rats were associated with histological changes i the liver which were reversible when the drug was discontinued. In dogs, doses of 20 mg/kg were also associate with hepatic changes; however, these changes were reversible with continued dosing.

**Drug Interaction.** Pharmacologic studies indicate that there may be additive effects in prolonging AV conductio when using beta-blockers or digitalis concomitantly with CARDIZEM. (See WARNINGS)

Uncontrolled domestic studies suggest that concomitant use of CARDIZEM and beta-blockers or digitalis i usually well tolerated. Available data are not sufficient, however, to predict the effects of concomitant treatment particularly in patients with left ventricular dysfunction or cardiac conduction abnormalities; the effect of diltiazem on serum digoxin levels has not been examined. The safety of the combination of CARDIZEM and beta-blockers o digitalis is currently being investigated in well-controlled studies.

**Carcinogenesis, Mutagenesis, Impairment of Fertility.** A 24-month study in rats and a 21-month study in mice showed no evidence of carcinogenicity. There was also no mutagenic response in in vitro bacterial tests. No intrinsic effect on fertility was observed in rats.

**Pregnancy.** Category C. Reproduction studies have been conducted in mice, rats, and rabbits. Administration of doses ranging from 5 to 10 times greater (on a mg/kg basis) than the daily recommended therapeutic dose has resulted in embryo and fetal lethality. These doses, in some studies, have been reported to cause skeletal abnormalities. In the perinatal/postnatal studies, there was some reduction in early individual pup weights and survival rates. There was an increased incidence of stillbirths at doses of 20 times the human dose or greater.

There are no well-controlled studies in pregnant women; therefore, use CARDIZEM in pregnant women only if the potential benefit justifies the potential risk to the fetus.

**Nursing Mothers.** It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, exercise caution when CARDIZEM is administered to a nursing woman if the drug's benefits are thought to outweigh its potential risks in this situation.

**Pediatric Use.** Safety and effectiveness in children have not been established.

## ADVERSE REACTIONS

Serious adverse reactions have been rare in studies carried out to date, but it should be recognized that patients with impaired ventricular function and cardiac conduction abnormalities have usually been excluded. Experience with an added beta-blocker is also extremely limited.

In domestic placebo-controlled trials, the incidence of adverse reactions reported during CARDIZEM therapy was not greater than that reported during placebo therapy.

In addition, the following have been reported infrequently and represent occurrences which can be at least reasonably associated with the pharmacology of calcium influx inhibition. In many cases, the relationship to CARDIZEM has not been established. The most common occurrences, as well as their frequency of presentation, are nausea (2.7%), swelling/edema (2.4%), arrhythmia (2.0%), headache (2.0%), rash (1.8%), and fatigue (1.1%). In addition, the following events were reported infrequently (<1.0%). The order of presentation corresponds to the relative frequency of occurrence.

| | |
|---|---|
| Cardiovascular: | Flushing, congestive heart failure, bradycardia, hypotension, syncope, pounding heart |
| Central Nervous System: | Drowsiness, dizziness, lightheadedness, nervousness, depression, weakness, insomnia, confusion, hallucinations |
| Gastrointestinal: | Vomiting, diarrhea, gastric upset, constipation, indigestion, pyrosis |
| Dermatologic: | Pruritus, petechiae, urticaria |
| Other: | Photosensitivity, nocturia, thirst, paresthesia, polyuria, osteoarticular pain |

The following additional experiences have been noted:

A patient with Prinzmetal's angina experiencing episodes of vasospastic angina developed periods of transient asymptomatic asystole approximately five hours after receiving a single 60-mg dose of CARDIZEM.

Experience in 959 patients taking oral doses of CARDIZEM resulted in three cases (0.31%) of second-degree AV block and one case (0.10%) of third-degree AV block at doses of 240 to 360 mg daily.

In rare instances, mild to moderate transient elevations of alkaline phosphatase, SGOT, SGPT, LDH, and CPK have been noted during CARDIZEM therapy. A single incident of markedly elevated liver enzymes associated with symptoms was reported in a patient taking 360 mg per day for four days. Drug was discontinued and enzymes normalized within 1 week.

## OVERDOSAGE OR EXAGGERATED RESPONSE

Overdosage experiences with oral diltiazem have not been reported. Single oral doses of 300 mg of CARDIZEM have been well tolerated by healthy volunteers. In the event of overdosage or exaggerated response, appropriate supportive measures should be employed in addition to gastric lavage. The following measures may be considered:

| | |
|---|---|
| Bradycardia | Administer atropine (0.60 to 1.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously. |
| High-Degree AV Block | Treat as for bradycardia above. Fixed high-degree AV block should be treated with cardiac pacing. |
| Cardiac Failure | Administer inotropic agents (isoproterenol, dopamine or dobutamine) and diuretics. |
| Hypotension | Vasopressors (eg, dopamine or levarterenol bitartrate). |

Actual treatment and dosage should depend on the severity of the clinical situation and the judgment and experience of the treating physician.

The oral $LD_{50}$'s in mice and rats range from 415 to 740 mg/kg and from 560 to 810 mg/kg, respectively. The intravenous $LD_{50}$'s in these species were 60 and 38 mg/kg, respectively. The oral $LD_{50}$ in dogs is considered to be in excess of 50 mg/kg while lethality was seen in monkeys at 360 mg/kg. The toxic dose in man is not known, but blood levels in excess of 800 ng/ml have not been associated with toxicity.

## DOSAGE AND ADMINISTRATION

**Exertional Angina Pectoris Due to Atherosclerotic Coronary Artery Disease or Angina Pectoris at Rest Due to Coronary Artery Spasm.** Dosage must be adjusted to each patient's needs. Starting with 30 mg four times daily, before meals and at bedtime, dosage should be increased gradually to 240 mg (given in divided doses three or four times daily) at one- to two-day intervals until optimum response is obtained. The effectiveness and safety of dosages exceeding 240 mg per day are currently being investigated. There are no available data concerning dosage requirements in patients with impaired renal or hepatic function. If the drug must be used in such patients, titration should be carried out with particular caution.

**Concomitant Use With Other Antianginal Agents.**

1. **Sublingual NTG** may be taken as required to abort acute anginal attacks during CARDIZEM therapy.
2. **Prophylactic Nitrate Therapy** — CARDIZEM may be safely co-administered with short- and long-acting nitrates, but there have been no controlled studies to evaluate the antianginal effectiveness of this combination.
3. **Beta-blockers** (See WARNINGS and PRECAUTIONS).

## HOW SUPPLIED

CARDIZEM 30-mg tablets are supplied in bottles of 100 (NDC 0088-1771-47). Each green tablet is engraved with MARION on one side and 1771 engraved on the other. CARDIZEM 60-mg scored tablets are supplied in bottles of 100 (NDC 0088-1772-47). Each yellow tablet is engraved with MARION on one side and 1772 on the other.

Issued 11/82

# Comparison of the Antithrombotic Action of Calcium Antagonist Drugs With Dipyridamole in Dogs

CHARLES W. PUMPHREY, DM, MRCP, VALENTIN FUSTER, MD,
MRINAL K. DEWANJEE, PhD, JAMES H. CHESEBRO, MD,
RONALD E. VLIETSTRA, MB, ChB, and MICHAEL P. KAYE, MD,
*With the technical assistance of* JOHN RITTER and JAMES ROSEMARK

**Because platelet activation is associated with fluxes of intracellular calcium, calcium antagonist drugs such as verapamil and nifedipine may have useful platelet inhibitor effects. Accordingly, the effect of these drugs was compared with that of dipyridamole, an established platelet inhibitor, in preventing the deposition of indium-111–labeled autologous platelets and thrombus development in polytetrafluoroethylene (Gore-Tex®) grafts interposed in both femoral arteries in mongrel dogs. Eight dogs received verapamil 7.5 μg/kg/min perioperatively, 8 dogs received nifedipine 4 μg/kg/h perioperatively, 8 dogs received dipyridamole 50 mg orally given twice during the 24 hours before operation, and 16 control dogs received isotonic saline solution perioperatively. After 3 hours of perfusion, the median weight of the grafts and luminal thrombus was less in dogs treated with dipyridamole (465.1 mg), verapamil (453.7 mg), or nifedipine (389.7 mg) than in control dogs (680.2 mg) ($p < 0.001$). In addition, the estimated total platelet deposition along the graft was reduced in dogs treated with dipyridamole (2,073.2 $\times 10^6$) ($p < 0.01$), verapamil (1,898.9 $\times 10^6$) ($p < 0.001$), and nifedipine (1,474.8 $\times 10^6$) ($p < 0.001$) as compared with controls (3,056.2 $\times 10^6$). When the mural thrombus was removed from 14 grafts, a median 73% of the platelets were located in the interface between thrombus and graft. We conclude that all 3 drugs prevent thrombus formation by inhibiting platelet activity in this model, and that the calcium antagonist drugs are as effective as dipyridamole.**

Thrombosis in the high-pressure arterial system is the result of a complex interaction between the vessel wall and blood components. Initially, a primary layer of platelets adhere to the vessel surface; subsequently, platelet-platelet aggregation ensues.[1,2] These platelet aggregates then interact with the coagulation system to form the characteristic red cell-fibrin body of an arterial thrombus.

Three independent biochemical pathways are responsible for the process of platelet activation, namely, cellular release of adenosine diphosphate,[3] the prostaglandin cyclic endoperoxides and thromboxane $A_2$,[4,5] and the platelet aggregating factor pathway.[6,7] The relative importance of these different pathways in arterial thrombosis remains to be established.[8,9] All 3 result in a decrease in cyclic adenosine 5[1]-monophosphate, an increase in cytoplasmic calcium, and a subsequent shape change and release.[10,11] Reduction of this flux of calcium into the cytoplasm might limit or abolish the platelet response, irrespective of the nature of the primary stimulus for activation. Thus, the calcium antagonist drugs nifedipine and verapamil may have a potential role as clinically useful platelet-inhibitor drugs.

In vivo platelet thrombus can now be identified by labeling autologous platelets with indium-111.[12] Therefore, we have developed a model of thrombosis in dogs, using femoral artery grafts, in which we compared the platelet-inhibitor effect of verapamil and nifedipine with that of the established platelet-inhibitor dipyridamole.[13,14]

## Methods

**The dog model:** Platelet deposition and thrombotic occlusion were studied in bilateral femoral artery grafts in mongrel dogs (weight 20 to 25 kg). After induction of anesthesia with pentobarbital (30 mg/kg), the femoral arteries were

exposed on each side and cross-clamped after a bolus of heparin (100 U/kg Upjohn Beef Lung, Upjohn) had been given intravenously. A 4-cm segment of each femoral artery was then replaced with 5 cm of expanded polytetrafluoroethylene (Gore-Tex, W. L. Gore and Associates), 4 mm in diameter, and running 7-0 Prolene sutures were used at the anastomoses. The longer length of graft used to replace the segment of artery reduced the tension on the anastomotic sites resulting from the intrinsic elasticity of the arteries. By interposing polytetrafluoroethylene grafts bilaterally, any thrombus formation that might have resulted from unilateral errors in surgical technique rather than differences in antithrombotic therapy could be recognized.

Three hours after blood flow was resumed through the grafts, the dogs were killed with an overdose of pentobarbital and the grafts were removed. By this time no effect of circulating heparin on the partial thromboplastin time was demonstrable.

**Treatment groups:** Forty animals were studied; 8 received intravenous verapamil (7.5 μg/kg/min), 8 received intravenous nifedipine (4 μg/kg/min), 8 received oral dipyridamole (100 mg in the 24 hours before the study), and 16 served as controls.

The dosage regimens were selected on the basis of published reports.[15–17] Both verapamil and nifedipine were given in isotonic saline solution immediately after induction of anesthesia before operation was begun, and the infusion was continued until the grafts were removed. Verapamil plasma levels were determined by a modification of the high pressure liquid chromatographic method of Harapat et al.[18] The median verapamil concentration was 174.5 ± 33.4 ng/ml (mean ± standard deviation) at 3 hours; this regimen caused a 7.8 ± 3.2% increase in femoral artery blood flow measured by a 2 channel electromagnetic flow meter (Carolina Medical Electronics), a 14.2 ± 2.7% increase in heart rate, and no alteration in mean aortic pressure. No plasma nifedipine levels were measured, but the dosage regimens used caused a 7.6 ± 4.5% increase in femoral artery blood flow, a 17.3 ± 6.7% increase in heart rate, and a 5.6 ± 1.8% decrease in mean aortic pressure. Because of the photosensitivity of nifedipine in solution, a light-free system of administration was used.

Dipyridamole was given orally in 2 doses during the 24 hours before the study. The second dose, given 1 to 2 hours before operation, resulted in a median plasma dipyridamole concentration of 370 ng/ml (range 235 to 550) at 3 hours. No hemodynamic measurements were made and, as with the control dogs, isotonic saline solution (100 ml/h) was given intravenously during the study to these dogs. This volume of saline solution was similar to that given to the dogs treated with verapamil and nifedipine.

**Indium-111 labeling of platelets:** Eighteen to 24 hours before operation, 43 ml of blood was withdrawn from the dog into 7 ml of acid-citrate-dextrose anticoagulant and labeled with indium-111 tropolone according to the method of Dewanjee et al.[19] Two hours later, the platelets, resuspended in plasma, were injected in doses of 300 to 500 μCi.

**Processing of grafts:** After the grafts were removed, they were gently perfused with isotonic saline solution and any blood was cleaned off the exterior surface. The grafts were then sectioned into 5 pieces in order to assess thrombus formation in different parts of the graft. Each anastomotic section consisted of 2 mm of native artery and 2 mm of polytetrafluoroethylene. The middle sections consisted of 3 equal lengths of polytetrafluoroethylene.

The effect of the drugs was assessed in 2 ways:

1. *Thrombus formation:* Formation of thrombus was estimated from the weights of the graft section; because the dry weight of each 5-cm length of polytetrafluoroethylene was found to be almost the same (257 to 264 mg), the increased weight of the graft sections represented thrombus formation. Before the sections were weighed, care was taken to ensure that no saline solution remained in these graft sections.
2. *Platelet deposition:* The radioactive counts arising from platelets deposited on the graft wall were measured in a gamma counter (Beckman Gamma 8000). The gamma-ray spectrometer was adjusted to include the 174, 247, and 421 (sum peak) keV of indium-111 radionuclide. The activities of 3 5-ml samples of blood, taken from each animal at the time the grafts were removed, were also counted. From the platelet count (measured on a sample taken before heparinization), the number of platelets deposited/centimeter length of graft could be estimated.

**Platelet distribution in thrombus:** To assess the relation between weight and platelet count, 14 grafts underwent further analysis. After weighing the graft and thrombus together, the body of each thrombus was removed and weighed separately. From the radioactivity of each graft and that of the thrombus removed from it (corrected for weight), the number of platelets located at the graft-thrombus interface and within the body of the thrombus could be measured.

**Analysis of data:** The results of thrombus weight and platelet deposition from the 2 grafts in each dog were averaged and the average values were analyzed.

For statistical analysis the Mann-Whitney U test for differences between independent samples was used.

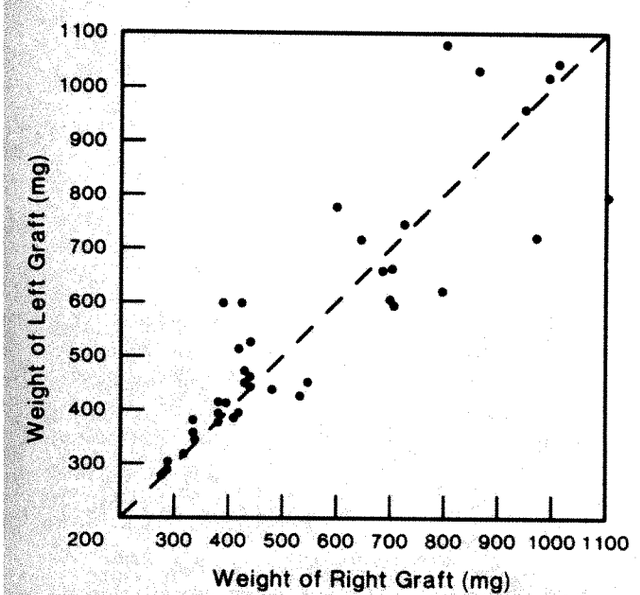

**FIGURE 1.** Comparison of total weights of right and left polytetrafluoroethylene grafts (including thrombus) after 3 hours of perfusion in control (n = 16) and treated (n = 8) dogs for each group.

## Results

The degree of occlusion observed in the grafts varied; there was usually either a white lining layer of platelets streaked with red cells, or partial occlusion of the graft by protruding red thrombus extending along its length. In 6 control dogs and in 2 dogs from each treatment group, however, the grafts were occluded.

**Thrombus weight:** For each dog studied a close correlation existed ($r = 0.88$, $p < 0.001$) between the

* Includes 2 mm of native artery at each anastomosis.

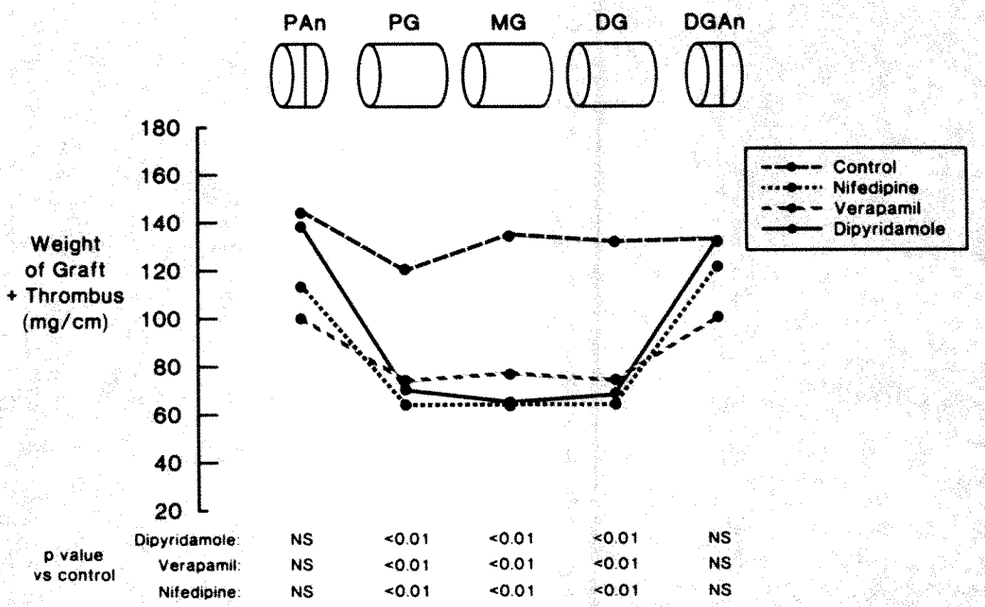

**FIGURE 2.** Distribution of thrombus formation in polytetrafluoroethylene grafts after 3 hours of perfusion (median values, mg/cm) in control (n = 16) and treated (n = 8) dogs for each group. (The weights of the anastomoses have been standardized to 1.0 cm for comparison with the rest of the graft sections.) DG = distal graft section; DGAn = distal anastomosis; MG = middle graft section; PAn = proximal anastomosis; PG = proximal graft section.

weight of the thrombus deposited in each of the 2 grafts (Fig. 1). The median weight of the grafts from the treated dogs was significantly lower than the median weight of those from the control dogs (Table I). No difference in median weights was observed among the various treatment groups.

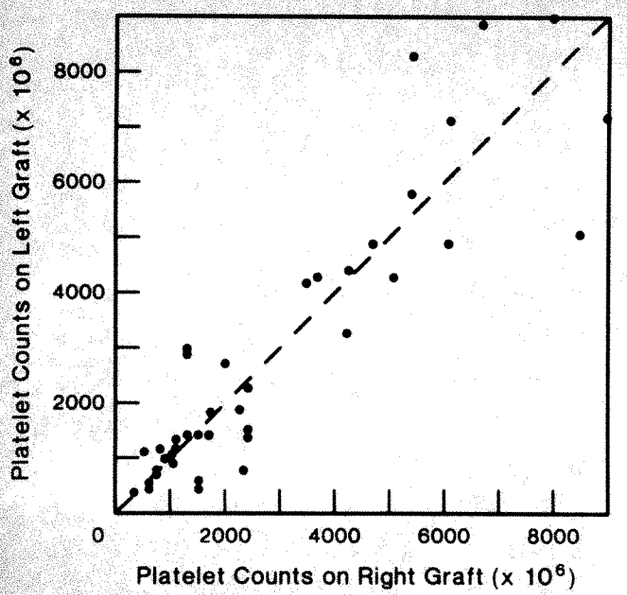
The reduction in weight occurred along all 3 middle sections of the grafts, but not at the anastomoses (Fig. 2).

**Platelet deposition:** For each of the dogs studied, a close correlation existed ($r = 0.89$, $p < 0.001$) between the number of platelets deposited in each of the 2 grafts (Fig. 3). Overall, significantly fewer platelets were deposited in the grafts of the treated dogs than in those of the control group (Table II). In the latter group, platelet accumulation was greatest at the distal anastomosis and diminished proximally; the platelet accumulation at the proximal anastomosis was only half that at the distal anastomosis (Fig. 4). The effect of the drugs was most significant on the 3 middle sections and although all of the drugs had an effect at the distal anastomosis, only verapamil reduced platelet accumulation at the proximal anastomosis.

**Platelet distribution in thrombus:** The median radioactivity of thrombus removed from 14 grafts was 27% (range 5 to 49) of that of the total graft. Thus, most platelets in the thrombosed grafts were located at the graft thrombus interface and few platelets were present in the body of the thrombus. This pattern of distribution of platelets within the thrombus indicated that the notable decrease in platelet deposition observed in the treated dogs was not merely caused by a reduction in the amount of mural thrombus, but also by an actual decrease in platelets deposited along the graft surface.

## Discussion

This in vivo model of thrombosis in a high-pressure, high-flow system has advantages over in vitro tests; that is, there is no unphysiologic separation of the sequence of events which take place during thrombosis, and calcium-chelating anticoagulants are not used. Although



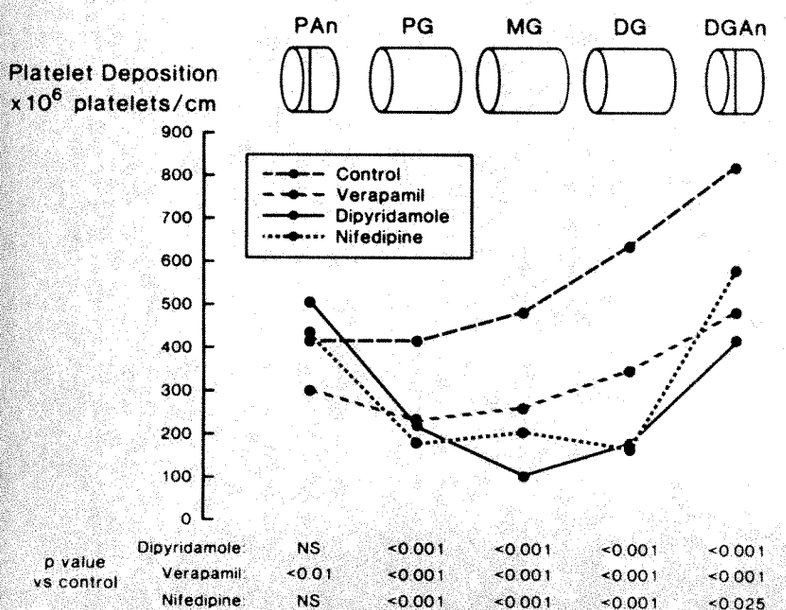


**FIGURE 3.** Comparison of total number of platelets deposited on right and left polytetrafluoroethylene grafts after 3 hours of perfusion in control (n = 16) and treated (n = 8) dogs for each group.

the contribution of circulating prostacyclin in preventing thrombosis is uncertain, the grafts do not have the protection of the prostaglandin and fibrinolytic systems located in the natural vascular endothelium. It therefore remains an artificial system in which the possible counterbalancing effect of drug treatment on these natural antithrombotic mechanisms cannot be totally assessed.

In this model, dipyridamole, verapamil, and nifedipine all had effective antithrombotic actions in the doses administered and this action seemed to be mediated through platelet inhibition. The activity of dog platelets is very variable and 6 control dogs and 2 dogs from each treated group developed occlusions in both grafts; however, no other tests of platelet function were performed which might have shown that these dogs had more active platelets. Frequently, only a lining white layer of platelets streaked with red cells was observed in the grafts of the treated animals. It is possible that a threshold number of platelets has to accumulate on the graft surface to trigger the formation of the red cell fibrin network of which the bulk of mural thrombi are made. The drugs may reduce this platelet accumulation and thereby prevent thrombus formation.

All 3 drugs are known to alter circulatory hemodynamics. Such changes might have contributed to the reduced thrombus formation observed in the treated dogs. However, only a small increase (<8%) in femoral artery blood flow was observed; this is unlikely to be a critical change. Furthermore, no relation was observed between femoral artery blood flow and thrombus formation.

The anastomotic sites of the grafts are important foci for thrombogenesis. Both the presence of sutures and difference in compliance of the artery and the graft result in turbulence which leads to thrombus formation. The effect of the drugs on these sites was less clear. The number of platelets on the anastomoses included those plugging the suture line and those trapped in extravascular thrombus adherent to the sutures; this is difficult to remove completely during the preparation of the graft for analysis, which may account for the lack of demonstrable effect of any of the drugs on thrombus weight at either anastomosis. Furthermore, in the control dogs, platelet deposition at the distal anastomosis was twice that at the proximal anastomosis, suggesting that thrombus formation begins distally. All 3 drugs reduced platelet deposition at the distal anastomosis, but only verapamil was effective at the proxi-

mal anastomosis. This may indicate that verapamil is a more effective platelet inhibitor than either dipyridamole or nifedipine.

**Dipyridamole:** This drug is often prescribed as a platelet inhibitor, particularly in combination with aspirin.[20] It appears that by blocking the platelet phosphodiesterase enzyme,[13,21] dipyridamole potentiates the increase in cyclic adenosine 5′ monophosphate and platelet inhibition caused by the vessel wall prostacyclin. The platelet-inhibition action of this drug was well demonstrated in this dog model and gives a point of reference against which other drugs may be compared.

**Nifedipine and verapamil:** Nifedipine and verapamil have different structural, electrophysiologic, and pharmacologic properties.[22] In this study, their antithrombotic effect was found to be similar and equivalent to that of dipyridamole. The plasma levels of verapamil and dipyridamole were in the range encountered in clinical practice[23,24]; the plasma level of nifedipine was not measured but produced hemodynamic changes similar to those of verapamil. Other investigators have differed about whether verapamil has a significant platelet inhibiting action at therapeutic plasma levels,[25,26] but in contrast to this study, their conclusions were based mainly on in vitro platelet function tests.

The mechanism by which these calcium antagonists inhibit platelets is uncertain. They may prevent internal release of calcium from the tubular system into the cytoplasm; alternately they may reduce calcium flux across the plasma membrane, a process that is known to occur during platelet activation, and which may be the stimulus for the mobilization of intracellular calcium.[27,28] Regardless of their specific action, however, the final effect may be equivalent to that of dipyridamole in that they inhibit the final stages of the biochemical pathways involved in platelet activation.

*In conclusion*, this study has demonstrated that in this model both nifedipine and verapamil have a platelet-inhibitor function equivalent to that of dipyridamole and both can reduce the development of thrombus on prosthetic material. The well-recognized species variability of platelet behavior prevents any direct comparisons between the findings in this study and the likely platelet inhibitory effect of these drugs in humans. Preliminary reports by other investigators,[27,28] however, suggest that human platelets can be inhibited by verapamil. If so, our findings may indicate another useful feature of 2 calcium antagonist drugs already of proven value in the management of cardiovascular disease.

# Influence of Intracoronary Platelet Aggregation on Ventricular Electrical Properties During Partial Coronary Artery Stenosis

PETER R. KOWEY, MD, RICHARD L. VERRIER, PhD, BERNARD LOWN, MD, and ROBERT I. HANDIN, MD

**Several clinical studies suggest that drugs which interfere with platelet function may protect persons at risk for sudden death. However, there is no direct evidence that intracoronary platelet aggregation produces cardiac arrhythmias. Induction of fixed partial coronary stenoses in dogs resulted in spontaneous cyclical reductions in coronary blood flow of 21 to 81% ($p < 0.01$). These changes are known to be associated with the formation and distal embolization of platelet aggregates. These reductions in coronary blood flow were accompanied by significant decreases in the repetitive extrasystole (−40%) and ventricular fibrillation (−38%) thresholds. Prostacyclin ($PGI_2$), a potent vasodilator and inhibitor of platelet activation, in increasing doses of from 25 to 100 ng/kg/min caused a stepwise decrease in the frequency and magnitude of coronary blood flow fluctuations and restored the vulnerable period thresholds to control levels. Indomethacin (5 mg/kg), an inhibitor of cyclo-oxygenase activation and platelet thromboxane $A_2$ production, produced similar results. The mechanism of coronary blood flow reduction appears to be mechanical blockade of the vessel lumen by platelet thrombi and production of myocardial ischemia. These results suggest that intracoronary platelet aggregation contributes to electrical destabilization of the myocardium and may predispose to ventricular fibrillation. A model is thus available for further investigating the role of platelets and antiplatelet drugs in modulating ventricular electrical stability.**

The problem of sudden cardiac death compels increasing attention because of the inordinate magnitude of fatality as well as the growing realization that the problem is reversible as well as preventable.[1] Although death is caused by ventricular fibrillation, the precipitating mechanisms of the lethal arrhythmia remain undefined. Since in most sudden death victims acute cardiac morphologic lesions are lacking, the possibility of a transient ischemic process needs to be considered. Intravascular platelet aggregates may contribute to the ischemic process. The induction of platelet aggregation in animals with adenosine diphosphate causes both myocardial infarction and lethal arrhythmias.[2,3] Pathologic studies on patients who have died suddenly have shown platelet microthrombi and platelet aggregates in numbers far greater than in those whose death was not sudden.[4–6] In a recent epidemiologic study involving patients who had recovered from acute myocardial infarction, the antiplatelet drug sulfinpyrazone decreased the occurrence of sudden death.[7]

While platelet aggregation may contribute to the pathophysiology of sudden death, there are no studies defining the effect of platelet aggregation on the electrical stability of the myocardium. A major methodologic advance has been provided by Uchida,[8] Folts,[9] and their co-workers, who developed a model of partial coronary stenosis in which cyclical reductions in coronary blood flow occur. These changes in coronary flow result from intermittent intracoronary platelet aggregation.[10]

The objectives of the present study were (1) to determine whether alterations in coronary flow brought about by intracoronary platelet aggregation result in

significant changes in the vulnerable period threshold, and (2) to define mechanisms involved in the observed effects.

## Methods

**General procedures:** Twenty-six healthy mongrel dogs of either sex, weighing 12 to 22 kg, were used in this study. Anesthesia was induced with intravenous alpha-chloralose, 100 mg/kg (Sigma Chemical, 10% weight/volume). Additional alpha-chloralose, 50 mg/kg, was given to maintain the level of anesthesia during the course of experiments. The animals were ventilated with a mixture of room air and 100% oxygen given through a cuffed endotracheal tube, using a Harvard respirator. The mixture contained approximately 40% oxygen and was adjusted, together with respiratory rate, to maintain arterial oxygen tension of 80 to 100 mm Hg and arterial pH of 7.35 to 7.45. A polyethylene catheter was inserted into a femoral artery to sample arterial blood and monitor systemic blood pressure. Mean pressures were obtained by electrically integrating the pulsatile output of the transducer. A femoral vein was cannulated for drug administration. Defibrillation was accomplished within 5 seconds of initiation of ventricular fibrillation, utilizing a direct current capacitor discharge from a Lown cardioverter. A 10 to 40 W second shock was delivered by means of 2 electrode paddles applied directly to the heart.

A left thoracotomy was performed through the fifth left intercostal space and the heart exposed after pericardiotomy. The left circumflex coronary artery was dissected about 1 cm from its origin and a 1.5 to 2.2 mm electromagnetic flow probe placed around it, proximal to any side branches. Coronary blood flow measurements were performed, using a Gould Statham Blood Flowmeter, model SP2202. Pulsatile and mean coronary artery blood flow were recorded throughout the experiment, together with aortic blood pressure, on a multichannel polygraph recorder.

**Cardiac testing:** Testing stimuli of variable duration were employed, using electrically isolated Grass S44 and S88 square wave pulse generators. A Kepco operational power supply (type OPS-100) provided constant current stimuli (2% accuracy). The current output was directly verified by means of a Tektronix P6021 alternating current probe attached to a Tektronix P6120N oscilloscope. Timing of stimuli was controlled, using a BRS digital timer with a crystal-controlled time base (±0.01% accuracy) and was synchronized from the peak of the QRS complex. The pulse generator was equipped with appropriate circuitry to shut off the pacemaker output for up to 3 seconds after delivery of the test stimuli. Ventricular fibrillation thresholds were determined using the single stimulus method.[11]

**Single stimulus method:** Two bipolar catheters were used. The first (Medtronic 5818 platinum electrodes with an interelectrode distance of 1.5 cm and a pole width of 3 mm) was placed in the right ventricular apex by way of a jugular vein. This catheter served to deliver test stimuli. The second catheter (U.S. Catheter Corporation, semifloating 003992 4F) was bound to the pacing catheter by silk ligatures and terminated 20 mm proximal to the tip of the pacing catheter. This catheter was used to record the intracavitary electrocardiogram. Heart rate was controlled using a variable rate pacemaker that delivered constant current rectangular stimuli with a duration of 2 ms. The current of the pacemaker was set at twice the diastolic threshold. Atrial pacing was carried out, using 2 Grass needle electrodes applied directly to the left atrial appendage. During cardiac testing, the heart rate was maintained at a constant level of 210 beats/min.

The duration of the test stimulus was set at 10 ms and the initial current at 4 mA. Electrical diastole was then scanned in 10 ms intervals beginning at the boundary of the effective refractory period and terminating beyond the T wave. The current was then increased in 2 mA steps and scanning was continued. The lowest stimulus intensity that elicited ventricular fibrillation was taken as the ventricular fibrillation threshold (VFT). The lowest stimulus provoking a single undriven extrasystole was taken as the repetitive extrasystole threshold (RET).

**Technique of partial coronary stenosis:** Partial coronary stenosis was produced using methods described by Folts et al.[9,10] Plastic cylinders 2.5 mm long and of variable internal diameter (1.3 to 1.8 mm) were placed around the left circumflex coronary artery distal to the coronary flow probe. Care was taken to leave no patent coronary branches between the flow probe and occluder. In each case, occluders of progressively smaller diameters were applied to the coronary vessel until no reactive hyperemic response could be elicited after a 20 second total coronary occlusion. When the proper cylinder had been selected, blood flow, heart rate, blood pressure, and intracavitary electrogram were monitored continuously for 1 hour. As soon as cyclical changes in coronary blood flow had been demonstrated to be a consistent phenomenon (3 cycles in a 30 minute period was the minimal requirement), determinations of the threshold current for ventricular fibrillation and repetitive extrasystole were made during control or high flow periods and during maximal observed reductions in coronary blood flow.

**Platelet aggregation studies:** After the partial obstruction was produced, a 5 ml blood sample was collected from the femoral artery catheter and discarded and a second 10 ml sample withdrawn into a plastic syringe containing 1 part of 3.8% sodium citrate for each 9 parts of blood. In all studies, samples for aggregation testing were collected before electrical testing and debrillation. Platelet-rich plasma was obtained by centrifuging this mixture at 800 rpm for 8 minutes at room temperature. After the platelet-rich plasma was withdrawn, platelet poor plasma was prepared by centrifuging the remaining mixture at 2,000 rpm for 15 minutes. Aggregation studies were performed by a modification of the method of Born[12] using a Chrono-Log Platelet Aggregometer model 330 (Chrono-Log Corporation, Broomall, Pennsylvania). Fourtenth ml platelet-rich plasma was placed at 37° in a siliconized cuvette in the aggregometer with a siliconized stirring bar. The aggregometer was adjusted to give 10 and 90% light transmission readings on a strip chart recorder with platelet-rich and platelet-poor plasma, respectively. Doses of 2.9 to 9.6 $\mu M$ adenosine diphosphate were used as the aggregating agent. The minimal concentrations of adenosine diphosphate that resulted in maximal platelet aggregation was then used in all subsequent phases of the experiment.

**Baroreceptor denervation:** Prostacyclin has been shown to cause significant systemic hypotension, which results from peripheral arterial vasodilation. The hypotension in turn causes an increase in reflex sympathetic tone[13] resulting in enhanced vulnerability to ventricular fibrillation. Baroreceptor denervation was therefore performed before the infusion of prostacyclin. The aortic arch was denervated by sectioning the cervical vagi bilaterally. This procedure completely eliminates the afferent fibers from the aortic arch pressor receptors.[14] To denervate the carotid sinus receptors, a dissection was performed bilaterally in the neck, midway between the mandibular angle and thyroid cartilage. The bifurcation of the internal and external carotid artery was located and the carotid sinus identified. By careful dissection, the sinus nerve was exposed and sectioned. To ensure completeness of denervation, the adventitia was stripped from the carotid vessels in the region of the sinuses. Successful denervation of the carotid sinus was always associated with a distinct heart rate

increase of 20 to 60 beats/min and an increase in blood pressure of 30 to 60 mm Hg.

**Balloon catheter placement:** In order to restrict coronary flow to a predetermined level, an occlusive balloon catheter (Brunswick, Quincy, Massachusetts) was used. A thoracotomy was performed through the fifth intercostal space and the catheter placed around the left circumflex coronary artery at the level of the left atrial appendage, distal to the coronary flow probe. The balloon was gradually inflated over 5 to 7 minutes to that point at which coronary blood flow was reduced by 50 to 80% of control values. Balloon inflation was continuously adjusted to keep coronary blood flow constant. When coronary blood flow was stabilized at the reduced value, and within 60 seconds of the occlusion, RET and VFT determinations were made. The balloon was deflated upon onset of ventricular fibrillation and remained deflated while defibrillation was performed.

**Prostaglandin infusion:** One to 5 mg of powdered prostacyclin (supplied in powder form by Upjohn Pharmaceutical) was dissolved in 1 to 5 ml of absolute ethanol to yield a stock solution concentration of 1 mg/ml. The stock solution was then diluted in a carbonate/bicarbonate buffer (0.01*M*/0.02*M*) with a pH of 10.0, and this solution was made isotonic by the addition of sodium chloride. Concentrations of the drug were prepared to allow for infusion volumes of 0.2 to 1.2 ml/min, using a Harvard infusion pump. Solutions were kept cool using a crushed ice bath. Conduit tubing from syringe to animal measured <10 cm to prevent inadvertant warming of the solution during infusion. The prostaglandin was infused into the femoral vein catheter in all experiments.

A solution of indomethacin (supplied in powder form by Merck, Sharp and Dohme) (3.6 mg/ml) was prepared by adding warm (50°C) sodium bicarbonate 300 mg in 30 ml 0.9% sodium chloride to 150 mg of indomethacin dissolved in 10 ml of 90% ethanol. Doses of 5 mg/kg were drawn up into a plastic syringe and infused into the femoral venous catheter over a 10 minute period using a Harvard infusion apparatus.

**Statistics and calculations:** Statistical analysis of the data was performed using the paired Student's *t* test wherein differences were considered significant when $p < 0.05$. All values in text and figures are expressed as mean ± standard error of the mean.

Percent decrease in coronary blood flow was calculated as follows: [(Control flow − reduced flow)/control flow] ×100.

**Experimental groups:** *Prostaglandin treatment:* Eleven animals underwent baroreceptor denervation and had an appropriately sized plastic cylinder affixed. Seven of the animals manifested cyclical changes in coronary blood flow; 4 animals had no demonstrable flow alterations. Control values for mean arterial blood pressure, coronary blood flow, platelet aggregation, RET, and VFT were obtained. Prostacyclin was infused at a constant dose of 25, 50, and 100 ng/kg/min in each animal. Each infusion lasted approximately 20 minutes, during which time coronary blood flow, and electrocardiographic mean arterial blood pressure, and electrocardiographic readings, were continually recorded and values for RET and VFT obtained. At each dose level, the number of cyclical changes in coronary blood flow together with the duration of each were noted. Before the termination of each prostacyclin infusion and before commencing electrical testing, arterial blood was sampled for a platelet aggregation study.

*Indomethacin treatment:* Indomethacin (5 mg/kg) was used in a group of 10 animals, 6 of which had reproducible cyclical blood flow changes. Baseline measurement of blood pressure, coronary blood flow, platelet aggregation, and ventricular vulnerability were made. Indomethacin was administered over a 10-minute period, after which all of the determinations were repeated.

*Balloon catheter coronary occlusion:* In 5 animals, coronary blood flow was interrupted using the externally applied balloon occluder to reduce coronary blood flow by 50 to 80%. Application of a balloon occluder was not accompanied by cyclical flow changes. Cardiac electrical testing was carried out before and after inflation of the balloon. After a recovery time of 30 minutes, indomethacin was administered (5 mg/kg), and the effect on platelet aggregation was determined. Determinations of the RET and VFT were again made before and during reduction in coronary blood flow.

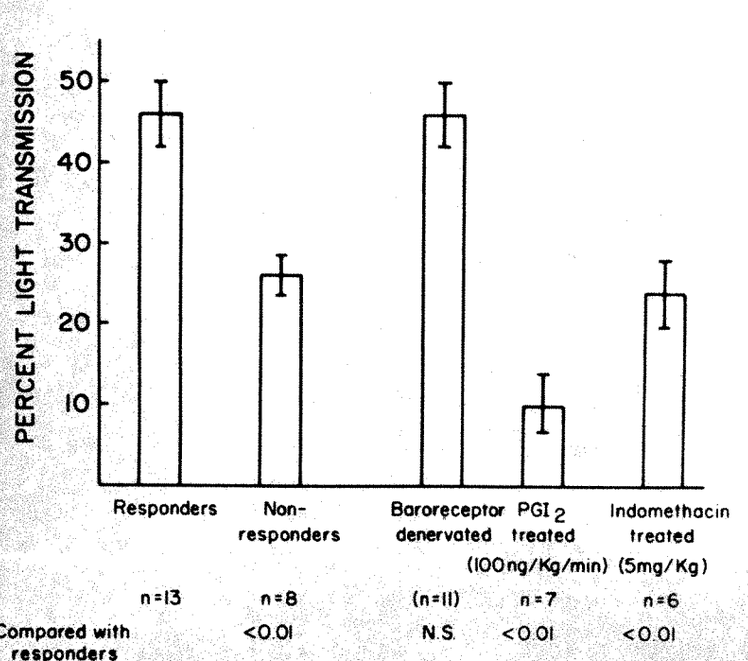

**FIGURE 1.** Adenosine diphosphate-mediated platelet aggregation in control animals before and after baroreceptor denervation, and after treatment with high-dose prostacyclin ($PGI_2$) and indomethacin.

**TABLE I Changes in Coronary Blood Flow (CBF), Repetitive Extrasystole Threshold (RET), Ventricular Fibrillation Threshold (VFT), and S-T Segments in 13 Animals Demonstrating Cyclical CBF Reductions After Application of the Plastic Cylinder**

Measurement of RET and VFT were made at control (C) and reduced (R) coronary blood flow. SEM = standard error of the mean.

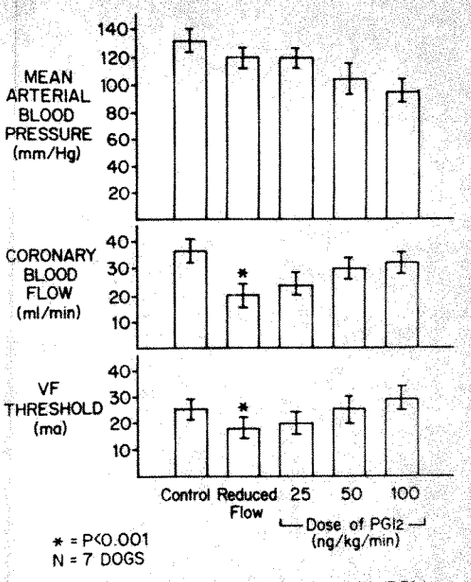

**FIGURE 2.** Influence of varying doses of prostacyclin ($PGI_2$) on coronary artery blood flow and ventricular vulnerability during partial coronary stenosis. VF = ventricular fibrillation.

## Results

**Effect of cyclical flow changes on VFT:** Thirteen of the 21 animals (62%) had cyclical reductions in coronary blood flow after induction of coronary stenosis. The platelet aggregation in response to adenosine diphosphate in these 13 responder animals is displayed in Figure 1. In the remaining 8 dogs, no cyclical flow changes could be elicited, despite the production of sufficient stenosis to abolish the hyperemic response, and no changes in the VFT or in the S-T segments were observed. Platelet aggregation in the 8 nonresponders was significantly less than that of responder animals despite the use of the same dose of adenosine diphosphate (Fig. 1). There was no statistical difference between the 2 groups of animals in baseline coronary blood flow or MABP and these measurements did not correlate with the extent of coronary blood flow reduction. Once cyclical flow changes were established, they continued for the remainder of the experiment or until a drug intervention was performed. The flow reduction cycles averaged 11/hour and the degree of reduction in coronary blood flow ranged from 21 to 80%. Each cyclical flow reduction was followed by an abrupt return of flow to control values which, in the majority of instances, occurred spontaneously. However, approximately 25 to 30% of these cycles were not self-terminating, and the vessel was tapped gently to dislodge thrombi and restore flow.

Determination of the RET and VFT were made at the following points: (1) when coronary blood blow was maximal (control flow), (2) when coronary blood flow was reduced by at least 30 but no more than 60% below control flow, and (3) immediately upon coronary reperfusion.

Nine of the 13 animals that had flow changes also manifested recurrent S-T segment alterations during flow reduction, consisting of S-T elevation or depression of from 1 to 3 mV (Table I). Such evidence of myocardial ischemia was noted during those sequences in which coronary flow fell to <50% of control. Five dogs had S-T segment elevation and 4 had S-T segment depression. There was no difference in extent or frequency of flow reduction in those animals with S-T segment elevation or depression. The S-T segment changes were accentuated with progressive decreases in coronary blood flow. S-T segments were restored to normal within 3 to 5 seconds of flow recovery.

Arterial blood pressure did not decrease during the cyclical coronary flow changes, unless coronary blood flow was reduced below 70% of control values when mean arterial blood pressure was lowered by 10 to 15 mm Hg. This blood pressure change was immediately reversed upon restitution of flow.

Reductions in coronary blood flow produced a significant decrease in both RET (15 ± 2 to 9 ± 1 mA) and VFT (23 ± 2 to 16 ± 1 mA) ($p < 0.001$) (Table I). Upon reperfusion, coronary blood flow increased to levels greater than control (hyperemic response) and VFT decreased to 11 ± 3 mA. Repetitive extrasystoles could not be consistently elicited without antecedent ventricular fibrillation during the reperfusion phase.

**Effects of prostacyclin:** Baroreceptor denervation was performed before prostacyclin infusion. In 11 animals tested, baroreceptor denervation did not cause a significant change in platelet aggregation to adenosine diphosphate (Fig. 1). Furthermore, control mean arterial blood pressure, coronary blood flow, RET, and VFT values were obtained after baroreceptor denervation.

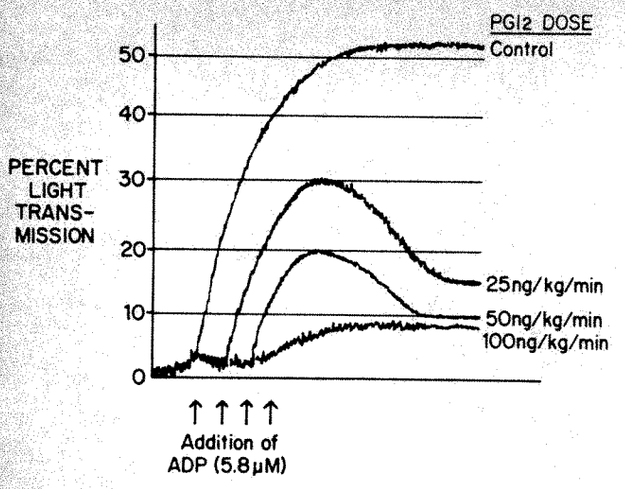

**FIGURE 3.** Effects of varying doses of prostacyclin ($PGI_2$) on adenosine diphosphate (ADP)-mediated platelet aggregation.

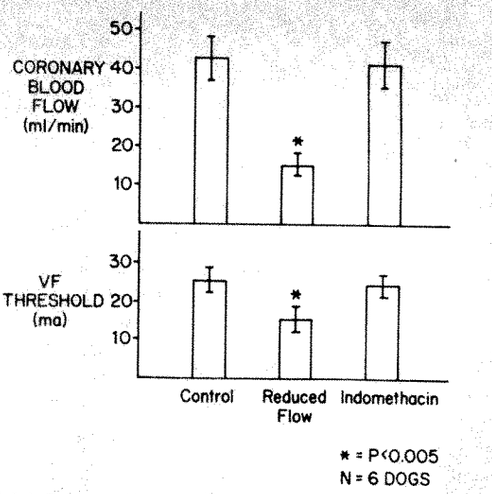

**FIGURE 4.** Influence of indomethacin (5 mg/kg) on coronary blood flow and ventricular vulnerability during partial coronary stenosis. VF = ventricular fibrillation.

Prostacyclin caused a progressive decrease in mean arterial blood pressure as a function of increasing dose. Prostacyclin also caused a decrease in the frequency and rapidity of coronary blood flow cycles, decreasing from 11/hour to 7/hour using 25 ng/kg/min and to 3/hour using doses of 50 ng/kg/min. Cyclical flow changes were completely abolished during an infusion rate of 100 ng/kg/min and coronary blood flow returned to control values (Fig. 2). Prostacyclin progressively inhibited platelet function and was most effective at the highest infusion rate (Fig. 1). The aggregation results from a single animal study are shown in Figure 3.

Four animals which exhibited no cyclical flow reductions underwent baroreceptor denervation and prostacyclin infusion. Although the hemodynamic responses to prostacyclin (100 ng/kg/min) were similar to those observed in dogs which manifested cyclical flow changes, no significant change in either the RET (18 ± 1 mA to 17 ± 2 mA) or VFT (27 ± 3 mA to 24 ± 3 mA) was observed in these 4 nonresponder animals.

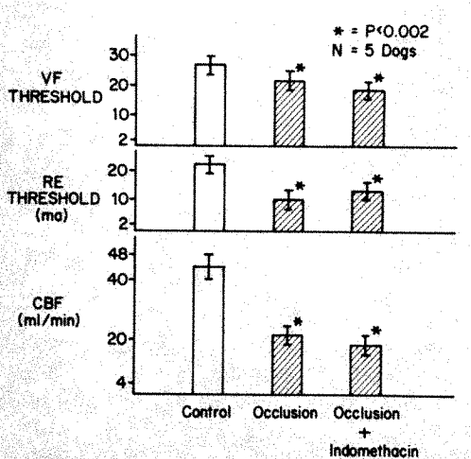

**FIGURE 5.** Effect of nonthrombotic coronary occlusion induced by a balloon catheter on ventricular fibrillation (VF) threshold and coronary blood flow (CBF) before and after treatment with indomethacin (5 mg/kg). RE = repetitive extrasystole.

**Effects of indomethacin:** Indomethacin (5 mg/kg) reduced platelet aggregation in response to adenosine diphosphate from 50 to 6 to 24 ± 4%, $p < 0.01$ (Fig. 1), and completely inhibited the second phase of aggregation to adenosine diphosphate in 6 animals manifesting cyclical changes in coronary blood flow. This effect on platelet aggregation was accompanied by a prompt (within 5 minutes) cessation of cyclical coronary blood flow changes and a return of the VFT to control values (Fig. 4). Indomethacin exerted no significant effect on VFT (23 ± 2 ± 1 mA) when administered in 4 animals that had no spontaneous cyclical flow changes.

**Effect of balloon catheter coronary occlusion and treatment with indomethacin:** In 5 animals, coronary occlusion was carried out with an external balloon catheter and coronary blood flow held at a level approximately 60% less than control values (44 ± 4 to 21 ± 3 ml/min). Reductions were observed in both the RET (−45%) and VFT (−28%). After treatment with indomethacin, RET and VFT remained unaltered (Fig. 5).

## Discussion

The role of intracoronary platelet aggregation in the genesis of malignant cardiac arrhythmias is an issue of significant clinical interest. The evidence implicating thrombus formation in sudden death, however, has been indirect, based on autopsy and epidemiologic data.[4–7] The studies of Uchida,[8,15] Folts,[9,10] Aiken,[16] and their co-workers have provided a new biologic model for investigating the effects of intracoronary platelet aggregation on myocardial ischemia. Specifically, Folts et al[9,10] demonstrated that application of a plastic cylinder around a major coronary artery causes platelets to adhere to adjacent coronary endothelium, resulting in cyclical reductions in coronary blood flow. Thus, it is

possible to stimulate and monitor spontaneous changes in intracoronary platelet aggregation and thereby induce myocardial ischemia. The present study examined the effects of platelet aggregation on ventricular electrical properties as assessed by the RET and VFT. These indexes were selected because they have been shown to provide accurate and reproducible measurements of myocardial electrical stability.[11,17]

This investigation demonstrates that with the onset of myocardial ischemia, there are marked reductions in RET and VFT. Our results also indicate that there is a significant increase in vulnerability to ventricular fibrillation during reperfusion which occurs as a result of platelet dislodgment. This phenomenon is in accord with that observed during reperfusion produced by abrupt deflation of a balloon occluder. The changes in vulnerability observed during decreased flow and reperfusion are completely abolished within 30 seconds of restoration of coronary blood flow.

**Effects of prostacyclin:** Prostacyclin is an effective agent for evaluating the role of platelet aggregation in the generation of both cyclical flow reduction[16] and ventricular electrical changes. First, this substance is devoid of any direct cardiac electrophysiologic effects. Changes in ventricular vulnerability may, however, be brought about by baroreceptor reflex activation.[13] Baroreceptor denervation was thus performed in the present study to preclude an indirect effect on RET and VFT. Second, prostacyclin is a most potent platelet inhibitor. It exerts its effects by binding to specific receptors and increasing platelet cyclic adenosine monophosphate levels.[18] These effects occur in a dose-dependent fashion, so that inhibition of platelet aggregation is related to the dose of prostacyclin.[19] Third, prostacyclin is produced by vascular endothelium and may inhibit platelet aggregation and thrombus formation on exposed subendothelium.[20] Human subjects have received prostacyclin in doses up to 50 ng/kg/min without adverse effects.[21] In fact, significantly smaller doses have eliminated the ischemic pain resulting from arteriosclerosis obliterans.[22] However, whether this agent will become useful in the clinical setting in the treatment of coronary disease is uncertain since the doses required for these purposes are quite high.

**Relation of platelet aggregation to cyclical flow changes:** Indomethacin caused an abrupt and long-lasting cessation of cyclical flow changes which correlated with inhibition of platelet aggregation and abolition of electrical changes. Indomethacin is an inhibitor of thromboxane $A_2$ synthesis. Therefore, the protective effect of indomethacin in this model suggests that thromboxane generation may be an important factor in the production of the myocardial ischemia and electrical instability that occurs during cyclical flow alterations. There was no significant change in the VFT with indomethacin in animals without cyclical blood flow changes. This suggests that changes in coronary vascular resistance seen with indomethacin in patients with coronary artery disease[23] do not influence ventricular vulnerability in the nonischemic canine heart. Indomethacin completely restored coronary blood flow in animals with partial stenosis, indicating that changes in coronary vascular resistance with indomethacin in this particular model of myocardial ischemia is not a significant factor.

There was a strong correlation between platelet sensitivity to adenosine diphosphate and the frequency and magnitude of cyclical flow changes. Animals which were less sensitive to adenosine diphosphate generally failed to manifest coronary flow alterations. While we did not specifically investigate the reason for intrinsic variability in platelet aggregability, interanimal differences in arachidonic acid metabolism may provide an explanation.[24,25] Furthermore, as platelets were progressively inhibited with increasing doses of prostacyclin, there was a corresponding restitution of coronary flow and abolition of electrical changes. Our findings of a correlation between reduced VFT, coronary blood flow, and the extent of platelet aggregation indicates a central role of platelet function in coronary perfusion changes when coronary flow is substantially restricted.

**Mechanisms for alteration of vulnerability:** We sought to determine whether changes in ventricular vulnerability during partial coronary stenosis are contributed to by impedance of flow by platelet plugs or are due to release of platelet factors. To shed light on this question, we utilized the balloon catheter to produce degrees of flow reduction comparable to those observed when cyclical flow reduction occurred during fixed partial stenosis. Reduction in flow produced nonthrombotically by balloon obstruction significantly decreased the vulnerable period threshold as previously reported.[26–28] These changes, moreover, were comparable to those observed during intracoronary platelet aggregation induced using the plastic cylinder. Use of the balloon occluder was not associated with a further gradual decrease in coronary flow attributable to intracoronary platelet aggregation. The reason for this difference is not clear but may have been due to a greater extent of endothelial disruption with a rigid cylinder. In any case, with nonthrombotic occlusion induced by means of the balloon catheter, platelet inhibition by indomethacin administration did not prevent the vulnerable period threshold changes associated with coronary obstruction. These results suggest that alterations in cardiac vulnerability noted during partial stenosis are due, at least in part, to the mechanical impairment of flow through the stenotic site.

**Acknowledgment:** We express our appreciation to Sally D. Carr, Jean M. Young, and James P. Kiely, BS, for their capable technical assistance and to Mary Cashman, Claudia Kenney, and Rachel Chatburn for preparation of the manuscript.

# Cardiac Bioprostheses

## Proceedings of the Second International Symposium Rome, Italy, May 17-19, 1982

**The most up-to-date presentation of the latest data on the entire range of clinical, bioengineering, pathology, and long-range follow-up issues on cardiac tissue valves.**

**To order your copy of this important new book use the order form below.**

**edited by Lawrence H. Cohn, MD, and Vincenzo Gallucci, MD**
**ISBN 0-914316-34-6, 609 pp., illus., Nov. 1982., $65.00**

An international program committee organized this symposium on a strictly competitive abstract basis. It was held less than six months ago. One-hundred-eighty abstracts were submitted and 45 in 8 categories were accepted. Virtually every major cardiovascular center in the world that has any meaningful experience with cardiac bioprosthetic valves was represented. Nowhere will you find between two covers as much *current* information on the field of cardiac valves.

Almost 20 years have gone by since the first reports of homograft valve replacement by Drs. Donald Ross and Brian Barratt-Boyes and almost 10 years since the first reports began to appear about commercially available, quality-controlled porcine bioprosthetic and bovine pericardial valves. This book brings you completely up-to-date on what has happened since and what is happening *today*.

If your interests include the clinical, pathological and bioengineering aspects of cardiac bioprostheses then this book is a *must buy!* It should not be missing from your own professional library.
